Notice

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

TERMS OF USE

Foreword

A little more than 25 years ago, Alexander Kugushev, then the editor for Lange Medical Publications, approached us to consider writing an introductory textbook in the specialty of anesthesiology that would be part of the popular Lange series of medical books. Mr. Kugushev proved to be a convincing salesman, in part by offering his experience with scores of authors, all of whom opined that their most satisfying career achievement was the fathering of their texts. We could not agree more.

Now in its fifth edition, the overall stylistic goal of *Clinical Anesthesiology* remains unchanged: to be written simply enough so that a third year medical student can understand all essential basic concepts, yet comprehensively enough to provide a strong foundation for a resident in anesthesiology. To quote C. Philip Larson, Jr, MD from the Foreword of the first edition: “The text is complete; nothing of consequence is omitted. The writing style is precise, concise and highly readable.”

The fifth edition features three new chapters: Ambulatory, Nonoperating Room, and Office-based Anesthesia; Perioperative Pain Management and Enhanced Outcomes; and Safety, Quality, and Performance Improvement. There are approximately 70 new figures and 20 new tables. The adoption of full color dramatically improves the aesthetic appeal of every page.

However, the biggest and most important change in the fifth edition is the “passing of the baton” to a distinguished and accomplished team of authors and editors. We were thrilled to learn that Drs. Butterworth, Mackey, and Wasnick would be succeeding us. The result of their hard work proves our enthusiasm was justified as they have taken *Clinical Anesthesiology* to a new level. We hope you, the readers, agree!

G. Edward Morgan, Jr, MD
Maged S. Mikhail, MD

Preface

Authors should be proud whenever a book is sufficiently successful to require a new edition. This is especially true when a book's consistent popularity over time leads to the succession of the original authors by a new set of authors. This latter circumstance is the case for the fifth edition of what most of us call "Morgan and Mikhail." We hope that you the reader will find this new edition as readable and useful as you have found the preceding four editions of the work.

This fifth edition, while retaining essential elements of its predecessors, represents a significant revision of the text. Only those who have written a book of this size and complexity will understand just how much effort was involved. Entirely new subjects (eg, Perioperative Pain Management and Enhanced Outcomes) have been added, and many other topics that previously lived in multiple chapters have been moved and consolidated. We have tried to eliminate redundancies and contradictions. The number of illustrations devoted to regional anesthesia and analgesia has been greatly increased to adequately address the rapidly growing importance of this perioperative management topic. The clarity of the illustrations is also enhanced by the widespread use of color throughout the book. We hope the product of this endeavor provides readers with as useful an exercise as was experienced by the authors in composing it.

- **Key Concepts** are listed at the beginning of each chapter and a corresponding numbered icon identifies the section(s) within the chapter in which each concept is discussed. These should help the reader focus on important concepts that underlie the core of anesthesiology.
- **Case Discussions** deal with clinical problems of current interest and are intended to stimulate discussion and critical thinking.
- The suggested reading has been revised and updated to include pertinent Web addresses and references to clinical practice guidelines and practice parameters. We have not tried to provide a comprehensive list of references: we expect that most readers of this text would normally perform their own literature searches on medical topics using Google, PubMed, and other electronic resources. Indeed, we expect that an ever-increasing segment of our readers will access this text in one of its several electronic forms.
- Multiple new illustrations and images have been added to this edition.

Nonetheless, our goal remains the same as that of the first edition: "to provide a concise, consistent presentation of the basic principles essential to the modern practice of anesthesia."

We would like to thank Brian Belval, Harriet Lebowitz, and Marsha Loeb for their invaluable assistance.

Despite our best intentions, various errors may have made their way into the fifth edition. We will be grateful to readers who report these to us at mm5edition@gmail.com so that we can correct them in reprints and future editions.

John F. Butterworth IV, MD
David C. Mackey, MD
John D. Wasnick, MD, MPH

The Practice of Anesthesiology

KEY CONCEPTS

- 1 Oliver Wendell Holmes in 1846 was the first to propose use of the term *anesthesia* to denote the state that incorporates amnesia, analgesia, and narcosis to make painless surgery possible.
- 2 Ether was used for frivolous purposes (“ether frolics”) and was not used as an anesthetic agent in humans until 1842, when Crawford W. Long and William E. Clark independently used it on patients. On October 16, 1846, William T.G. Morton conducted the first publicized demonstration of general anesthesia for surgical operation using ether.
- 3 The original application of modern local anesthesia is credited to Carl Koller, at the time a house officer in ophthalmology, who demonstrated topical anesthesia of the eye with cocaine in 1884.
- 4 Curare greatly facilitated tracheal intubation and muscle relaxation during surgery. For the first time, operations could be performed on patients without the requirement that relatively deep levels of inhaled general anesthetic be used to produce muscle relaxation.
- 5 John Snow, often considered the father of the anesthesia specialty, was the first to scientifically investigate ether and the physiology of general anesthesia.
- 6 The “captain of the ship” doctrine, which held the surgeon responsible for every aspect of the patient’s perioperative care (including anesthesia), is no longer a valid notion when an anesthesiologist is present.

The Greek philosopher Dioscorides first used the term *anesthesia* in the first century AD to describe the narcotic-like effects of the plant mandragora. The term subsequently was defined in Bailey’s *An Universal Etymological English Dictionary* (1721) as “a defect of sensation” and again in the *Encyclopedia Britannica* (1771) as “privation of the senses.”

1 Oliver Wendell Holmes in 1846 was the first to propose use of the term to denote the state that incorporates amnesia, analgesia, and narcosis to make painless surgery possible. In the United States, use of the term *anesthesiology* to denote the practice or study of anesthesia was first proposed in the

second decade of the twentieth century to emphasize the growing scientific basis of the specialty.

Although anesthesia now rests on scientific foundations comparable to those of other specialties, the practice of anesthesia remains very much a mixture of science and art. Moreover, the practice has expanded well beyond rendering patients insensible to pain during surgery or obstetric delivery ([Table 1–1](#)). The specialty uniquely requires a working familiarity with a long list of other specialties, including surgery and its subspecialties, internal medicine, pediatrics, and obstetrics as well as clinical pharmacology, applied physiology, and biomedical

TABLE 1–1 Definition of the practice of anesthesiology within the practice of medicine.¹

Assessment and preparation of patients for surgery and anesthesia.
Prevention, diagnosis, and treatment of pain during and following surgical, obstetric, therapeutic, and diagnostic procedures.
Acute care of patients during the perioperative period.
Diagnosis and treatment of critical illness.
Diagnosis and treatment of acute, chronic, and cancer-related pain.
Cardiac, pulmonary, and trauma resuscitation.
Evaluation of respiratory function and application of treatments in respiratory therapy.
Instruction, evaluation of the performance, and supervision of both medical and paramedical personnel involved in perioperative care.
Administration in health care facilities, organizations, and medical schools necessary to implement these responsibilities.
Conduct of clinical, translational, and basic science research.

¹Data from the American Board of Anesthesiology Booklet of Information, February 2012.

technology. Recent advances in biomedical technology, neuroscience, and pharmacology continue to make anesthesia an intellectually stimulating and rapidly evolving specialty. Many physicians entering residency positions in anesthesiology will already have multiple years of graduate medical education and perhaps even certification in other medical specialties.

This chapter reviews the history of anesthesia, emphasizing its British and American roots, and considers the current scope of the specialty.

The History of Anesthesia

The specialty of anesthesia began in the mid-nineteenth century and became firmly established less than six decades ago. Ancient civilizations had used opium poppy, coca leaves, mandrake root,

alcohol, and even phlebotomy (to the point of unconsciousness) to allow surgeons to operate. Ancient Egyptians used the combination of opium poppy (containing morphine) and hyoscyamus (containing scopolamine); a similar combination, morphine and scopolamine, has been used parenterally for premedication. What passed for regional anesthesia in ancient times consisted of compression of nerve trunks (nerve ischemia) or the application of cold (cryoanalgesia). The Incas may have practiced local anesthesia as their surgeons chewed coca leaves and applied them to operative wounds, particularly prior to trephining for headache.

The evolution of modern surgery was hampered not only by a poor understanding of disease processes, anatomy, and surgical asepsis but also by the lack of reliable and safe anesthetic techniques. These techniques evolved first with inhalation anesthesia, followed by local and regional anesthesia, and finally intravenous anesthesia. The development of surgical anesthesia is considered one of the most important discoveries in human history.

INHALATION ANESTHESIA

Because the hypodermic needle was not invented until 1855, the first general anesthetics were destined to be inhalation agents. Diethyl ether (known at the time as “sulfuric ether” because it was produced by a simple chemical reaction between ethyl alcohol and sulfuric acid) was originally prepared in

2 1540 by Valerius Cordus. Ether was used for frivolous purposes (“ether frolics”), but not as an anesthetic agent in humans until 1842, when Crawford W. Long and William E. Clark independently used it on patients for surgery and dental extraction, respectively. However, they did not publicize their discovery. Four years later, in Boston, on October 16, 1846, William T.G. Morton conducted the first publicized demonstration of general anesthesia for surgical operation using ether. The dramatic success of that exhibition led the operating surgeon to exclaim to a skeptical audience: “Gentlemen, this is no humbug!”

Chloroform was independently prepared by von Leibig, Guthrie, and Soubeiran in 1831. Although first used by Holmes Coote in 1847,

chloroform was introduced into clinical practice by the Scot Sir James Simpson, who administered it to his patients to relieve the pain of labor. Ironically, Simpson had almost abandoned his medical practice after witnessing the terrible despair and agony of patients undergoing operations without anesthesia.

Joseph Priestley produced nitrous oxide in 1772, and Humphry Davy first noted its analgesic properties in 1800. Gardner Colton and Horace Wells are credited with having first used nitrous oxide as an anesthetic for dental extractions in humans in 1844. Nitrous oxide's lack of potency (an 80% nitrous oxide concentration results in analgesia but not surgical anesthesia) led to clinical demonstrations that were less convincing than those with ether.

Nitrous oxide was the least popular of the three early inhalation anesthetics because of its low potency and its tendency to cause asphyxia when used alone (see Chapter 8). Interest in nitrous oxide was revived in 1868 when Edmund Andrews administered it in 20% oxygen; its use was, however, overshadowed by the popularity of ether and chloroform. Ironically, nitrous oxide is the only one of these three agents still in widespread use today. Chloroform superseded ether in popularity in many areas (particularly in the United Kingdom), but reports of chloroform-related cardiac arrhythmias, respiratory depression, and hepatotoxicity eventually caused practitioners to abandon it in favor of ether, particularly in North America.

Even after the introduction of other inhalation anesthetics (ethyl chloride, ethylene, divinyl ether, cyclopropane, trichloroethylene, and fluroxene), ether remained the standard inhaled anesthetic until the early 1960s. The only inhalation agent that rivaled ether's safety and popularity was cyclopropane (introduced in 1934). However, both are highly combustible and both have since been replaced by a succession of nonflammable potent fluorinated hydrocarbons: halothane (developed in 1951; released in 1956), methoxyflurane (developed in 1958; released in 1960), enflurane (developed in 1963; released in 1973), and isoflurane (developed in 1965; released in 1981).

Two newer agents are now the most popular in developed countries. Desflurane (released

in 1992), has many of the desirable properties of isoflurane as well as more rapid uptake and elimination (nearly as fast as nitrous oxide). Sevoflurane, has low blood solubility, but concerns about the potential toxicity of its degradation products delayed its release in the United States until 1994 (see Chapter 8). These concerns have proved to be largely theoretical, and sevoflurane, not desflurane, has become the most widely used inhaled anesthetic in the United States, largely replacing halothane in pediatric practice.

LOCAL & REGIONAL ANESTHESIA

The medicinal qualities of coca had been used by the Incas for centuries before its actions were first observed by Europeans. Cocaine was isolated from coca leaves in 1855 by Gaedicke and was purified in

3 1860 by Albert Niemann. The original application of modern local anesthesia is credited to Carl Koller, at the time a house officer in ophthalmology, who demonstrated topical anesthesia of the eye with cocaine in 1884. Later in 1884 William Halsted used cocaine for intradermal infiltration and nerve blocks (including blocks of the facial nerve, brachial plexus, pudendal nerve, and posterior tibial nerve). August Bier is credited with administering the first spinal anesthetic in 1898. He was also the first to describe intravenous regional anesthesia (Bier block) in 1908. Procaine was synthesized in 1904 by Alfred Einhorn and within a year was used clinically as a local anesthetic by Heinrich Braun. Braun was also the first to add epinephrine to prolong the duration of local anesthetics. Ferdinand Cathelin and Jean Sicard introduced caudal epidural anesthesia in 1901. Lumbar epidural anesthesia was described first in 1921 by Fidel Pages and again (independently) in 1931 by Achille Dogliotti. Additional local anesthetics subsequently introduced include dibucaine (1930), tetracaine (1932), lidocaine (1947), chloroprocaine (1955), mepivacaine (1957), prilocaine (1960), bupivacaine (1963), and etidocaine (1972). The most recent additions, ropivacaine and levobupivacaine, have durations of action similar to bupivacaine but less cardiac toxicity (see Chapter 16).

INTRAVENOUS ANESTHESIA

Induction Agents

Intravenous anesthesia required the invention of the hypodermic syringe and needle by Alexander Wood in 1855. Early attempts at intravenous anesthesia included the use of chloral hydrate (by Oré in 1872), chloroform and ether (Burkhardt in 1909), and the combination of morphine and scopolamine (Bredenfeld in 1916). Barbiturates were first synthesized in 1903 by Fischer and von Mering. The first barbiturate used for induction of anesthesia was diethylbarbituric acid (barbital), but it was not until the introduction of hexobarbital in 1927 that barbiturate induction became popular. Thiopental, synthesized in 1932 by Volwiler and Tabern, was first used clinically by John Lundy and Ralph Waters in 1934 and for many years remained the most common agent for intravenous induction of anesthesia. Methohexital was first used clinically in 1957 by V. K. Stoelting and is the only other barbiturate used for induction of anesthesia in humans. After chloridiazepoxide was discovered in 1955 and released for clinical use in 1960, other benzodiazepines—diazepam, lorazepam, and midazolam—came to be used extensively for premedication, conscious sedation, and induction of general anesthesia. Ketamine was synthesized in 1962 by Stevens and first used clinically in 1965 by Corssen and Domino; it was released in 1970 and continues to be popular today, particular when administered in combination with other agents. Etomidate was synthesized in 1964 and released in 1972. Initial enthusiasm over its relative lack of circulatory and respiratory effects was tempered by evidence of adrenal suppression, reported after even a single dose. The release of propofol in 1986 (1989 in the United States) was a major advance in outpatient anesthesia because of its short duration of action (see Chapter 9). Propofol is currently the most popular agent for intravenous induction worldwide.

Neuromuscular Blocking Agents

The introduction of curare by Harold Griffith and Enid Johnson in 1942 was a milestone in anesthesia.

4 Curare greatly facilitated tracheal intubation and muscle relaxation during surgery. For the

first time, operations could be performed on patients without the requirement that relatively deep levels of inhaled general anesthetic be used to produce muscle relaxation. Such large doses of anesthetic often resulted in excessive cardiovascular and respiratory depression as well as prolonged emergence. Moreover, larger doses were often not tolerated by frail patients.

Succinylcholine was synthesized by Bovet in 1949 and released in 1951; it has become a standard agent for facilitating tracheal intubation during rapid sequence induction. Until recently, succinylcholine remained unchallenged in its rapid onset of profound muscle relaxation, but its side effects prompted the search for a comparable substitute. Other neuromuscular blockers (NMBs; discussed in Chapter 11)—gallamine, decamethonium, metocurine, alcuronium, and pancuronium—were subsequently introduced. Unfortunately, these agents were often associated with side effects (see Chapter 11), and the search for the ideal NMB continued. Recently introduced agents that more closely resemble an ideal NMB include vecuronium, atracurium, rocuronium, and *cis*-atracurium.

Opioids

Morphine, isolated from opium in 1805 by Sertürner, was also tried as an intravenous anesthetic. The adverse events associated with large doses of opioids in early reports caused many anesthetists to avoid opioids and favor pure inhalation anesthesia. Interest in opioids in anesthesia returned following the synthesis and introduction of meperidine in 1939. The concept of *balanced anesthesia* was introduced in 1926 by Lundy and others and evolved to include thiopental for induction, nitrous oxide for amnesia, an opioid for analgesia, and curare for muscle relaxation. In 1969, Lowenstein rekindled interest in “pure” opioid anesthesia by reintroducing the concept of large doses of opioids as complete anesthetics. Morphine was the first agent so employed, but fentanyl and sufentanil have been preferred by a large margin as sole agents. As experience grew with this technique, its multiple limitations—unreliably preventing patient awareness, incompletely suppressing autonomic responses during surgery, and prolonged respiratory depression—were realized.

Remifentanyl, an opioid subject to rapid degradation by nonspecific plasma and tissue esterases, permits profound levels of opioid analgesia to be employed without concerns regarding the need for postoperative ventilation.

EVOLUTION OF THE SPECIALTY

British Origins

Following its first public demonstration in the United States, ether anesthesia quickly was adopted **5** in England. John Snow, often considered the father of the anesthesia specialty, was the first physician to take a full-time interest in this new anesthetic. He was the first to scientifically investigate ether and the physiology of general anesthesia. Of course, Snow was also a pioneer in epidemiology. He helped stop a cholera epidemic in London by proving that the causative agent was transmitted by ingestion of contaminated well water rather than by inhalation. In 1847, Snow published the first book on general anesthesia, *On the Inhalation of Ether*. When the anesthetic properties of chloroform were made known, he quickly investigated and developed an inhaler for that agent as well. He believed that an inhaler should be used in administering ether or chloroform to control the dose of the anesthetic. His second book, *On Chloroform and Other Anaesthetics*, was published posthumously in 1858.

After Snow's death, Dr. Joseph T. Clover took his place as England's leading anesthetist. Clover emphasized continuously monitoring the patient's pulse during anesthesia, a practice that was not yet standard at the time. He was the first to use the jaw-thrust maneuver for relieving airway obstruction, the first to insist that resuscitation equipment always be available during anesthesia, and the first to use a cricthyroid cannula (to save a patient with an oral tumor who developed complete airway obstruction). After Clover, Sir Frederic Hewitt became England's foremost anesthetist at the turn of the last century. He was responsible for many inventions, including the oral airway. Hewitt also wrote what many consider to be the first true textbook of

anesthesia, which went through five editions. Snow, Clover, and Hewitt established the tradition of physician anesthetists in England. In 1893, the first organization of physician specialists in anesthesia, the London Society of Anaesthetists, was formed in England by J.F. Silk.

The first elective tracheal intubations during anesthesia were performed in the late nineteenth century by surgeons Sir William MacEwen in Scotland, Joseph O'Dwyer in the United States, and Franz Kuhn in Germany. Tracheal intubation during anesthesia was popularized in England by Sir Ivan Magill and Stanley Rowbotham in the 1920s.

American Origins

In the United States, only a few physicians had specialized in anesthesia by 1900. The task of providing general anesthesia was often delegated to junior surgical house officers or medical students, if they were available.

The first organization of physician anesthetists in the United States was the Long Island Society of Anesthetists formed in 1905, which, as it grew, was renamed the New York Society of Anesthetists in 1911. The International Anesthesia Research Society (IARS) was founded in 1922, and in that same year the IARS-sponsored scientific journal *Current Researches in Anesthesia and Analgesia* (now called *Anesthesia and Analgesia*) began publication. In 1936, the New York Society of Anesthetists became the American Society of Anesthetists, and later, in 1945, the American Society of Anesthesiologists (ASA). The scientific journal *Anesthesiology* was first published in 1940.

Four physicians stand out in the early development of anesthesia in the United States after 1900: F.H. McMechan, Arthur E. Guedel, Ralph M. Waters, and John S. Lundy. McMechan was the driving force behind both the IARS and *Current Researches in Anesthesia and Analgesia*, and tirelessly organized physicians specializing in anesthesia into national and international organizations until his death in 1939. Guedel was the first to describe the signs and stages of general anesthesia. He advocated cuffed tracheal tubes and introduced artificial ventilation during ether anesthesia (later termed *controlled respiration* by

Waters). Ralph Waters made a long list of contributions to the specialty, probably the most important of which was his insistence on the proper education of specialists in anesthesia. Waters developed the first academic department of anesthesiology at the University of Wisconsin in Madison. Lundy was instrumental in the formation of the American Board of Anesthesiology and chaired the American Medical Association's Section on Anesthesiology for 17 years.

Because of the scarcity of physicians specializing in anesthesia in the United States and the perceived relative safety of ether anesthesia, surgeons at both the Mayo Clinic and Cleveland Clinic began training and employing nurses as anesthetists in the early 1900s. As the numbers of nurse anesthetists increased, a national organization (now called the American Association of Nurse Anesthetists) was incorporated in 1932. The AANA first offered a certification examination in 1945. In 1969 two Anesthesiology Assistant programs began accepting students, and in 1989 the first certification examinations for AAs were administered. Certified Registered Nurse Anesthetists and Anesthesiologist Assistants represent important members of the anesthesia workforce in the United States and in other countries.

Official Recognition

In 1889 Henry Isaiah Dorr, a dentist, was appointed Professor of the Practice of Dentistry, Anaesthetics and Anaesthesia at the Philadelphia College of Dentistry. Thus he was the first known professor of anesthesia worldwide. Thomas D. Buchanan, of the New York Medical College, was the first physician to be appointed Professor of Anesthesia (in 1905). When the American Board of Anesthesiology was established in 1938, Dr. Buchanan served as its first president. In England, the first examination for the Diploma in Anaesthetics took place in 1935, and the first Chair in Anaesthetics was awarded to Sir Robert Macintosh in 1937 at Oxford University. Anesthesia became an officially recognized specialty in England only in 1947, when the Royal College of Surgeons established its Faculty of Anaesthetists. In 1992 an independent Royal College of Anaesthetists was granted its charter.

The Scope of Anesthesia

The practice of anesthesia has changed dramatically since the days of John Snow. The modern anesthesiologist is now both a perioperative consultant and a primary deliverer of care to patients. In general, anesthesiologists manage nearly all “noncutting” aspects of the patient's medical care in the immediate perioperative period. The “captain of the ship” doctrine, which held the surgeon responsible for every aspect of the patient's perioperative care (including anesthesia), is no longer a valid notion when an anesthesiologist is present. The surgeon and anesthesiologist must function together as an effective team, and both are ultimately answerable to the patient rather than to each other.

The modern practice of anesthesia is not confined to rendering patients insensible to pain (Table 1–1). Anesthesiologists monitor, sedate, and provide general or regional anesthesia outside the operating room for various imaging procedures, endoscopy, electroconvulsive therapy, and cardiac catheterization. Anesthesiologists have traditionally been pioneers in cardiopulmonary resuscitation and continue to be integral members of resuscitation teams.

An increasing number of practitioners pursue a subspecialty in anesthesia for cardiothoracic surgery (see Chapter 22), critical care (see Chapter 57), neuroanesthesia (see Chapter 27), obstetric anesthesia (see Chapter 41), pediatric anesthesia (see Chapter 42), and pain medicine (see Chapter 47). Certification requirements for special competence in critical care and pain medicine already exist in the United States. Fellowship programs in Adult Cardiothoracic Anesthesia and Pediatric Anesthesiology have specific accreditation requirements, and soon those in Obstetric Anesthesiology will as well. A certification examination will soon be available in Pediatric Anesthesiology. Education and certification in anesthesiology can also be used as the basis for certification in Sleep Medicine or in Palliative Medicine.

Anesthesiologists are actively involved in the administration and medical direction of many ambulatory surgery facilities, operating room suites, intensive care units, and respiratory therapy

departments. They have also assumed administrative and leadership positions on the medical staffs of many hospitals and ambulatory care facilities. They serve as deans of medical schools and chief executives of health systems.

The Operating Room Environment

Charles E. Cowles, MD

KEY CONCEPTS

- 1 A pressure of 1000 psig indicates an E-cylinder that is approximately half full and represents 330 L of oxygen.
- 2 The only reliable way to determine residual volume of nitrous oxide is to weigh the cylinder.
- 3 To discourage incorrect cylinder attachments, cylinder manufacturers have adopted a pin index safety system.
- 4 A basic principle of radiation safety is to keep exposure “as low as reasonably practical” (ALARP). The principles of ALARP are protection from radiation exposure by the use of time, distance, and shielding.
- 5 The magnitude of a leakage current is normally imperceptible to touch (<1 mA, and well below the fibrillation threshold of 100 mA). If the current bypasses the high resistance offered by skin, however, and is applied directly to the heart (microshock), current as low as 100 μ A may be fatal. The maximum leakage allowed in operating room equipment is 10 μ A.
- 6 To reduce the chance of two coexisting faults, a line isolation monitor measures the potential for current flow from the isolated power supply to the ground. Basically, the line isolation monitor determines the degree of isolation between the two power wires and the ground and predicts the amount of current that *could* flow if a second short circuit were to develop.
- 7 Almost all surgical fires can be prevented. Unlike medical complications, fires are a product of simple physical and chemistry properties. Occurrence is guaranteed given the proper combination of factors but can be eliminated almost entirely by understanding the basic principles of fire risk.
- 8 Likely the most common risk factor for surgical fire relates to the open delivery of oxygen.
- 9 Administration of oxygen to concentrations of greater than 30% should be guided by clinical presentation of the patient and not solely by protocols or habits.
- 10 The sequence of stopping gas flow and removal of the endotracheal tube when fire occurs in the airway is not as important as ensuring that both actions are performed quickly.
- 11 Before beginning laser surgery, the laser device should be in the operating room, warning signs should be posted on the doors, and protective eyewear should be issued. The anesthesia provider should ensure that the warning signs and eyewear match the labeling on the laser device as laser protection is specific to the type of laser.

Anesthesiologists, who spend more time in operating rooms than any other group of physicians, are responsible for protecting patients and operating room personnel from a multitude of dangers during surgery. Some of these threats are unique to the operating room. As a result, the anesthesiologist may be responsible for ensuring proper functioning of the operating room's medical gases, fire prevention and management, environmental factors (eg, temperature, humidity, ventilation, and noise), and electrical safety. The role of the anesthesiologist also may include coordination of or assistance with layout and design of surgical suites, including workflow enhancements. This chapter describes the major operating room features that are of special interest to anesthesiologists and the potential hazards associated with these systems.

Safety Culture

Patients often think of the operating room as a safe place where the care given is centered around protecting the patient. Medical providers such as anesthesia personnel, surgeons, and nurses are responsible for carrying out several critical tasks at a fast pace. Unless members of the operating room team look out for one another, errors can occur. The best way of preventing serious harm to a patient is by creating a culture of safety. When the safety culture is effectively applied in the operating room, unsafe acts are stopped before harm occurs.

One tool that fosters the safety culture is the use of a surgical safety checklist. Such checklists are used prior to incision on every case and can include components agreed upon by the facility as crucial. Many surgical checklists are derived from the surgical safety checklist published by the World Health Organization (WHO). For checklists to be effective, they must first be used; secondly, all members of the surgical team should be engaged when the checklist is being used. Checklists are most effective when performed in an interactive fashion. An example of a suboptimally executed checklist is one that is read in entirety, after which the surgeon asks whether everyone agrees. This format makes it difficult to identify possible problems. A better method is one that elicits a response after each point; eg, “Does everyone agree this is John Doe?”

followed by “Does everyone agree we are performing a removal of the left kidney?”, and so forth. Optimal checklists do not attempt to cover every possibility but rather address only key components, allowing them to be completed in less than 90 seconds.

Some practitioners argue that checklists waste too much time; they fail to realize that cutting corners to save time often leads to problems later, resulting in a net loss of time. If safety checklists were followed in every case, significant reductions could be seen in the incidence of surgical complications such as wrong-site surgery, procedures on the wrong patient, retained foreign objects, and other easily prevented mistakes. Anesthesia providers are leaders in patient safety initiatives and should take a proactive role to utilize checklists and other activities that foster the safety culture.

Medical Gas Systems

The medical gases commonly used in operating rooms are oxygen, nitrous oxide, air, and nitrogen. Although technically not a gas, vacuum exhaust for waste anesthetic gas disposal (WAGD or scavenging) and surgical suction must also be provided and is considered an integral part of the medical gas system. Patients are endangered if medical gas systems, particularly oxygen, are misconfigured or malfunction. The main features of such systems are the sources of the gases and the means of their delivery to the operating room. The anesthesiologist must understand both these elements to prevent and detect medical gas depletion or supply line misconnection. Estimates of a particular hospital's peak demand determine the type of medical gas supply system required. Design and standards follow National Fire Protection Association (NFPA) 99 in the United States and HTM 2022 in the United Kingdom.

SOURCES OF MEDICAL GASES

Oxygen

A reliable supply of oxygen is a critical requirement in any surgical area. Medical grade oxygen (99% or 99.5% pure) is manufactured by fractional distillation of liquefied air. Oxygen is stored as a compressed

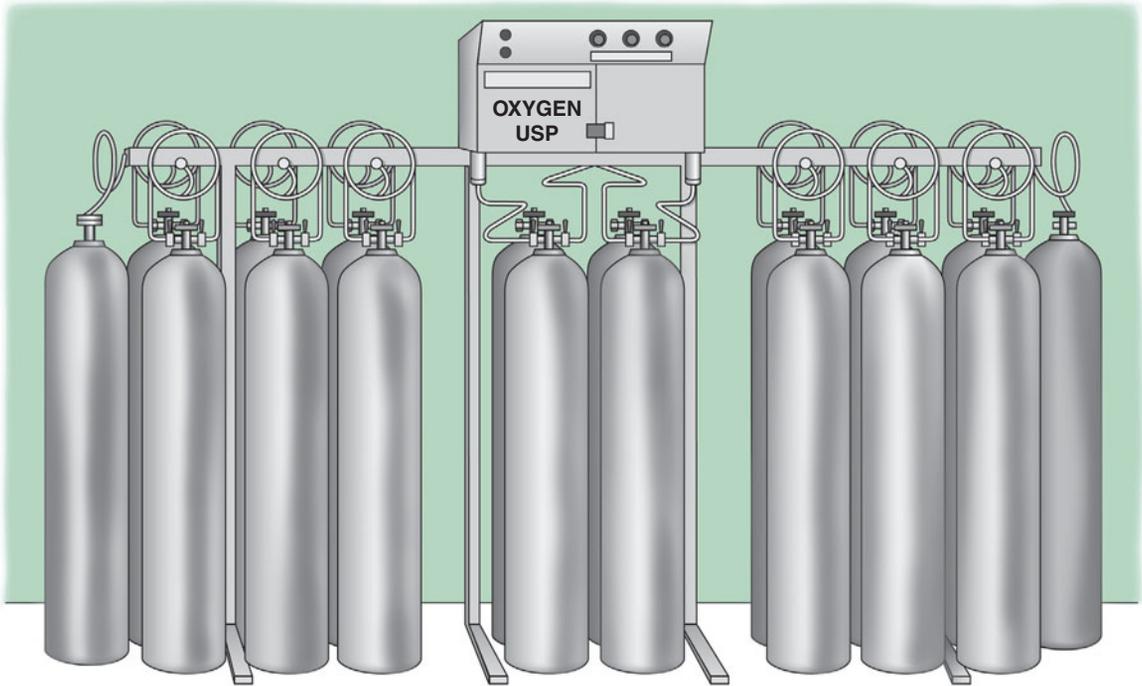

FIGURE 2-1 A bank of oxygen H-cylinders connected by a manifold.

gas at room temperature or refrigerated as a liquid. Most small hospitals store oxygen in two separate banks of high-pressure cylinders (H-cylinders) connected by a manifold (Figure 2-1). Only one bank is utilized at a time. The number of cylinders in each bank depends on anticipated daily demand. The manifold contains valves that reduce the cylinder pressure (approximately 2000 pounds per square inch [psig]) to line pressure (55 ± 5 psig) and automatically switch banks when one group of cylinders is exhausted.

A liquid oxygen storage system (Figure 2-2) is more economical for large hospitals. Liquid oxygen must be stored well below its critical temperature of -119°C because gases can be liquefied by pressure *only* if stored below their critical temperature. A large hospital may have a smaller liquid oxygen supply or a bank of compressed gas cylinders that can provide one day's oxygen requirements as a reserve. To guard against a hospital gas-system failure, the anesthesiologist must always have an emergency (E-cylinder) supply of oxygen available during anesthesia.

Most anesthesia machines accommodate E-cylinders of oxygen (Table 2-1). As oxygen is expended, the cylinder's pressure falls in proportion to its content. A pressure of 1000 psig indicates an E-cylinder that is approximately half full and represents 330 L of oxygen at atmospheric pressure and a temperature of 20°C . If the oxygen is exhausted at a rate of 3 L/min, a cylinder that is half full will be empty in 110 min. Oxygen cylinder pressure should be monitored before use and periodically during use. Anesthesia machines usually also accommodate E-cylinders for medical air and nitrous oxide, and may accept cylinders of helium. Compressed medical gases utilize a pin index safety system for these cylinders to prevent inadvertent crossover and connections for different gas types. As a safety feature of oxygen E-cylinders, the yoke has integral components made from Wood's metal. This metallurgic alloy has a low melting point, which allows dissipation of pressure that might otherwise heat the bottle to the point of ballistic explosion. This pressure-relief "valve" is

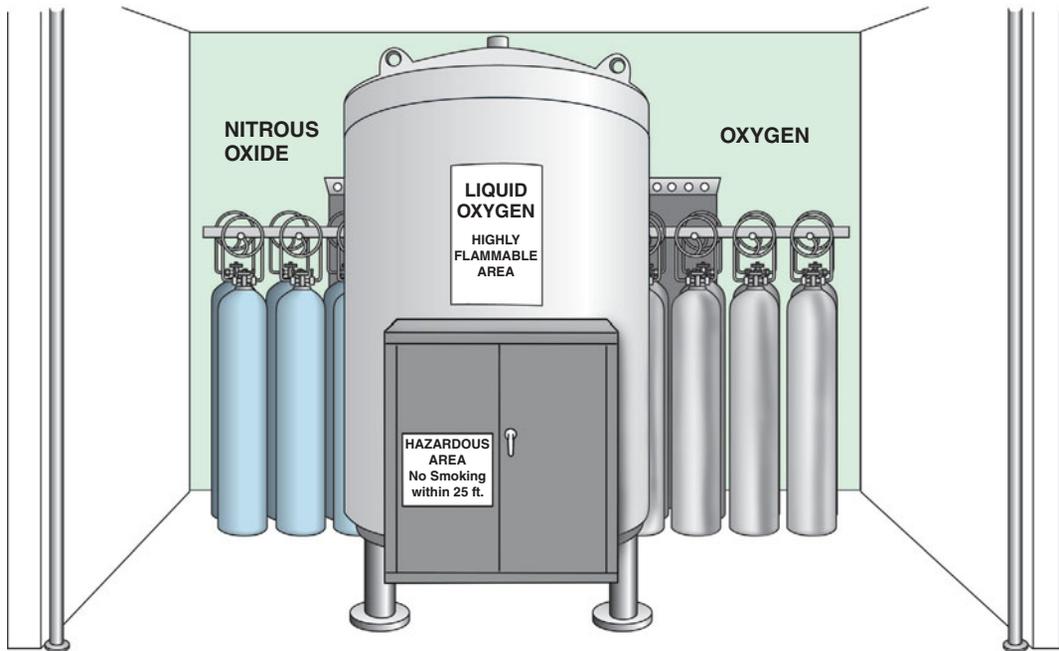

FIGURE 2-2 A liquid storage tank with reserve oxygen tanks in the background.

designed to rupture at 3300 psig, well below the pressure E-cylinder walls should be able to withstand (more than 5000 psig).

Nitrous Oxide

Nitrous oxide is manufactured by heating ammonium nitrate (thermal decomposition). It is almost always stored by hospitals in large H-cylinders connected by a manifold with an automatic crossover feature. Bulk liquid storage of nitrous oxide is economical only in very large institutions.

Because the critical temperature of nitrous oxide (36.5°C) is above room temperature, it can be kept liquefied without an elaborate refrigeration system. If the liquefied nitrous oxide rises above its critical temperature, it will revert to its gaseous phase. Because nitrous oxide is not an ideal gas and is easily compressible, this transformation into a gaseous phase is not accompanied by a great rise in tank pressure. Nonetheless, as with oxygen cylinders, all nitrous oxide E-cylinders are equipped with a Wood's metal yoke to prevent

TABLE 2-1 Characteristics of medical gas cylinders.

Gas	E-Cylinder Capacity ¹ (L)	H-Cylinder Capacity ¹ (L)	Pressure ¹ (psig at 20°C)	Color (USA)	Color (International)	Form
O ₂	625–700	6000–8000	1800–2200	Green	White	Gas
Air	625–700	6000–8000	1800–2200	Yellow	White and black	Gas
N ₂ O	1590	15,900	745	Blue	Blue	Liquid
N ₂	625–700	6000–8000	1800–2200	Black	Black	Gas

¹Depending on the manufacturer.

explosion under conditions of unexpectedly high gas pressure (eg, unintentional overfilling), particularly during fires.

Although a disruption in supply is usually not catastrophic, most anesthesia machines have reserve nitrous oxide E-cylinders. Because these smaller cylinders also contain nitrous oxide in its liquid state, the volume remaining in a cylinder is *not* proportional to cylinder pressure. By the time the liquid nitrous oxide is expended and the tank pressure begins to fall, only about 400 L of nitrous oxide remains. **If liquid nitrous oxide is kept at a constant temperature (20°C), it will vaporize at the same rate at which it is consumed and will maintain a constant pressure (745 psig) until the liquid is exhausted.**

2 The only reliable way to determine residual volume of nitrous oxide is to weigh the cylinder. For this reason, the tare weight (TW), or empty weight, of cylinders containing a liquefied compressed gas (eg, nitrous oxide) is often stamped on the shoulder of the cylinder. The pressure gauge of a nitrous oxide cylinder should not exceed 745 psig at 20°C. A higher reading implies gauge malfunction, tank overfill (liquid fill), or a cylinder containing a gas other than nitrous oxide.

Because energy is consumed in the conversion of a liquid to a gas (the latent heat of vaporization), the liquid nitrous oxide cools. The drop in temperature results in a lower vapor pressure and lower cylinder pressure. The cooling is so pronounced at high flow rates that there is often frost on the tank, and pressure regulators may freeze.

Medical Air

The use of air is becoming more frequent in anesthesiology as the popularity of nitrous oxide and unnecessarily high concentrations of oxygen has declined. Cylinder air is medical grade and is obtained by blending oxygen and nitrogen. Dehumidified but unsterile air is provided to the hospital pipeline system by compression pumps. The inlets of these pumps must be distant from vacuum exhaust vents and machinery to minimize contamination. Because the critical temperature of air is -140.6°C , it exists as a gas in cylinders whose pressures fall in proportion to their content.

Nitrogen

Although compressed nitrogen is not administered to patients, it may be used to drive some operating room equipment, such as saws, drills, and surgical handpieces. Nitrogen supply systems either incorporate the use of H-cylinders connected by a manifold or a wall system supplied by a compressor driven central supply.

Vacuum

A central hospital vacuum system usually consists of independent suction pumps, each capable of handling peak requirements. Traps at every user location prevent contamination of the system with foreign matter. The medical-surgical vacuum may be used for waste anesthetic gas disposal (WAGD) providing it does not affect the performance of the system. Medical vacuum receptacles are usually black in color with white lettering. A dedicated WAGD vacuum system is generally required with modern anesthesia machines. The WAGD outlet may incorporate the use of a suction regulator with a float indicator. The float should be maintained between the designated markings. Excess suction may result in inadequate patient ventilation, and insufficient suction levels may result in the failure to evaluate WAGD. WAGD receptacles and tubing are usually lavender in color.

Carbon Dioxide

Many surgical procedures are performed using laparoscopic or robotic-assisted techniques requiring insufflation of body cavities with carbon dioxide, an odorless, colorless, nonflammable and slightly acidic gas. Large cylinders containing carbon dioxide, such as M-cylinders or LK-cylinders, are frequently found in the operating room; these cylinders share a common size orifice and thread with oxygen cylinders and can be inadvertently interchanged.

DELIVERY OF MEDICAL GASES

Medical gases are delivered from their central supply source to the operating room through a piping network. Pipes are sized such that the pressure drop across the whole system never exceeds 5 psig. Gas pipes are usually constructed of seamless copper tubing using a special welding technique. Internal

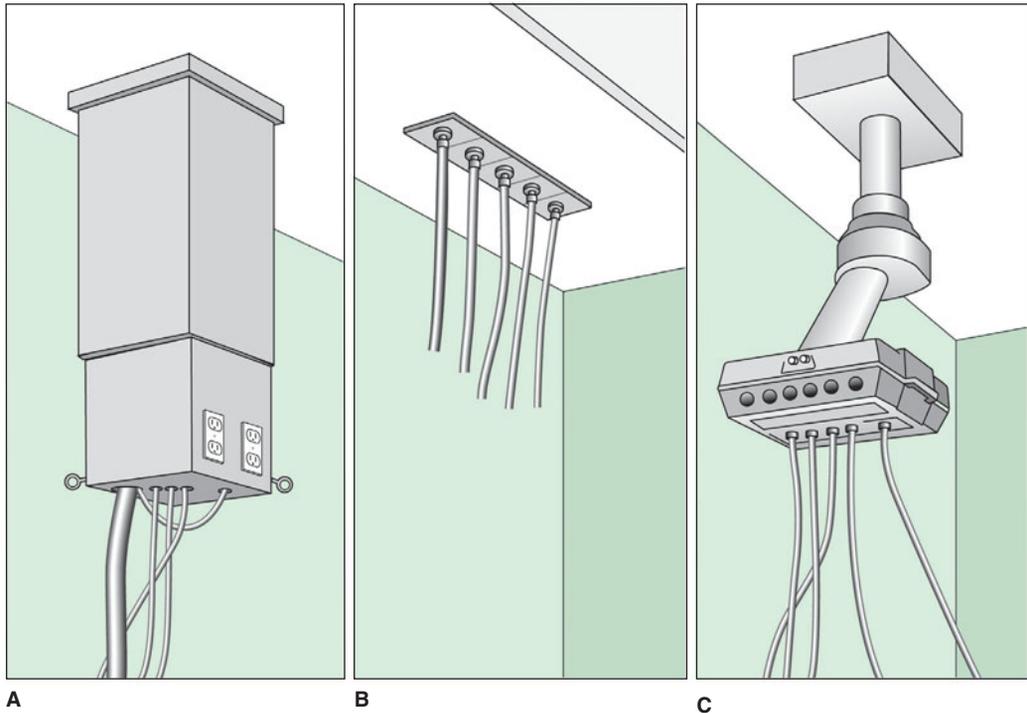

FIGURE 2-3 Typical examples of (A) gas columns, (B) ceiling hose drops, and (C) articulating arms. One end of a color-coded hose connects to the hospital medical

gas supply system by way of a quick-coupler mechanism. The other end connects to the anesthesia machine through the diameter index safety system.

contamination of the pipelines with dust, grease, or water must be avoided. The hospital's gas delivery system appears in the operating room as hose drops, gas columns, or elaborate articulating arms (Figure 2-3). Operating room equipment, including the anesthesia machine, interfaces with these pipeline system outlets by color-coded hoses. Quick-coupler mechanisms, which vary in design with different manufacturers, connect one end of the hose to the appropriate gas outlet. The other end connects to the anesthesia machine through a non-interchangeable diameter index safety system fitting that prevents incorrect hose attachment.

E-cylinders of oxygen, nitrous oxide, and air attach directly to the anesthesia machine. To discourage incorrect cylinder attachments, cylinder manufacturers have adopted a pin index safety system. Each gas cylinder (sizes A–E) has two holes in its cylinder valve that mate with corresponding

pins in the yoke of the anesthesia machine (Figure 2-4). The relative positioning of the pins and holes is unique for each gas. Multiple washers placed between the cylinder and yoke, which prevent proper engagement of the pins and holes, have unintentionally defeated this system. The pin index safety system is also ineffective if yoke pins are damaged or the cylinder is filled with the wrong gas.

The functioning of medical gas supply sources and pipeline systems is constantly monitored by central and area alarm systems. Indicator lights and audible signals warn of changeover to secondary gas sources and abnormally high (eg, pressure regulator malfunction) or low (eg, supply depletion) pipeline pressures (Figure 2-5).

Modern anesthesia machines and anesthetic gas analyzers continuously measure the fraction of inspired oxygen (FiO_2). Analyzers have a variable threshold setting for the minimal FiO_2 but should

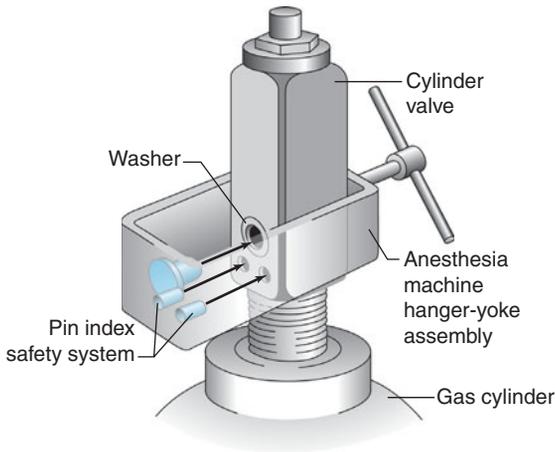

FIGURE 2-4 Pin index safety system interlink between the anesthesia machine and gas cylinder.

be configured to prevent disabling this alarm. The monitoring of FiO_2 does not reflect the oxygen concentration distal to the monitoring port and should not be used to reference the oxygen concentration

within devices such as endotracheal tubes or at the distal tip of the tube. Due to gas exchange, flow rates, and shunting a marked difference can exist between the monitored FiO_2 and oxygen concentration at the tissue level.

Environmental Factors in the Operating Room

TEMPERATURE

The temperature in most operating rooms seems uncomfortably cold to many conscious patients and, at times, to anesthesiologists. However, scrub nurses and surgeons stand in surgical garb for hours under hot operating room lights. As a general principle, the comfort of operating room personnel must be reconciled with patient care. Hypothermia has been associated with an increased incidence of wound infection, greater intraoperative blood loss (impaired coagulation assessed by thromboelastography), and prolonged hospitalization (see Chapter 52).

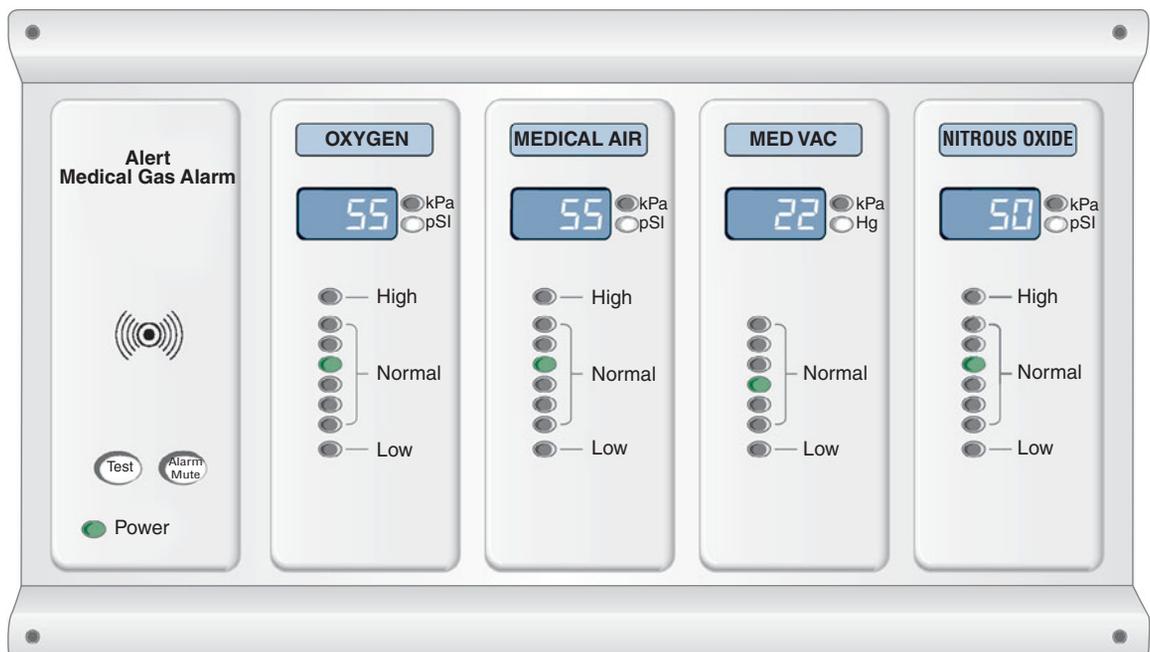

FIGURE 2-5 An example of a master alarm panel that monitors gasline pressure.

HUMIDITY

In past decades, static discharges were a feared source of ignition in an operating room filled with flammable anesthetic vapors. Now humidity control is more relevant to infection control practices. Optimally humidity levels in the operating room should be maintained between 50% and 55%. Below this range the dry air facilitates airborne motility of particulate matter, which can be a vector for infection. At high humidity, dampness can affect the integrity of barrier devices such as sterile cloth drapes and pan liners.

VENTILATION

A high rate of operating room airflow decreases contamination of the surgical site. These flow rates, usually achieved by blending up to 80% recirculated air with fresh air, are engineered in a manner to decrease turbulent flow and be unidirectional. Although recirculation conserves energy costs associated with heating and air conditioning, it is unsuitable for WAGD. Therefore, a separate anesthetic gas scavenging system must always supplement operating room ventilation. The operating room should maintain a slightly positive pressure to drive away gases that escape scavenging and should be designed so fresh air is introduced through or near the ceiling and air return is handled at or near floor level. Ventilation considerations must address air quality and volume changes. The National Fire Protection Agency (NFPA) recommends 25 air volume exchanges per hour to decrease risk of stagnation and bacterial growth. Air quality should be maintained by adequate air filtration using a 90% filter, defined simply as one that filters out 90% of particles presented. High-efficiency particulate filters (HEPA) are frequently used but are not required by engineering or infection control standards.

NOISE

Multiple studies have demonstrated that exposure to noise can have a detrimental effect on multiple human cognitive functions and may result in hearing impairment with prolonged exposure.

Operating room noise has been measured at 70–80 decibels (dB) with frequent sound peaks exceeding 80 dB. As a reference, if your speaking voice has to be raised above conversational level, then ambient noise is approximated at 80 dB. Noise levels in the operating room approach the time-weighted average (TWA) for which the Occupational Safety and Health Administration (OSHA) requires hearing protection. Orthopedic air chisels and neurosurgical drills can approach the noise levels of 125 dB, the level at which most human subjects begin to experience pain.

IONIZING RADIATION

Radiation is an energy form that is found in specific beams. For the anesthesia provider radiation is usually a component of either diagnostic imaging or radiation therapy. Examples include fluoroscopy, linear accelerators, computed tomography, directed beam therapy, proton therapy, and diagnostic radiographs. Human effects of radiation are measured by units of absorbed doses such as the gray (Gy) and rads or equivalent dose units such as the Sievert (Sv) and Roentgen equivalent in man (REM). Radiation-sensitive organs such as eyes, thyroid, and gonads must be protected, as well as blood, bone marrow, and fetus. Radiation levels must be monitored if individuals are exposed to greater than 40 REM. The most common method of measurement is by film badge. Lifetime exposure can be tabulated by a required database of film badge wearers.

4 A basic principle of radiation safety is to keep exposure “as low as reasonably practical” (ALARP). The principles of ALARP are protection from radiation exposure by the use of time, distance, and shielding. The length of time of exposure is usually not an issue for simple radiographs such as chest films but can be significant in fluoroscopic procedures such as those commonly performed during interventional radiology, c-arm use, and in the diagnostic gastroenterology lab. Exposure can be reduced to the provider by increasing the distance between the beam and the provider. Radiation exposure over distance follows the inverse square law. To illustrate, intensity is represented as $1/d^2$

(where d = distance) so that 100 mRADs at 1 inch will be 0.01 mRADs at 100 inches. Shielding is the most reliable form of radiation protection; typical personal shielding is in the form of leaded apron and glasses. Physical shields are usually incorporated into radiological suites and can be as simple as a wall to stand behind or a rolling leaded shield to place between the beam and the provider. Although most modern facilities are designed in a very safe manner, providers can still be exposed to scattered radiation as atomic particles are bounced off shielding. For this reason radiation protection should be donned whenever ionizing radiation is used.

As use of reliable shielding has increased, the incidence of radiation-associated diseases of sensitive organs has decreased, with the exception of radiation-induced cataracts. Because protective eyewear has not been consistently used to the same degree as other types of personal protection, radiation-induced cataracts are increasing among employees working in interventional radiology suites. Anesthesia providers who work in these environments should consider the use of leaded goggles or glasses to decrease the risk of such problems.

Electrical Safety

THE RISK OF ELECTROCUTION

The use of electronic medical equipment subjects patients and hospital personnel to the risk of electrocution. Anesthesiologists must have at least a basic understanding of electrical hazards and their prevention.

Body contact with two conductive materials at different voltage potentials may complete a circuit and result in an electrical shock. Usually, one point of exposure is a live 110-V or 240-V conductor, with the circuit completed through a ground contact. For example, a grounded person need contact only one live conductor to complete a circuit and receive a shock. The live conductor could be the frame of a patient monitor that has developed a fault to the hot side of the power line. A circuit is now complete between the power line (which is earth grounded at the utility company's pole-top

transformer) through the victim and back to the ground (Figure 2-6). The physiological effect of electrical current depends on the location, duration, frequency, and magnitude (more accurately, current density) of the shock.

Leakage current is present in all electrical equipment as a result of capacitive coupling, induction between internal electrical components, or defective insulation. Current can flow as a result of capacitive coupling between two conductive bodies (eg, a circuit board and its casing) even though they are not physically connected. Some monitors are doubly insulated to decrease the effect of capacitive coupling. Other monitors are designed to be connected to a low-impedance ground (the safety ground wire) that should divert the current away from a person touching the instrument's case.

5 The magnitude of such leaks is normally imperceptible to touch (<1 mA, and well below the fibrillation threshold of 100 mA). If the current bypasses the high resistance offered by skin, however, and is applied directly to the heart (**microshock**), current as low as 100 μ A may be fatal. The maximum leakage allowed in operating room equipment is 10 μ A.

Cardiac pacing wires and invasive monitoring catheters provide a conductive pathway to the myocardium. In fact, blood and normal saline can serve as electrical conductors. The exact amount of current required to produce fibrillation depends on the timing of the shock relative to the vulnerable period of heart repolarization (the T wave on the electrocardiogram). Even small differences in potential between the earth connections of two electrical outlets in the same operating room might place a patient at risk for microelectrocution.

PROTECTION FROM ELECTRICAL SHOCK

Most patient electrocutions are caused by current flow from the live conductor of a grounded circuit through the body and back to a ground (Figure 2-6). This would be prevented if everything in the operating room were grounded except the patient. Although direct patient grounds should be avoided, complete patient isolation is not feasible

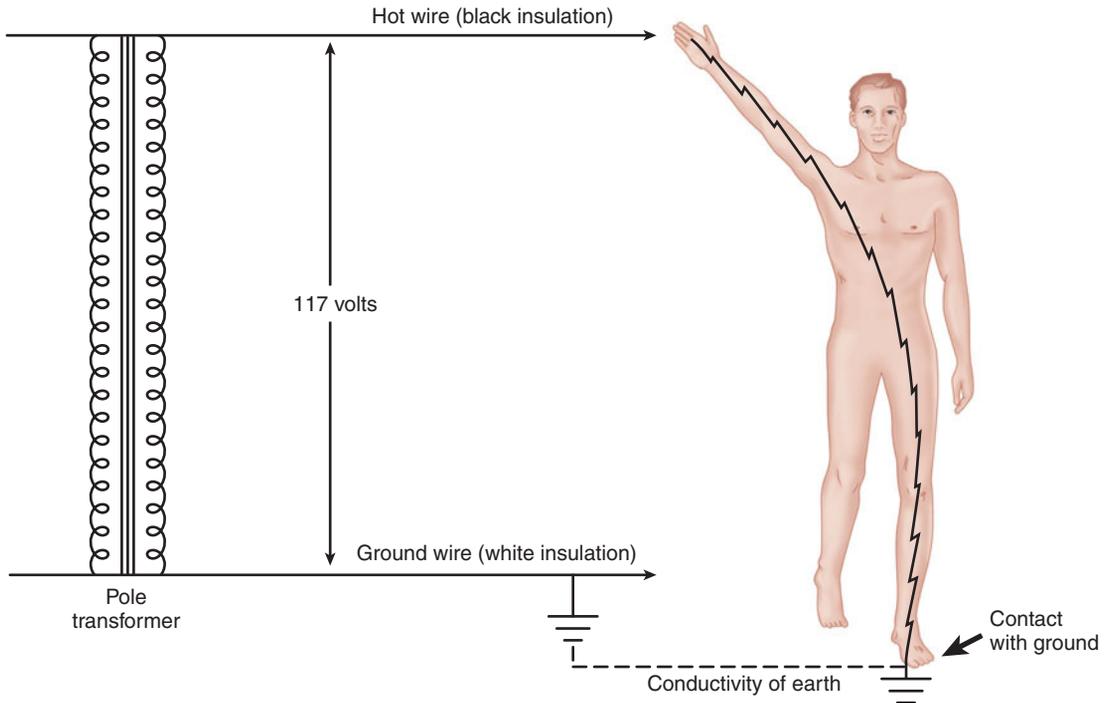

FIGURE 2-6 The setting for the great majority of electric shocks. An accidentally grounded person simultaneously contacts the hot wire of the electric service, usually via defective equipment that provides a pathway linking the hot wire to an exposed conductive surface. The complete electrical loop originates with the secondary of the pole transformer (the voltage source)

and extends through the hot wire, the victim and the victim’s contact with a ground, the earth itself, the neutral ground rod at the service entrance, and back to the transformer via the neutral (or ground) wire. (Modified and reproduced, with permission, from Bruner J, Leonard PF: *Electricity, Safety, and the Patient*. Mosby Year Book, 1989.)

during surgery. Instead, the operating room power supply can be isolated from grounds by an **isolation transformer** (Figure 2-7).

Unlike the utility company’s pole-top transformer, the secondary wiring of an isolation transformer is not grounded and provides two live ungrounded voltage lines for operating room equipment. Equipment casing—but not the electrical circuits—is grounded through the longest blade of a three-pronged plug (the safety ground). If a live wire is then unintentionally contacted by a grounded patient, current will not flow through the patient since no circuit back to the secondary coil has been completed (Figure 2-8).

Of course, if both power lines are contacted, a circuit is completed and a shock is possible. In addition, if either power line comes into contact

with a ground through a fault, contact with the other power line will complete a circuit through a **6** grounded patient. To reduce the chance of two coexisting faults, a **line isolation monitor** measures the potential for current flow from the isolated power supply to the ground (Figure 2-9). Basically, the line isolation monitor determines the degree of isolation between the two power wires and the ground and predicts the amount of current that *could* flow if a second short circuit were to develop. An alarm is activated if an unacceptably high current flow to the ground becomes possible (usually 2 mA or 5 mA), but power is not interrupted unless a ground-fault circuit interrupter is also activated. The latter, a feature of household bathrooms, is usually not installed in locations such as operating rooms,

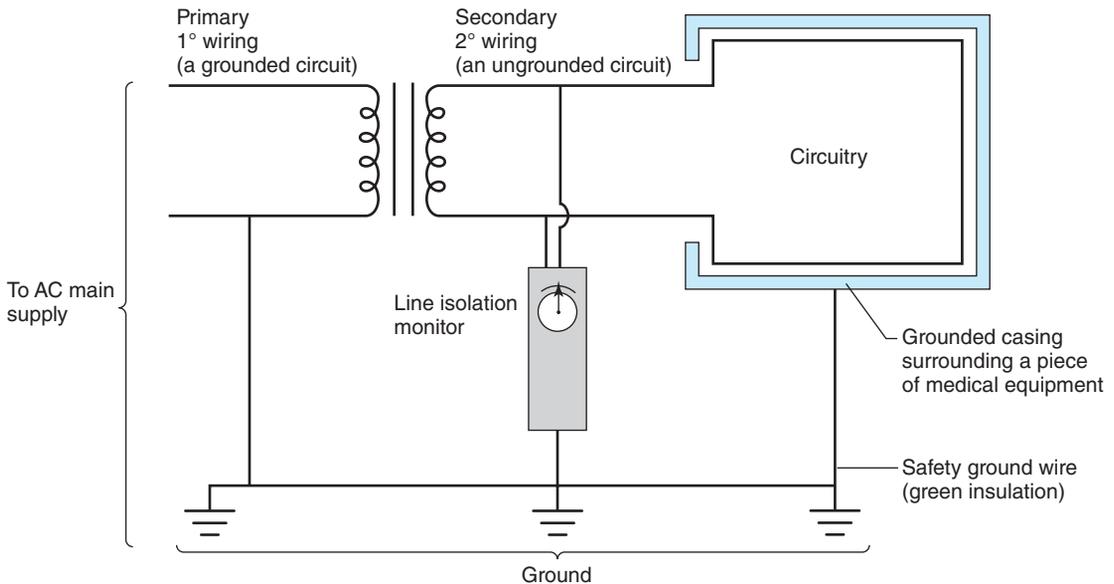

FIGURE 2-7 A circuit diagram of an isolation transformer and monitor.

where discontinuation of life support systems (eg, cardiopulmonary bypass machine) is more hazardous than the risk of electrical shock. The alarm of the line isolation monitor merely indicates that the power supply has partially reverted to a grounded system. In other words, while the line isolation monitor warns of the existence of a single fault (between a power line and a ground), two faults are required for a shock to occur. Since the line isolation monitor alarms when the sum of leakage current exceeds the set threshold, the last piece of equipment is usually the defective one; however, if this item is life-sustaining, other equipment can be removed from the circuit to evaluate whether the life safety item is truly at fault.

Even isolated power circuits do not provide complete protection from the small currents capable of causing microshock fibrillation. Furthermore, the line isolation monitor cannot detect all faults, such as a broken safety ground wire within a piece of equipment. Despite the overall utility of isolated power systems, they add to construction costs. Their requirement in operating rooms was deleted from the National Electrical Code in 1984, and circuits of newer or remodeled operating rooms may offer less

protection from electroshock injury than circuits of a household bathroom.

There are, however, modern equipment designs that decrease the possibility of microelectrocution. These include double insulation of the chassis and casing, ungrounded battery power supplies, and patient isolation from equipment-connected grounds by using optical coupling or transformers.

SURGICAL DIATHERMY

Electrosurgical units (ESUs) generate an ultrahigh-frequency electrical current that passes from a small active electrode (the cautery tip) through the patient and exits by way of a large plate electrode (the dispersal pad, or return electrode). The high current density at the cautery tip is capable of tissue coagulation or cutting, depending on the electrical waveform. Ventricular fibrillation is prevented by the use of ultrahigh electrical frequencies (0.1–3 MHz) compared with line power (50–60 Hz). The large surface area of the low-impedance return electrode avoids burns at the current's point of exit by providing a low current density (the concept of *exit* is technically incorrect, as the current

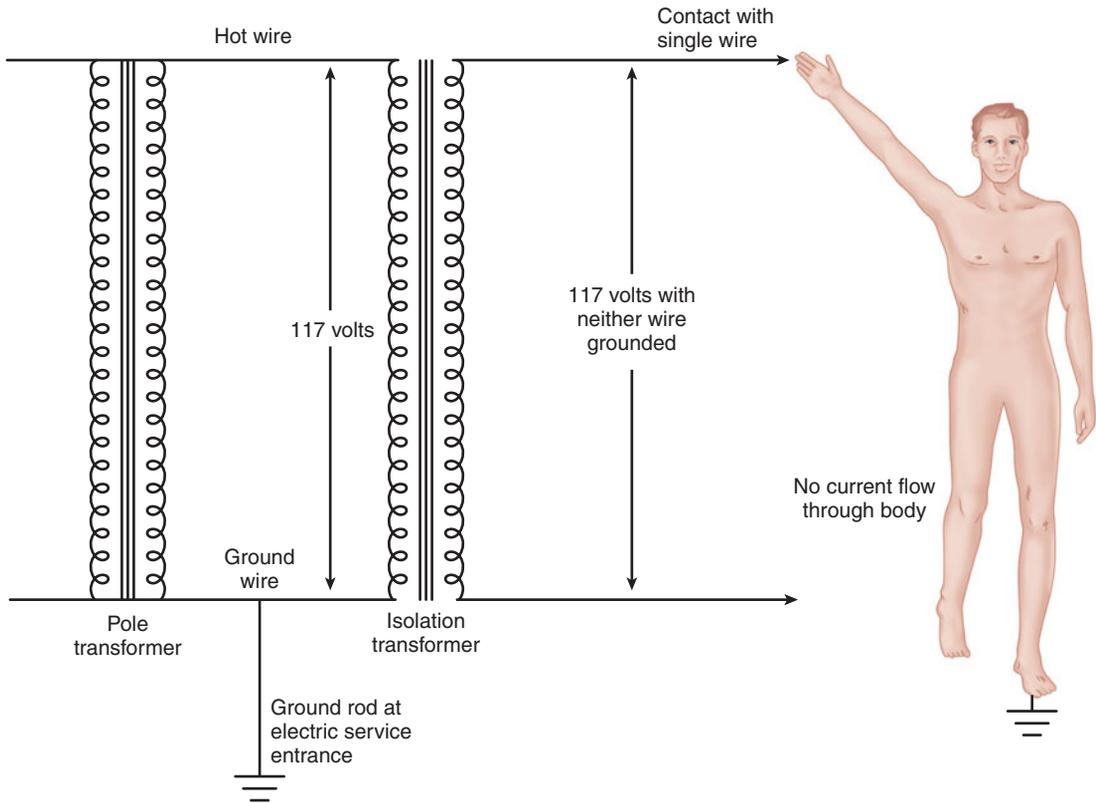

FIGURE 2-8 Even though a person is grounded, no shock results from contact with one wire of an isolated circuit. The individual is in simultaneous contact with two separate voltage sources but does not close a loop

including either source. (Modified and reproduced, with permission, from Bruner J, Leonard PF: *Electricity, Safety, and the Patient*. Mosby Year Book, 1989.)

is alternating rather than direct). The high power levels of ESUs (up to 400 W) can cause inductive coupling with monitor cables, leading to electrical interference.

Malfunction of the dispersal pad may result from disconnection from the ESU, inadequate patient contact, or insufficient conductive gel. In these situations, the current will find another place to exit (eg, electrocardiogram pads or metal parts of the operating table), which may result in a burn (Figure 2-10). Precautions to prevent diathermy burns include proper return electrode placement, avoiding prostheses and bony protuberances, and elimination of patient-to-ground contacts. Current flow through the heart may lead to dysfunction of

an implanted cardiac rhythm management device (CRMD). This can be minimized by placing the return electrode as close to the surgical field and as far from the CRMD as practical.

Newer ESUs are isolated from grounds using the same principles as the isolated power supply (isolated output versus ground-referenced units). Because this second layer of protection provides ESUs with their own isolated power supply, the operating room's line isolation monitor may not detect an electrical fault. Although some ESUs are capable of detecting poor contact between the return electrode and the patient by monitoring impedance, many older units trigger the alarm only if the return electrode is unplugged from the machine. Bipolar

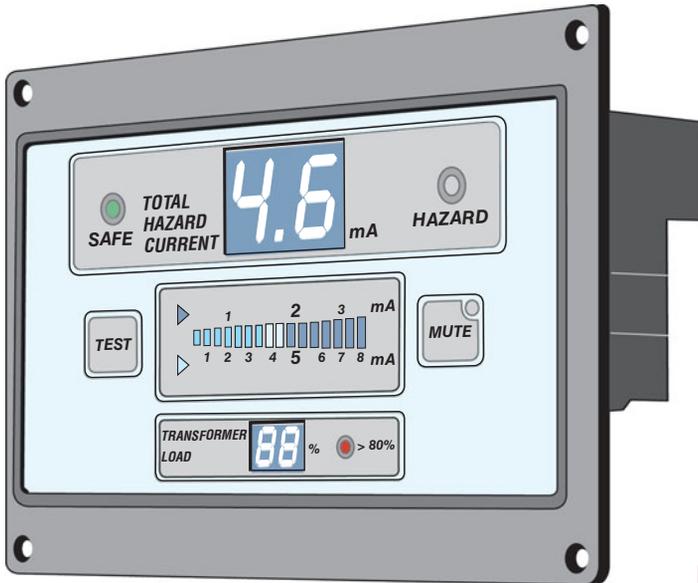

FIGURE 2-9 A line isolation monitor.

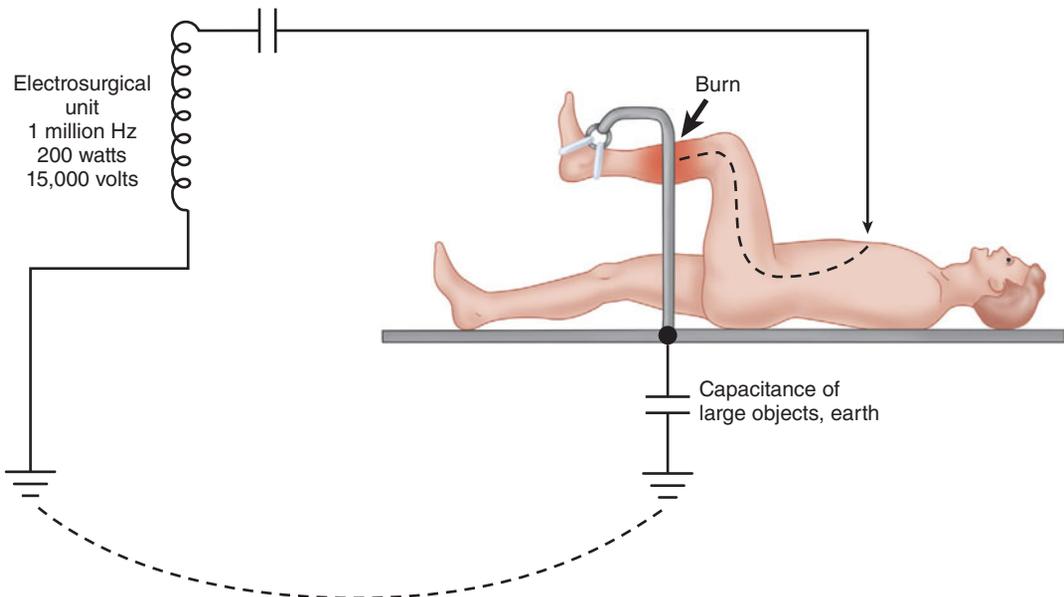

FIGURE 2-10 Electro-surgical burn. If the intended path is compromised, the circuit may be completed through other routes. Because the current is of high frequency, recognized conductors are not essential; capacitances can complete gaps in the circuit. Current passing through the patient to a contact of small area may produce a burn. (A leg drape would not offer protection in the situation

depicted.) The isolated output electro-surgical unit (ESU) is much less likely than the ground-referenced ESU to provoke burns at ectopic sites. *Ground-referenced* in this context applies to the ESU output and has nothing to do with isolated versus grounded power systems. (Modified and reproduced, with permission, from Bruner J, Leonard PF: *Electricity, Safety, and the Patient*. Mosby Year Book, 1989.)

electrodes confine current propagation to a few millimeters, eliminating the need for a return electrode. Because pacemaker and electrocardiogram interference is possible, pulse or heart sounds should be closely monitored when any ESU is used. Automatic implanted cardioversion and defibrillator devices may need to be suspended if monopolar ESU is used and any implanted CRMD should be interrogated after use of a monopolar ESU.

Surgical Fires & Thermal Injury

FIRE PREVENTION & PREPARATION

Surgical fires are relatively rare, with an incidence of about 1:87,000 cases, which is close to the incidence rate of other events such as retained foreign objects after surgery and wrong-site surgery.

7 Almost all surgical fires can be prevented. Unlike medical complications, fires are a product of simple physical and chemical properties. Occurrence is guaranteed given the proper combination of factors but can be eliminated almost entirely by understanding the basic principles of fire risk. Likely the most common risk factor for surgical fire relates to the open delivery of oxygen.

Situations classified as carrying a high risk for a surgical fire are those that involve an ignition source used in close proximity to an oxidizer. The simple chemical combination required for any fire is commonly referred to as the fire triad or fire triangle. The triad is composed of fuel, oxidizer, and ignition source (heat). **Table 2–2** lists potential contributors to fires and explosions in the operating room. Surgical fires can be managed and possibly avoided completely by incorporating education, fire drills, preparation, prevention, and response into educational programs provided to operating room personnel.

For anesthesia providers, fire prevention education should place a heavy emphasis on the risk relating to the open delivery of oxygen. The Anesthesia Patient Safety Foundation has developed an educational video and online teaching module that

Lasers
Electrosurgical units
Fiberoptic light sources (distal tip)
Drills and burrs
External defibrillators

provides fire safety education from the perspective of the anesthesia provider.

Operating room fire drills increase awareness of the fire hazards associated with surgical procedures. In contrast to the typical institutional fire drill, these drills should be specific to the operating room and should place a greater emphasis on the particular risks associated with that setting. For example, consideration should be given to both vertical and horizontal evacuation of surgical patients, movement of patients requiring ventilatory assistance, and unique situations such as prone or lateral positioning and movement of patients who may be fixed in neurosurgical pins.

Preparation for surgical fires can be incorporated into the time-out process of the universal protocol. Team members should be introduced and specific roles agreed upon should a fire erupt. Items needed to properly manage a fire can be assembled

or identified beforehand (eg, ensuring the proper endotracheal tube for patients undergoing laser surgery; having water or saline ready on the surgical field; identifying the location of fire extinguishers, gas cutoff valves, and escape routes). A poster or flowsheet to standardize the preparation may be of benefit.

Preventing catastrophic fires in the operating room begins with a strong level of communication among all members of the surgical team. Different aspects of the fire triad are typically under the domain of particular surgical team members. Fuels such as alcohol-based solutions, adhesive removers, and surgical drapes and towels are typically controlled by the circulating nurse. Ignition sources such as electrocautery, lasers, drills, burrs, and light sources for headlamps and laparoscopes are usually controlled by the surgeon. The anesthesia provider maintains control of the oxidizer concentration of oxygen and nitrous oxide. Communication between personnel is evident when a surgeon enters the airway and verifies the concentration of oxygen before using cautery, or when an anesthesiologist asks the circulator to configure drapes to prevent the accumulation of oxygen in a surgical case that involves sedation and use of a nasal cannula.

9 Administration of oxygen in concentrations of greater than 30% should be guided by clinical presentation of the patient and not solely by protocols or habits. If oxygen is being delivered via nasal cannula or face mask, and if increased oxygen levels are needed, then the airway should be secured by either endotracheal tube or supraglottic device. This is of prime importance when the surgical site is above the level of the xiphoid.

When the surgical site is in or near the airway and a flammable tube is present, the oxygen concentration should be reduced for a sufficient period of time before use of an ignition device (eg, laser or cautery) to allow reduction of oxygen concentration at the site. Laser airway surgery should incorporate either jet ventilation without an endotracheal tube or the appropriate protective tube specific for the wavelength of the laser. Precautions for laser cases are outlined below.

Alcohol-based skin preparations are extremely flammable and require an adequate drying time.

Pooling of solutions must be avoided. Large pre-filled swabs of alcohol-based solution should be used with caution on the head or neck to avoid both oversaturation of the product and excess flammable waste. Product inserts are a good source of information about these preparations. Surgical gauze and sponges should be moistened with sterile water or saline if used in close proximity to an ignition source.

Should a fire occur in the operating room it is important to determine whether the fire is located *on the patient, in the airway, or elsewhere in the operating room*. For fires occurring in the airway, the delivery of fresh gases to the patient must be stopped. Effective means of stopping fresh gases to the patient can be accomplished by turning off flowmeters, disconnecting the circuit from the machine, or disconnecting the circuit from the endotracheal tube. The endotracheal tube should be removed and either sterile water or saline should be poured into the airway to extinguish any burning embers. The sequence of stopping gas flow and removal of the endotracheal tube when fire occurs in the airway is not as important as ensuring that both actions are performed quickly. Often the two tasks can be accomplished at the same time and even by the same individual. If carried out by different team members, the personnel should act without waiting for a predetermined sequence of events. After these actions are carried out, ventilation may be resumed, preferably using room air and avoiding oxygen or nitrous oxide-enriched gases. The tube should be examined for missing pieces. The airway should be reestablished and, if indicated, examined with a bronchoscope. Treatment for smoke inhalation and possible transfer to a burn center should also be considered.

For fires on the patient, the flow of oxidizing gases should be stopped, the surgical drapes removed, and the fire extinguished by water or smothering. The patient should be assessed for injury. If the fire is not immediately extinguished by first attempts, then a carbon dioxide (CO₂) fire extinguisher may be used. Further actions may include evacuation of the patient and activation of the nearest pull station. As noted previously, prior to an actual emergency, the location of fire extinguishers, emergency exits,

and fresh gas cutoff valves should be established by the anesthesia provider.

Fires that result in injuries requiring medical treatment or death must be reported to the fire marshal, who retains jurisdiction over the facility. Providers should gain basic familiarity with local reporting standards, which can vary according to location.

Cases in which supplemental delivery of oxygen is used and the surgical site is above the xiphoid constitute the most commonly reported scenario for surgical fires. Frequently the face or airway is involved, resulting in life-threatening injuries and the potential for severe facial disfigurement. For the most part, these fires can be avoided by the elimination of the open delivery of oxygen, by use of an oxygen blender, or by securing the airway.

FIRE EXTINGUISHERS

For fires not suppressed by initial attempts or those in which evacuation may be hindered by the location or intensity of the fire, the use of a portable fire extinguisher is warranted. A CO₂ extinguisher should be safe during external and internal exposure for fires on the patient in the operating room. CO₂ readily dissipates, is not toxic, and as used in an actual fire is not likely to result in thermal injury. FE-36, manufactured by DuPont, also can be used to extinguish fires but is expensive. Both choices are equally effective and acceptable agents as reflected by manufacturers' product information.

"A"-rated extinguishers contain water, which makes their use in the operating room problematic because of the presence of so much electrical equipment. A water mist "AC"-rated extinguisher is excellent but requires time and an adequate volume of mist over multiple attempts to extinguish the fire. Furthermore, these devices are large and difficult to maneuver. Both can be made cheaply in a nonferromagnetic extinguisher, making them the best choice for fires involving magnetic resonance imagers. Halon extinguishers, although very effective, are being phased out because of concerns about depletion of the ozone layer, as well as the hypoxic atmosphere that results for rescuers. Halotrons are

"greener" halon-type extinguishers that may have fewer effects on the ozone layer.

LASER SAFETY

Lasers are commonly used in operating rooms and procedure areas. When lasers are used for airway surgeries or for procedures involving the neck and face, the case should be considered as high risk for surgical fire and managed as previously discussed. The type of laser (CO₂, neodymium yttrium aluminum garnet [NG:YAG], or potassium titanyl phosphate [KTP]), wavelength, and focal length are all important considerations for the safe operation of medical lasers. Without this vital information, operating room personnel cannot adequately protect

11 themselves or the patient from harm. Before beginning laser surgery, the laser device should be in the operating room, warning signs should be posted on the doors, and protective eyewear should be issued. The anesthesia provider should ensure that the warning signs and eyewear match the labeling on the device as protection is specific to the type of laser. The American National Standards Institute (ANSI) standards specify that eyewear and laser devices must be labeled for the wavelength emitted or protection offered. Some ophthalmologic lasers and vascular mapping lasers have such a short focal length that protective eyewear is not needed. For other devices, protective goggles should be worn by personnel at all times during laser use, and eye protection in the form of either goggles or protective eye patches should be used on the patient.

Laser endotracheal tube selection should be based on laser type and wavelength. The product insert and labeling for each type of tube should be compared to the type of laser used. Certain technical limitations are present when selecting laser tubes. For instance, tubes less than 4.0 mm in diameter are not compatible with the ND:YAG or argon laser nor are ND:YAG-compatible tubes available in half sizes. Attempts to wrap conventional endotracheal tubes with foil should be avoided. This archaic method is not approved by either manufacturers or the U.S. Food and Drug Administration, is prone to breaking or unraveling, and does not confer protection against laser penetration. Alternatively, jet

ventilation without an endotracheal tube can offer a reduced risk of airway fire.

CREW RESOURCE MANAGEMENT: CREATING A CULTURE OF SAFETY IN THE OPERATING ROOM

Crew resource management (CRM) was developed in the aviation industry to allow personnel to intervene or call for investigation of any situation thought to be unsafe. Comprising seven principles, its goal is to avoid errors caused by human actions. In the airline model CRM gives any crew member the authority to question situations that fall outside the range of normal practice. Before the implementation of CRM, crew members other than the captain had little or no input on aircraft operations. After CRM was instituted, anyone identifying a safety issue could take steps to ensure adequate resolution of the situation. The benefit of this method in the operating room is clear, given the potential for a deadly mistake to be made.

The seven principles of CRM are (1) adaptability/flexibility, (2) assertiveness, (3) communication, (4) decision making, (5) leadership, (6) analysis, and (7) situational awareness. *Adaptability/flexibility* refers to the ability to alter a course of action when new information becomes available. For example, if a major blood vessel is unintentionally cut in a routine procedure, the anesthesiologist must recognize that the anesthetic plan has changed and volume resuscitation must be made even in presence of medical conditions that typically contraindicate large-volume fluid administration.

Assertiveness is the willingness and readiness to actively participate, state, and maintain a position until convinced by the facts that other options are better; this requires the initiative and the courage to act. For instance, if a senior and well-respected surgeon tells the anesthesiologist that the patient's aortic stenosis is not a problem because it is a chronic condition and the procedure will be relatively quick, the anesthesiologist should respond by voicing concerns about the management of the patient and should not proceed until a safe anesthetic and surgical plan have been agreed upon.

Communication is defined simply as the clear and accurate sending and receiving of information, instructions, or commands, and providing useful feedback. Communication is a two-way process and should continue in a loop fashion.

Decision making is the ability to use logical and sound judgment to make decisions based on available information. Decision-making processes are involved when a less experienced clinician seeks out the advice of a more experienced clinician or when a person defers important clinical decisions because of fatigue. Good decision making is based on realization of personal limitations.

Leadership is the ability to direct and coordinate the activities of other crew members and to encourage the crew to work together as a team. *Analysis* refers to the ability to develop short-term, long-term, and contingency plans, as well as to coordinate, allocate, and monitor crew and operating room resources.

The last and most important principle is *situational awareness*; that is, the accuracy with which a person's perception of the current environment mirrors reality. In the operating room, lack of situational awareness can cost precious minutes, as when readings from a monitor (eg, capnograph or arterial line) suddenly change and the operator focuses on the monitor rather than on the patient, who may have had an embolism. One must decide whether the monitor is correct and the patient is critically ill or the monitor is incorrect and the patient is fine. The problem-solving method utilized should consider both possibilities but quickly eliminate one. In this scenario, tunnel vision can result in catastrophic mistakes. Furthermore, if the sampling line has come loose and the capnograph indicates low end-tidal CO₂, this finding does not exclude the possibility that at the same time or even a bit later, the patient could have a pulmonary embolus resulting in decreased end-tidal CO₂.

If all members of the operating room team apply these seven principles, problems arising from human factors can almost entirely be eliminated. A culture of safety must also exist if the operating room is to be made a safer place. These seven principles serve no purpose when applied in a suppressive surgical environment. Anyone with a concern must be able to speak up without fear of repercussion.

Chapter 58 provides further discussion of these and other issues relating to patient safety.

FUTURE DESIGN OF OPERATING ROOMS

Safety Interlock Technology

Despite heightened awareness of safety factors and increased educational efforts among operating room personnel, harm to patients still occurs at a rate that most industries and the public deem unacceptably high. Similarly, despite threats of payment withholding, public scoring of medical personnel and hospital systems, provider rating web sites, and punitive legal consequences, the human factors resulting in medical errors have not been completely eliminated. In future, safety-engineered designs may assist in the reduction of medical errors. One developing area is the use of interlock devices in the operating room. An interlock device is simply a device that cannot be operated until a defined sequence of events occurs. Anesthesia personnel use interlock technology with anesthesia vaporizers that prevent the use of more than one vaporizer at a time. Expansion of this technology might prevent release of a drug from an automated dispensing device until a barcode is scanned from a patient's hospital armband or, at a minimum, the patient's drug allergies have been entered into the machine's database. Other applications might include an electrosurgical device or laser that could not be used when the FiO_2 content was higher than 30%, thus eliminating the risk of fire. Likewise, computers, monitors, and other devices could be designed to be inoperable until patient identification was confirmed.

Workflow Design

Coordinating the activities of surgical personnel, anesthesia providers, and operating room nurses is essential to the day-to-day running of a surgical suite. Clinical directors in facilities ranging from one- or two-room suites to multiroom centers must accommodate surgical procedures of varying durations, requiring varying degrees of surgical skill and efficiency, while allowing for sudden, unplanned, or emergency operations. The need to monitor workflow and analyze data for optimizing scheduling and

staffing prompted the development of software systems that anticipate and record the timing of surgical events; these systems are constantly being refined.

Surgical suites are also being designed to augment workflow by incorporating separate induction areas to decrease nonsurgical time spent in operating rooms. Several models exist for induction room design and staffing. Although uncommon in the United States, induction rooms have long been employed in the United Kingdom.

One induction room model uses rotating anesthesia teams. One team is assigned to the first patient of the day; a second team induces anesthesia for the next patient in an adjacent area while the operating room is being turned over. The second team continues caring for that patient after transfer to the operating room, leaving the first team available to induce anesthesia in the third patient as the operating room is being turned over. The advantage of this model is continuity of care; the disadvantage is the need for two anesthesia teams for every operating room.

Another model uses separate induction and anesthesia teams. The induction team induces anesthesia for all patients on a given day and then transfers care to the anesthesia team, which is assigned to an individual operating room. The advantage of this model is the reduction in anesthesia personnel to staff induction rooms; disadvantages include failure to maintain continuity of care and staffing problems that occur when several patients must undergo induction concurrently. This model can utilize either a separate induction room adjacent to each operating room or one common induction room that services several operating rooms.

The final model uses several staffed operating rooms, one of which is kept open. After the first patient of the day is transferred to the initial room, subsequent patients always proceed to the open room, thus eliminating the wait for room turnover and readiness of personnel. All of these models assume that the increased overhead cost of maintaining additional anesthesia personnel can be justified by the increased surgical productivity.

Radio Frequency Identification (RFID)

Radio frequency identification (RFID) technology utilizes a chip with a small transmitter whose

signal is read by a reader; each chip yields a unique signal. The technology has many potential applications in the modern operating room. Using RFID in employee identification (ID) badges could enable surgical control rooms to keep track of nursing, surgical faculty, and anesthesia personnel, obviating the need for paging systems and telephony to establish the location of key personnel. Incorporating the technology in patient ID bands and hospital gurneys could allow a patient's flow to be tracked through an entire facility. The ability to project an identifying signal to hospital systems would offer an additional degree of safety for patients unable to communicate with hospital personnel. Finally, RFID could be incorporated into surgical instruments and sponges, allowing surgical counts to be performed by identification of the objects as they are passed on and off the surgical field. In the event that counts are mismatched, a wand could then be placed over the patient to screen for retained objects.

CASE DISCUSSION

Monitored Anesthesia Care with Oxygen Supplementation

You are asked to provide monitored anesthesia care for a patient undergoing simple removal of a lesion on the cheek. The patient is morbidly obese and has a history of sleep apnea. He states, "It bothers me when people are working on my face," and indicates that he does not want to remember anything about the surgery. The surgeon assures you the procedure will not last more than 5 minutes. The patient's wife mentions that they are from out of town and have made flight arrangements to return home soon after the procedure.

What features of this case indicate a high risk for surgical fire?

Patients with a clinical history of obstructive sleep apnea usually have a sensitivity to sedating medications, especially opioid narcotics. Typically administration of even small doses of narcotics obstructs the upper airways, resulting in hypoventilation and hypercapnia. In the obese patient, this response combined with decreased functional

reserve capacity results in rapid oxygen desaturation. Most anesthesia providers respond by increasing the amount of oxygen supplementation delivered via face mask or nasal cannula. Open delivery of oxygen in concentrations greater than 30% is one of the elements of the fire triad. Another consideration is the anatomical location of the procedure. A location above the xiphoid process in this patient would place an ignition source (if used) in close proximity to the open delivery of an oxidizer.

What is the safest manner in which to proceed?

There are three strategies that can be implemented to improve safety in this scenario: avoid oxygen supplementation, secure the airway with an endotracheal tube or supraglottic device, or avoid use of an ignition source.

Are there any concerns relating to airway management or selection of the delivery device?

As previously noted, the patient is likely to manifest airway changes associated with obstructive sleep apnea and obesity. Selection of a delivery device should take into consideration the need to prevent the open delivery of oxygen.

How would the length of the procedure affect the management of anesthesia?

Practically speaking, if the patient requires a lengthy procedure, local anesthetics may wear off; the cumulative dose of narcotics provided may exacerbate the patient's obstructive sleep apnea and increase recovery time. Additionally, more complex surgical excision may result in bleeding requiring the use of cautery.

Does the patient's expectation of discharge soon after the procedure affect your anesthesia plans?

The expectation of an accelerated recovery period may not be feasible if the patient requires general anesthesia or significant amounts of opioid narcotics. The American Society of Anesthesiologists (ASA) has published a practice advisory providing direction for the safe postoperative assessment and discharge of patients with obstructive sleep apnea. See www.asahq.org.

What if the surgeon thinks your plans are “overkill”?

The first and most effective means for conflict resolution is to communicate your specific concerns to the surgeon. If this fails, the procedure must not be allowed to proceed as long as any team member has a legitimate safety concern. Many ASA safety-related guidelines and advisories are also endorsed by professional societies such as the American College of Surgeons (ACS) and other organizations. The anesthesiologist should also gain familiarity with a facility's methods of dispute resolution before an event occurs.

Breathing Systems

KEY CONCEPTS

- 1 Because insufflation avoids any direct patient contact, there is no rebreathing of exhaled gases if the flow is high enough. Ventilation cannot be controlled with this technique, however, and the inspired gas contains unpredictable amounts of entrained atmospheric air.
- 2 Long breathing tubes with high compliance increase the difference between the volume of gas delivered to a circuit by a reservoir bag or ventilator and the volume actually delivered to the patient.
- 3 The adjustable pressure-limiting (APL) valve should be fully open during spontaneous ventilation so that circuit pressure remains negligible throughout inspiration and expiration.
- 4 Because a fresh gas flow equal to minute ventilation is sufficient to prevent rebreathing, the Mapleson A design is the most efficient Mapleson circuit for spontaneous ventilation.
- 5 The Mapleson D circuit is efficient during controlled ventilation, because fresh gas flow forces alveolar air away from the patient and toward the APL valve.
- 6 The drier the soda lime, the more likely it will absorb and degrade volatile anesthetics.
- 7 Malfunction of either unidirectional valve in a circle system may allow rebreathing of carbon dioxide, resulting in hypercapnia.
- 8 With an absorber, the circle system prevents rebreathing of carbon dioxide at fresh gas flows that are considered low (fresh gas flow ≤ 1 L) or even fresh gas flows equal to the uptake of anesthetic gases and oxygen by the patient and the circuit itself (closed-system anesthesia).
- 9 Because of the unidirectional valves, apparatus dead space in a circle system is limited to the area distal to the point of inspiratory and expiratory gas mixing at the Y-piece. Unlike Mapleson circuits, the circle system tube length does not directly affect dead space.
- 10 The fraction of inspired oxygen (F_{iO_2}) delivered by a resuscitator breathing system to the patient is directly proportional to the oxygen concentration and flow rate of the gas mixture supplied to the resuscitator (usually 100% oxygen) and inversely proportional to the minute ventilation delivered to the patient.

Breathing *systems* provide the final conduit for the delivery of anesthetic gases to the patient. Breathing *circuits* link a patient to an anesthesia machine (Figure 3-1). Many different circuit designs have been developed, each with varying

degrees of efficiency, convenience, and complexity. This chapter reviews the most important breathing systems: insufflation, draw-over, Mapleson circuits, the circle system, and resuscitation systems.

FIGURE 3-1 The relationship between the patient, the breathing system, and the anesthesia machine.

Most classifications of breathing systems artificially consolidate functional characteristics (eg, the extent of rebreathing) with physical characteristics (eg, the presence of unidirectional valves). Because these seemingly contradictory classifications (eg, open, closed, semiopen, semiclosed) often tend to confuse rather than aid understanding, they are avoided in this discussion.

INSUFFLATION

The term insufflation usually denotes the blowing of anesthetic gases across a patient's face. Although insufflation is categorized as a breathing system, it is perhaps better considered a technique that avoids direct connection between a breathing circuit and a patient's airway. Because children often resist the placement of a face mask (or an intravenous line), insufflation is particularly valuable during inductions with inhalation anesthetics in children (**Figure 3-2**). It is useful in other situations as well. Carbon dioxide accumulation under head and neck draping is a hazard of ophthalmic surgery performed with local anesthesia. Insufflation of air across the patient's face at a high flow rate (>10 L/min) avoids this problem, while not increasing the risk of fire from accumulation of oxygen

1 (**Figure 3-3**). Because insufflation avoids any direct patient contact, there is no rebreathing of exhaled gases if the flow is high enough. Ventilation cannot be controlled with this technique, however, and the inspired gas contains unpredictable amounts of entrained atmospheric air.

FIGURE 3-2 Insufflation of an anesthetic agent across a child's face during induction.

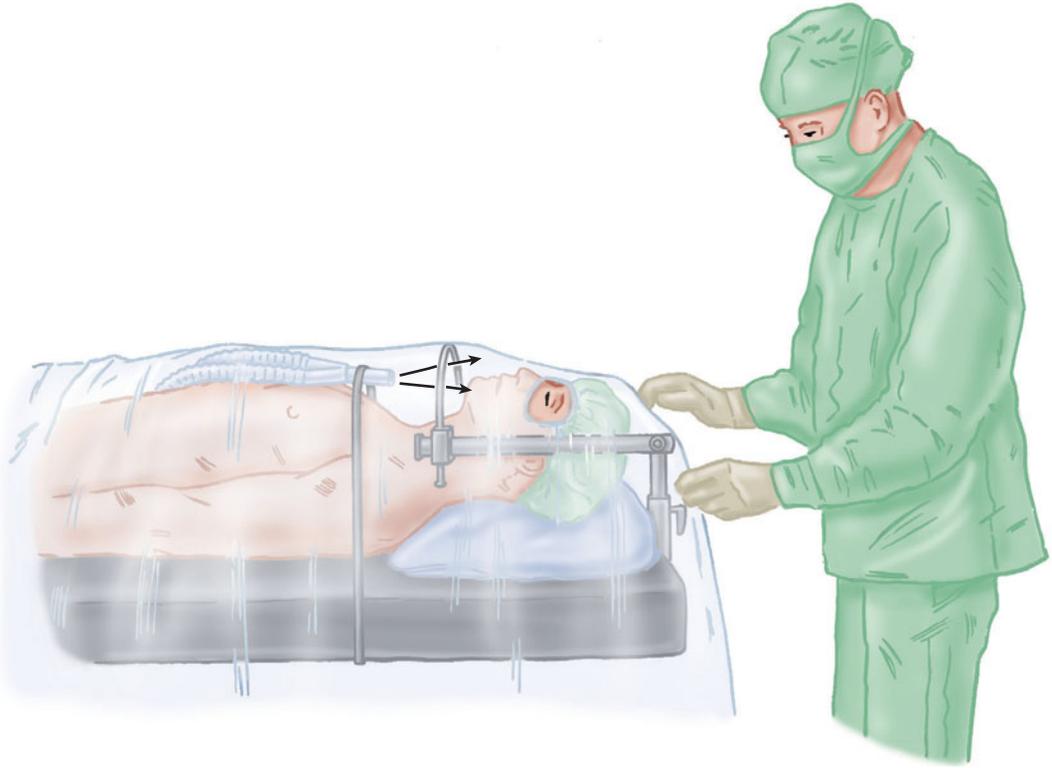

FIGURE 3-3 Insufflation of oxygen and air under a head drape.

Insufflation can also be used to maintain arterial oxygenation during brief periods of apnea (eg, during bronchoscopy). Instead of blowing gases across the face, oxygen is directed into the lungs through a device placed in the trachea.

OPEN-DROP ANESTHESIA

Although open-drop anesthesia is not used in modern medicine, its historic significance warrants a brief description here. A highly volatile anesthetic—historically, ether or chloroform—was dripped onto a gauze-covered mask (Schimmelbusch mask) applied to the patient's face. As the patient inhales, air passes through the gauze, vaporizing the liquid agent, and carrying high concentrations of anesthetic to the patient. The vaporization lowers mask temperature, resulting in moisture condensation

and a drop in anesthetic vapor pressure (vapor pressure is proportional to temperature).

A modern derivative of open-drop anesthesia utilizes draw-over vaporizers that depend on the patient's inspiratory efforts to draw ambient air through a vaporization chamber. This technique may be used in locations or situations in which compressed medical gases are unavailable (eg, battlefields).

DRAW-OVER ANESTHESIA

Draw-over devices have nonbreathing circuits that use ambient air as the carrier gas, although supplemental oxygen can be used, if available. The devices can be fitted with connections and equipment that allow intermittent positive-pressure ventilation (IPPV) and passive scavenging, as well as

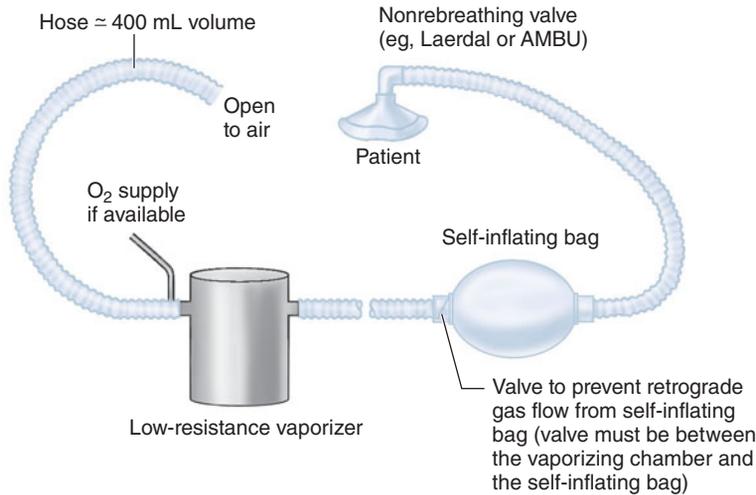

FIGURE 3-4 Schematic diagram of a draw-over anesthesia device/circuit.

continuous positive airway pressure (CPAP) and positive end-expiratory pressure (PEEP).

In its most basic application (**Figure 3-4**), air is drawn through a low-resistance vaporizer as the patient inspires. Patients spontaneously breathing room air and a potent halogenated agent often manifest an oxygen saturation (SpO_2) $<90\%$, a situation treated with IPPV, supplemental oxygen, or both. The fraction of inspired oxygen (F_{IO_2}) can be supplemented using an open-ended reservoir tube of about 400 mL, attached to a t-piece at the upstream side of the vaporizer. Across the clinical range of tidal volume and respiratory rate, an oxygen flow rate of 1 L/min gives an F_{IO_2} of 30% to 40%, or with 4 L/min, an F_{IO_2} of 60% to 80%. There are several commercial draw-over systems available that share common properties (**Table 3-1**).

The greatest advantage of draw-over systems is their simplicity and portability, making them useful

in locations where compressed gases or ventilators are not available. The presence of the nonbreathing valve, PEEP valve, and circuit filter close to the patient's head makes the technique awkward for head and neck surgery and pediatric cases. If the head is draped, the nonbreathing valve is often covered as well.

The original design of a draw-over system has recently been modified to include a self-inflating bag, a ventilator, and/or a heat and moisture exchanger. The Ohmeda Universal Portable Anesthesia Complete (U-PAC) is one example of a draw-over anesthesia system.

MAPLESON CIRCUITS

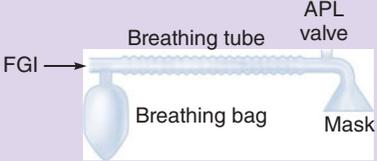

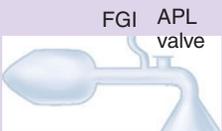

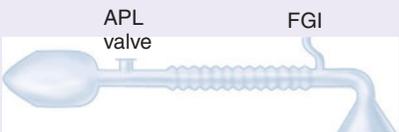

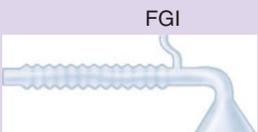

The insufflation and draw-over systems have several disadvantages: poor control of inspired gas concentration (and, therefore, poor control of depth of anesthesia), mechanical drawbacks during head and neck surgery, and pollution of the operating room with large volumes of waste gas. The **Mapleson systems** solve some of these problems by incorporating additional components (breathing tubes, fresh gas inlets, adjustable pressure-limiting [APL] valves, and reservoir bags) into the breathing circuit. The relative location of these components determines circuit performance and is the basis of the Mapleson classification (**Table 3-2**).

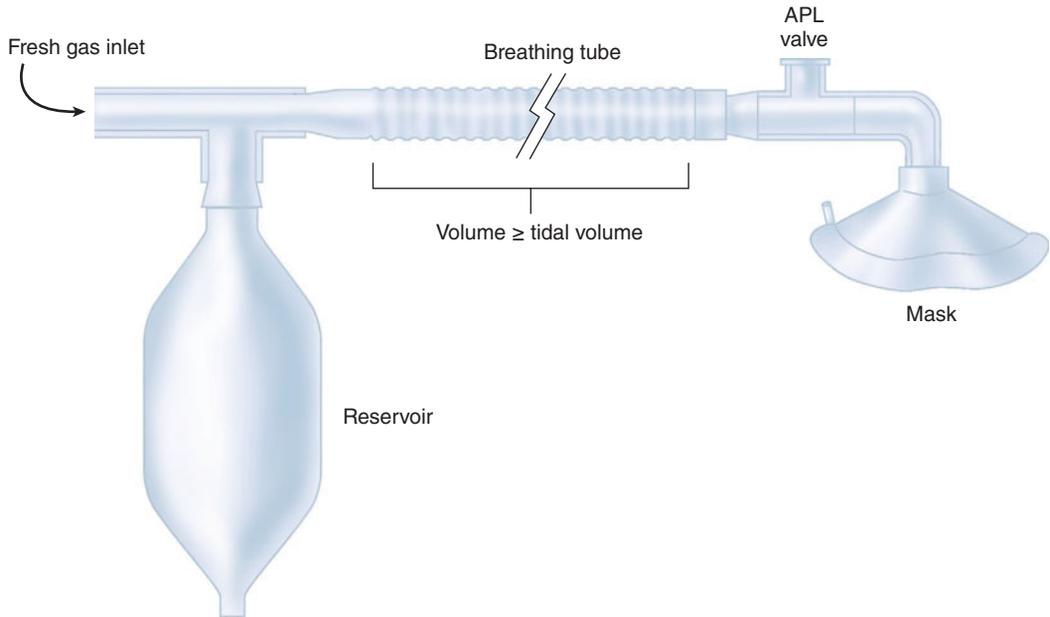

FIGURE 3-5 Components of a Mapleson circuit. APL, adjustable pressure-limiting (valve).

Components of Mapleson Circuits

A. Breathing Tubes

Corrugated tubes—made of rubber (reusable) or plastic (disposable)—connect the components of the Mapleson circuit to the patient (Figure 3-5). The large diameter of the tubes (22 mm) creates a low-resistance pathway and a potential reservoir for anesthetic gases. To minimize fresh gas flow requirements, the volume of gas within the breathing tubes in most Mapleson circuits should be at least as great as the patient's tidal volume.

The compliance of the breathing tubes largely determines the compliance of the circuit. (Compliance is defined as the change of volume produced by **2** a change in pressure.) Long breathing tubes with high compliance increase the difference between the volume of gas delivered to a circuit by a reservoir bag or ventilator and the volume actually delivered to the patient. For example, if a breathing circuit with a compliance of 8 mL gas/cm H₂O is pressurized during delivery of a tidal volume to 20 cm H₂O, 160 mL of the tidal volume will be lost to the circuit. The 160 mL represent a combination of

gas compression and breathing-tube expansion. This is an important consideration in any circuit delivering positive-pressure ventilation through breathing tubes (eg, circle systems).

B. Fresh Gas Inlet

Gases (anesthetics mixed with oxygen or air) from the anesthesia machine continuously enter the circuit through the fresh gas inlet. As discussed below, the relative position of the fresh gas inlet is a key differentiating factor in Mapleson circuit performance.

C. Adjustable Pressure-Limiting Valve (Pressure-Relief Valve, Pop-Off Valve)

As anesthetic gases enter the breathing circuit, pressure will rise if the gas inflow is greater than the combined uptake of the patient and the circuit. Gases may exit the circuit through an APL valve, controlling this pressure buildup. Exiting gases enter the operating room atmosphere or, preferably, a waste-gas scavenging system. All APL valves allow a **3** variable pressure threshold for venting. The APL valve should be fully open during

spontaneous ventilation so that circuit pressure remains negligible throughout inspiration and expiration. Assisted and controlled ventilation require positive pressure during inspiration to expand the lungs. Partial closure of the APL valve limits gas exit, permitting positive circuit pressures during reservoir bag compressions.

D. Reservoir Bag (Breathing Bag)

Reservoir bags function as a reservoir of anesthetic gas and a method of generating positive-pressure ventilation. They are designed to increase in compliance as their volume increases. Three distinct phases of reservoir bag filling are recognizable (Figure 3-6). After the nominal 3-L capacity of an adult reservoir bag is achieved (phase I), pressure rises rapidly to a peak (phase II). Further increases in volume result in a plateau or even a slight decrease in pressure (phase III). This ceiling effect provides some minimal protection of the patient's lungs against high airway pressures, if the APL valve is unintentionally left in the closed position while fresh gas continues to flow into the circuit.

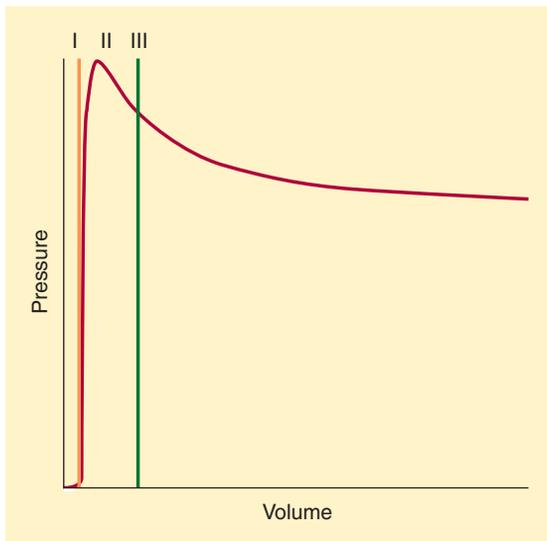

FIGURE 3-6 The increasing compliance and elasticity of breathing bags as demonstrated by three phases of filling (see text). (Reproduced, with permission, from Johnstone RE, Smith TC: Rebreathing bags as pressure limiting devices. *Anesthesiology* 1973;38:192.)

Performance Characteristics of Mapleson Circuits

Mapleson circuits are lightweight, inexpensive, and simple. Breathing-circuit efficiency is measured by the fresh gas flow required to reduce CO_2 rebreathing to a negligible value. Because there are no unidirectional valves or CO_2 absorption in Mapleson circuits, rebreathing is prevented by adequate fresh gas flow into the circuit and venting exhaled gas through the APL valve before inspiration. There is usually some rebreathing in any Mapleson circuit. The total fresh gas flow into the circuit controls the amount. To attenuate rebreathing, high fresh gas flows are required. The APL valve in Mapleson A, B, and C circuits is located near the face mask, and the reservoir bag is located at the opposite end of the circuit.

Reexamine the drawing of a Mapleson A circuit in Figure 3-5. During spontaneous ventilation, alveolar gas containing CO_2 will be exhaled into the breathing tube or directly vented through an open APL valve. Before inhalation occurs, if the fresh gas flow exceeds alveolar minute ventilation, the inflow of fresh gas will force the alveolar gas remaining in the breathing tube to exit from the APL valve. If the breathing-tube volume is equal to or greater than the patient's tidal volume, the next inspiration will contain only **4** fresh gas. Because a fresh gas flow equal to minute ventilation is sufficient to prevent rebreathing, the Mapleson A design is the most efficient Mapleson circuit for *spontaneous* ventilation.

Positive pressure during *controlled* ventilation, however, requires a partially closed APL valve. Although some alveolar and fresh gas exits through the valve during inspiration, no gas is vented during expiration, since the exhaled gas stagnates during the expiratory phase of positive pressure ventilation. As a result, very high fresh gas flows (greater than three times minute ventilation) are required to prevent rebreathing with a Mapleson A circuit during controlled ventilation. Fresh gas flows are conveniently available because the fresh gas inlet is in close proximity to the APL valve in a Mapleson B circuit.

Interchanging the position of the APL valve and the fresh gas inlet transforms a Mapleson A into a **5** **Mapleson D circuit** (Table 3-2). The Mapleson D circuit is efficient during controlled ventilation, since fresh gas flow forces alveolar air *away*

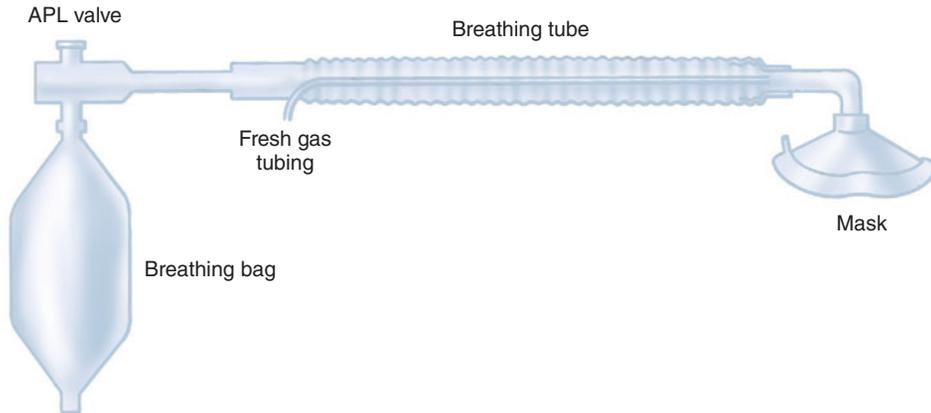

FIGURE 3-7 A Bain circuit is a Mapleson D circuit design with the fresh gas tubing inside the corrugated breathing tube. APL, adjustable pressure-limiting (valve).

from the patient and *toward* the APL valve. Thus, simply moving components completely alters the fresh gas requirements of the Mapleson circuits.

The **Bain circuit** is a coaxial version of the Mapleson D system that incorporates the fresh gas inlet tubing inside the breathing tube (Figure 3-7). This modification decreases the circuit's bulk and retains heat and humidity better than a conventional Mapleson D circuit as a result of partial warming of the inspiratory gas by countercurrent exchange with the warmer expired gases. A disadvantage of this coaxial circuit is the possibility of kinking or disconnection of the fresh gas inlet tubing. Periodic inspection of the inner tubing is mandatory to prevent this complication; if unrecognized, either of these mishaps could result in significant rebreathing of exhaled gas.

THE CIRCLE SYSTEM

Although Mapleson circuits overcome some of the disadvantages of the insufflation and draw-over systems, the high fresh gas flows required to prevent rebreathing of CO_2 result in waste of anesthetic agent, pollution of the operating room environment, and loss of patient heat and humidity (Table 3-3). In an attempt to avoid these problems, the **circle system** adds more components to the breathing system.

The components of a circle system include: (1) a CO_2 absorber containing CO_2 absorbent; (2) a fresh gas inlet; (3) an inspiratory unidirectional valve and

(Redrawn and reproduced, with permission, from Bain JA, Spoerel WE: Flow requirements for a modified Mapleson D system during controlled ventilation. *Can Anaesth Soc J* 1973;20:629.)

inspiratory breathing tube; (4) a Y-connector; (5) an expiratory unidirectional valve and expiratory breathing tube; (6) an APL valve; and (7) a reservoir (Figure 3-8).

Components of the Circle System

combines with water to form carbonic acid. CO_2 absorbents (eg, soda lime or calcium hydroxide lime) contain hydroxide salts that are capable of neutralizing carbonic acid (Table 3-4). Reaction end products include heat (the heat of neutralization), water, and calcium carbonate. **Soda lime** is the more common absorbent and is capable of absorbing up to 23 L of CO_2 per 100 g of absorbent. It consists primarily of calcium hydroxide (80%), along with sodium hydroxide, water, and a small amount of potassium hydroxide. Its reactions are as follows:

Note that the water and sodium hydroxide initially required are regenerated. Another absorbent, barium hydroxide lime, is no longer used due to the

possible increased hazard of fire in the breathing system.

A pH indicator dye (eg, ethyl violet) changes color from white to purple as a consequence of increasing hydrogen ion concentration and absorbent exhaustion (Table 3-5). Absorbent should be replaced when 50% to 70% has changed color. Although exhausted granules may revert to their original color if rested, no significant recovery of absorptive capacity occurs. Granule size is a compromise between the higher absorptive surface area of small granules and the lower resistance to gas flow of larger granules. The granules commonly used as CO₂ absorbent are between 4 and 8 mesh; the number of mesh corresponds to the number of holes per square inch of a screen. The hydroxide salts are irritating to the skin and mucous membranes. Increasing the hardness of soda lime by adding silica minimizes the risk of inhalation of sodium hydroxide dust and also decreases resistance of gas flow. Additional water is added to absorbent during packaging to provide optimal conditions for carbonic acid formation. Commercial soda lime has a water content of 14% to 19%.

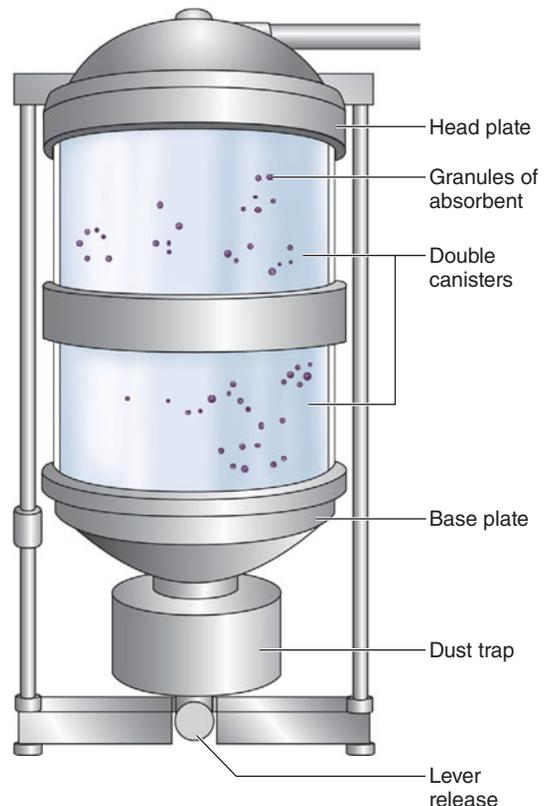

Absorbent granules can absorb and later release medically important amounts of volatile anesthetic. This property can be responsible for modest delays of induction or emergence. The drier the soda lime, the more likely it will absorb and degrade volatile anesthetics. Volatile anesthetics can be broken down to carbon monoxide by dry absorbent (eg, sodium or potassium hydroxide) to such a degree that it is capable of causing clinically significant carbon monoxide poisoning. The formation of carbon

monoxide is highest with desflurane; with sevoflurane, it occurs at a higher temperature.

Amsorb is a CO₂ absorbent consisting of calcium hydroxide and calcium chloride (with calcium sulfate and polyvinylpyrrolidone added to increase hardness). It possesses greater inertness than soda lime, resulting in less degradation of volatile anesthetics (eg, sevoflurane into compound A or desflurane into carbon monoxide).

Compound A is one of the by-products of degradation of sevoflurane by absorbent. Higher concentrations of sevoflurane, prolonged exposure, and low-flow anesthetic technique seem to increase the formation of Compound A. Compound A has been shown to produce nephrotoxicity in animals.

The granules of absorbent are contained within one or two canisters that fit snugly between a head and base plate. Together, this unit is called an absorber (Figure 3-9). Although bulky, double

**FIGURE 3-9** A carbon dioxide absorber.

canisters permit more complete CO_2 absorption, less frequent absorbent changes, and lower gas flow resistance. To ensure complete absorption, a patient's tidal volume should not exceed the air space between absorbent granules, which is roughly equal to 50% of the absorber's capacity. Indicator dye color is monitored through the absorber's transparent walls. Absorbent exhaustion typically occurs first where exhaled gas enters the absorber and along the canister's smooth inner walls. Channeling through areas of loosely packed granules is minimized by a baffle system, which directs gas flow through the center, thereby allowing greater utilization of the absorbent. A trap at the base of the absorber collects dust and moisture. Newer absorbers are used until CO_2 is found in the inhaled gas on the anesthetic-gas monitor, at which time the canister(s) are replaced.

B. Unidirectional Valves

Unidirectional valves, which function as check valves, contain a ceramic or mica disk resting horizontally on an annular valve seat (Figure 3-10). Forward flow displaces the disk upward, permitting the gas to proceed through the circuit. Reverse flow pushes the disk against its seat, preventing reflux. Valve incompetence is usually due to a warped disk or seat irregularities. The expiratory valve is exposed to the humidity of alveolar gas. Condensation and resultant moisture formation may prevent upward

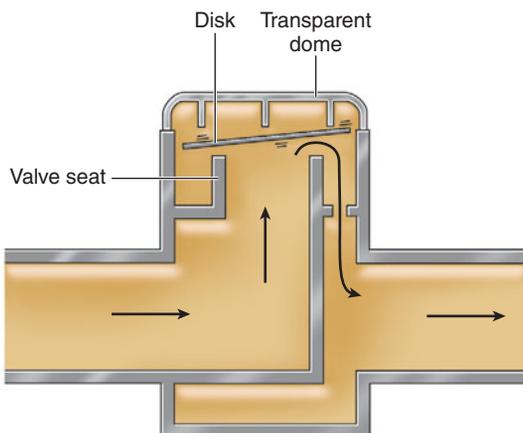

FIGURE 3-10 A unidirectional valve.

displacement of the disks, resulting in incomplete escape of expired gases and rebreathing.

Inhalation opens the inspiratory valve, allowing the patient to breathe a mixture of fresh and exhaled gas that has passed through the CO_2 absorber. Simultaneously, the expiratory valve closes to prevent rebreathing of exhaled gas that still contains CO_2 . The subsequent flow of gas away from the patient during exhalation opens the expiratory valve. This gas is vented through the APL valve or rebreathed by the patient after passing through the absorber. Closure of the inspiratory valve during exhalation prevents expiratory gas from mixing with fresh gas in the inspiratory limb. Malfunction of either unidirectional valve may allow rebreathing of CO_2 , resulting in hypercapnia.

Optimization of Circle System Design

Although the major components of the circle system (unidirectional valves, fresh gas inlet, APL valve, CO_2 absorber, and a reservoir bag) can be placed in several configurations, the following arrangement is preferred (Figure 3-8):

- Unidirectional valves are relatively close to the patient to prevent backflow into the inspiratory limb if a circuit leak develops. However, unidirectional valves are not placed in the Y-piece, as that makes it difficult to confirm proper orientation and intraoperative function.
- The fresh gas inlet is placed between the absorber and the inspiratory valve. Positioning it downstream from the inspiratory valve would allow fresh gas to bypass the patient during exhalation and be wasted. Fresh gas introduced between the expiratory valve and the absorber would be diluted by recirculating gas. Furthermore, inhalation anesthetics may be absorbed or released by soda lime granules, thus slowing induction and emergence.
- The APL valve is usually placed between the absorber and the expiratory valve and close to the reservoir bag. Positioning of the APL valve in this location (ie, before the absorber) helps to conserve absorption capacity and minimizes the venting of fresh gas.

- Resistance to exhalation is decreased by locating the reservoir bag in the expiratory limb. Bag compression during controlled ventilation will vent expired gas through the APL valve, conserving absorbent.

Performance Characteristics of the Circle System

A. Fresh Gas Requirement

8 With an absorber, the circle system prevents rebreathing of CO₂ at reduced fresh gas flows (≤ 1 L) or even fresh gas flows equal to the uptake of anesthetic gases and oxygen by the patient and the circuit itself (closed-system anesthesia). At fresh gas flows greater than 5 L/min, rebreathing is so minimal that a CO₂ absorber is usually unnecessary.

With low fresh gas flows, concentrations of oxygen and inhalation anesthetics can vary markedly between fresh gas (ie, gas in the fresh gas inlet) and inspired gas (ie, gas in the inspiratory limb of the breathing tubes). The latter is a mixture of fresh gas and exhaled gas that has passed through the absorber. The greater the fresh gas flow rate, the less time it will take for a change in fresh gas anesthetic concentration to be reflected in a change in inspired gas anesthetic concentration. Higher flows speed induction and recovery, compensate for leaks in the circuit, and decrease the risks of unanticipated gas mixtures.

B. Dead Space

That part of a tidal volume that does not undergo alveolar ventilation is referred to as dead space. Thus, any increase in dead space must be accompanied by a corresponding increase in tidal volume, if alveolar ventilation is to remain unchanged.

9 Because of the unidirectional valves, apparatus dead space in a circle system is limited to the area distal to the point of inspiratory and expiratory gas mixing at the Y-piece. Unlike Mapleson circuits, the circle system tube length does not affect dead space. Like Mapleson circuits, length does affect circuit compliance and thus the amount of tidal volume lost to the circuit during positive-pressure ventilation. Pediatric circle systems may have both a septum dividing the inspiratory and expiratory gas in the Y-piece and low-compliance

breathing tubes to further reduce dead space, and are lighter in weight.

C. Resistance

The unidirectional valves and absorber increase circle system resistance, especially at high respiratory rates and large tidal volumes. Nonetheless, even premature neonates can be successfully ventilated using a circle system.

D. Humidity and Heat Conservation

Medical gas delivery systems supply dehumidified gases to the anesthesia circuit at room temperature. Exhaled gas, on the other hand, is saturated with water at body temperature. Therefore, the heat and humidity of inspired gas depend on the relative proportion of rebreathed gas to fresh gas. High flows are accompanied by low relative humidity, whereas low flows allow greater water saturation. Absorbent granules provide a significant source of heat and moisture in the circle system.

E. Bacterial Contamination

The minimal risk of microorganism retention in circle system components could theoretically lead to respiratory infections in subsequent patients. For this reason, bacterial filters are sometimes incorporated into the inspiratory or expiratory breathing tubes or at the Y-piece.

Disadvantages of the Circle System

Although most of the problems of Mapleson circuits are solved by the circle system, the improvements have led to other disadvantages: greater size and less portability; increased complexity, resulting in a higher risk of disconnection or malfunction; complications related to use of absorbent; and the difficulty of predicting inspired gas concentrations during low fresh gas flows.

RESUSCITATION BREATHING SYSTEMS

Resuscitation bags (AMBU bags or bag-mask units) are commonly used for emergency ventilation because of their simplicity, portability, and ability to deliver almost 100% oxygen (**Figure 3-11**). A

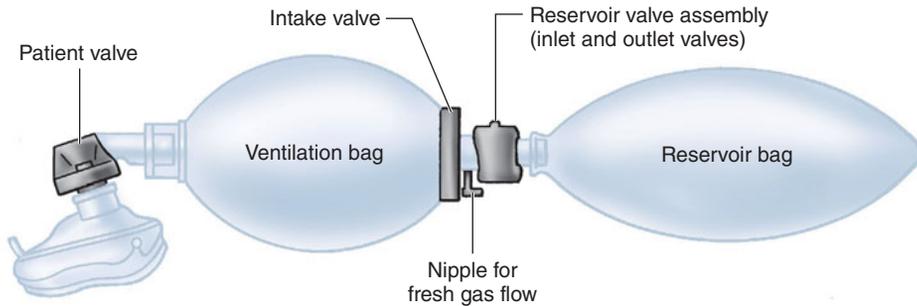

FIGURE 3-11 The Laerdal resuscitator. (Reproduced, with permission, from Laerdal Medical Corp.)

resuscitator is unlike a Mapleson circuit or a circle system because it contains a **nonbreathing valve**. (Remember that a Mapleson system is considered valveless even though it contains an APL valve, whereas a circle system contains unidirectional valves that direct flow through an absorber but allow rebreathing of exhaled gases.)

High concentrations of oxygen can be delivered to a mask or tracheal tube during spontaneous or controlled ventilation if a source of high fresh gas flow is connected to the inlet nipple. The patient valve opens during controlled or spontaneous inspiration to allow gas flow from the ventilation bag to the patient. Rebreathing is prevented by venting exhaled gas to the atmosphere through exhalation ports in this valve. The compressible, self-refilling ventilation bag also contains an intake valve. This valve closes during bag compression, permitting positive-pressure ventilation. The bag is refilled by flow through the fresh gas inlet and across the intake valve. Connecting a reservoir to the intake valve helps prevent the entrainment of room air. The reservoir valve assembly is really two unidirectional valves: the inlet valve and the outlet valve. The inlet valve allows ambient air to enter the ventilation bag if fresh gas flow is inadequate to maintain reservoir filling. Positive pressure in the reservoir bag opens the outlet valve, which vents oxygen if fresh gas flow is excessive.

There are several disadvantages to resuscitator breathing systems. First, they require high fresh gas flows to achieve a high FIO_2 . FIO_2 is directly proportional to the oxygen concentration and flow rate of the gas mixture supplied to the resuscitator

(usually 100% oxygen) and inversely proportional to the minute ventilation delivered to the patient. For example, a Laerdal resuscitator equipped with a reservoir requires a flow of 10 L/min to achieve an inspired oxygen concentration approaching 100% if a patient with a tidal volume of 750 mL is ventilated at a rate of 12 breaths/min. The maximum achievable tidal volumes are less than those that can be achieved with a system that uses a 3-L breathing bag. In fact, most adult resuscitators have a maximum tidal volume of 1000 mL, which is sufficient for the lower tidal volumes generally employed in patient management. Finally, although a normally functioning patient valve has low resistance to inspiration and expiration, exhaled moisture can cause valve sticking.

CASE DISCUSSION

Unexplained Light Anesthesia

An extremely obese but otherwise healthy 5-year-old girl presents for inguinal hernia repair. After uneventful induction of general anesthesia and tracheal intubation, the patient is placed on a ventilator set to deliver a tidal volume of 7 mL/kg at a rate of 16 breaths/min. Despite delivery of high concentrations of sevoflurane in 50% nitrous oxide, tachycardia (145 beats/min) and mild hypertension (144/94 mm Hg) are noted. To increase anesthetic depth, fentanyl (3 mcg/kg) is administered. Heart rate and blood pressure continue to rise and are accompanied by frequent premature ventricular contractions.

What should be considered in the differential diagnosis of this patient's cardiovascular changes?

The combination of tachycardia and hypertension during general anesthesia should always alert the anesthesiologist to the possibility of hypercapnia or hypoxia, both of which produce signs of increased sympathetic activity. These life-threatening conditions should be quickly and immediately ruled out by end-tidal CO₂ monitoring, pulse oximetry, or arterial blood gas analysis.

A common cause of intraoperative tachycardia and hypertension is an inadequate level of anesthesia. Normally, this is confirmed by movement. If the patient is paralyzed, however, there are few reliable indicators of light anesthesia. The lack of a response to a dose of an opioid should alert the anesthesiologist to the possibility of other, perhaps more serious, causes.

Malignant hyperthermia is rare but must be considered in cases of unexplained tachycardia, especially if accompanied by premature contractions. Certain drugs used in anesthesia (eg, pancuronium, ketamine, ephedrine) stimulate the sympathetic nervous system and can produce or exacerbate tachycardia and hypertension. Diabetic patients who become hypoglycemic from administration of insulin or long-acting oral hypoglycemic agents can have similar cardiovascular changes. Other endocrine abnormalities (eg, pheochromocytoma, thyroid storm, carcinoid) should also be considered.

Could any of these problems be related to an equipment malfunction?

Gas analysis can confirm the delivery of anesthetic gases to the patient.

A misconnection of the ventilator could result in hypoxia or hypercapnia. In addition, a malfunctioning unidirectional valve will increase circuit dead space and allow rebreathing of expired CO₂. Soda lime exhaustion could also lead to rebreathing in the presence of a low fresh gas flow. Rebreathing of CO₂ can be detected during the inspiratory phase on a capnograph. If rebreathing

appears to be due to an equipment malfunction, the patient should be disconnected from the anesthesia machine and ventilated with a resuscitation bag until repairs are possible.

What are some other consequences of hypercapnia?

Hypercapnia has a multitude of effects, most of them masked by general anesthesia. Cerebral blood flow increases proportionately with arterial CO₂. This effect is dangerous in patients with increased intracranial pressure (eg, from brain tumor). Extremely high levels of CO₂ (>80 mm Hg) can cause unconsciousness related to a fall in cerebrospinal fluid pH. CO₂ depresses the myocardium, but this direct effect is usually overshadowed by activation of the sympathetic nervous system. During general anesthesia, hypercapnia usually results in an increased cardiac output, an elevation in arterial blood pressure, and a propensity toward arrhythmias.

Elevated serum CO₂ concentrations can overwhelm the blood's buffering capacity, leading to respiratory acidosis. This causes other cations such as Ca²⁺ and K⁺ to shift extracellularly. Acidosis also shifts the oxyhemoglobin dissociation curve to the right.

Carbon dioxide is a powerful respiratory stimulant. In fact, for each mm Hg rise of PaCO₂ above baseline, normal awake subjects increase their minute ventilation by about 2–3 L/min. General anesthesia markedly decreases this response, and paralysis eliminates it. Finally, severe hypercapnia can produce hypoxia by displacement of oxygen from alveoli.

- Dorsch JA, Dorsch SE: *Understanding Anesthesia Equipment*, 5th ed. Lippincott, Williams & Wilkins, 2008.

The Anesthesia Machine

KEY CONCEPTS

- 1 Misuse of anesthesia gas delivery systems is three times more likely than failure of the device to cause equipment-related adverse outcomes. An operator's lack of familiarity with the equipment or a failure to check machine function, or both, are the most frequent causes. These mishaps account for only about 2% of cases in the ASA Closed Claims Project database. The breathing circuit was the most common single source of injury (39%); nearly all damaging events were related to misconnects or disconnects.
- 2 The anesthesia machine receives medical gases from a gas supply, controls the flow and reduces the pressure of desired gases to a safe level, vaporizes volatile anesthetics into the final gas mixture, and delivers the gases to a breathing circuit that is connected to the patient's airway. A mechanical ventilator attaches to the breathing circuit but can be excluded with a switch during spontaneous or manual (bag) ventilation.
- 3 Whereas the oxygen supply can pass directly to its flow control valve, nitrous oxide, air, and other gases must first pass through safety devices before reaching their respective flow control valves. These devices permit the flow of other gases only if there is sufficient oxygen pressure in the safety device and help prevent accidental delivery of a hypoxic mixture in the event of oxygen supply failure.
- 4 Another safety feature of anesthesia machines is a linkage of the nitrous oxide gas flow to the oxygen gas flow; this arrangement helps ensure a minimum oxygen concentration of 25%.
- 5 All modern vaporizers are agent specific and temperature corrected, capable of delivering a constant concentration of agent regardless of temperature changes or flow through the vaporizer.
- 6 A rise in airway pressure may signal worsening pulmonary compliance, an increase in tidal volume, or an obstruction in the breathing circuit, tracheal tube, or the patient's airway. A drop in pressure may indicate an improvement in compliance, a decrease in tidal volume, or a leak in the circuit.
- 7 Traditionally ventilators on anesthesia machines have a double-circuit system design and are pneumatically powered and electronically controlled. Newer machines also incorporate microprocessor control that relies on sophisticated pressure and flow sensors. Some anesthesia machines have ventilators that use a single-circuit piston design.
- 8 The major advantage of a piston ventilator is its ability to deliver accurate tidal volumes to patients with very poor lung compliance and to very small patients.

—Continued next page

Continued—

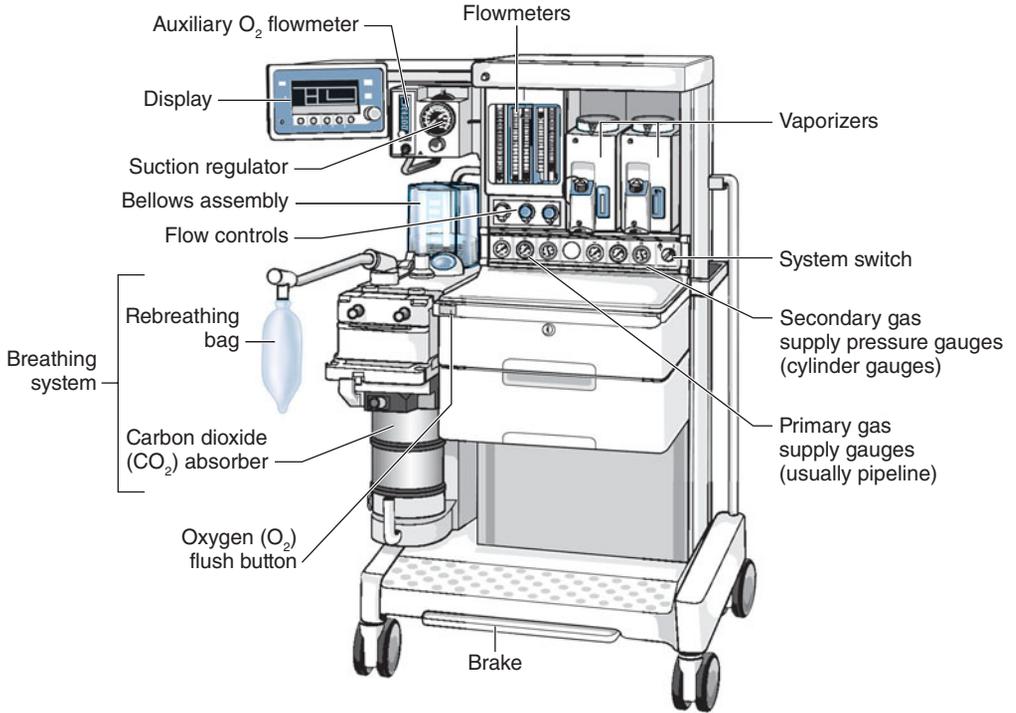

- 9 Whenever a ventilator is used “disconnect alarms” must be passively activated. Anesthesia workstations should have at least three disconnect alarms: low pressure, low exhaled tidal volume, and low exhaled carbon dioxide.
- 10 Because the ventilator’s spill valve is closed during inspiration, fresh gas flow from the machine’s common gas outlet normally contributes to the tidal volume delivered to the patient.
- 11 Use of the oxygen flush valve during the inspiratory cycle of a ventilator must be avoided because the ventilator spill valve will be closed and the adjustable pressure-limiting (APL) valve is excluded; the surge of oxygen (600–1200 mL/s) and circuit pressure will be transferred to the patient’s lungs.
- 12 Large discrepancies between the set and actual tidal volume are often observed in the operating room during volume-controlled ventilation. Causes include breathing circuit compliance, gas compression, ventilator–fresh gas flow coupling, and leaks in the anesthesia machine, the breathing circuit, or the patient’s airway.
- 13 Waste-gas scavengers dispose of gases that have been vented from the breathing circuit by the APL valve and ventilator spill valve. Pollution of the operating room environment with anesthetic gases may pose a health hazard to surgical personnel.
- 14 A routine inspection of anesthesia equipment before each use increases operator familiarity and confirms proper functioning. The U.S. Food and Drug Administration has made available a generic checkout procedure for anesthesia gas machines and breathing systems.

No piece of equipment is more intimately associated with the practice of anesthesiology than the anesthesia machine (Figure 4–1). On the most basic level, the anesthesiologist uses the anesthesia machine to control the patient’s ventilation and oxygen delivery and to administer inhalation anesthetics. Proper functioning of the machine is crucial for patient safety. Modern anesthesia machines have become very sophisticated, incorporating many built-in safety features and devices, monitors, and multiple microprocessors that can integrate and monitor all components. Additional monitors can be added externally and often still be fully integrated. Moreover, modular machine designs allow a wide variety of configurations and features within the same product line. The term *anesthesia workstation* is therefore often used for modern anesthesia machines. There are two major manufacturers of anesthesia machines in the United States, Datex-Ohmeda (GE Healthcare) and Dräger Medical. Other manufacturers (eg, Mindray) produce anesthesia delivery systems. Anesthesia

providers should carefully review the operations manuals of the machines present in their clinical practice.

Much progress has been made in reducing the number of adverse outcomes arising from anesthetic gas delivery equipment, through redesign of equipment and education. Misuse of anesthesia gas delivery systems is three times more likely than failure of the device to cause equipment-related adverse outcomes. Equipment misuse is characterized as errors in preparation, maintenance, or deployment of a device. Preventable anesthetic mishaps are frequently traced to an operator’s lack of familiarity with the equipment or a failure to check machine function, or both. These mishaps account for only about 2% of cases in the American Society of Anesthesiologists’ (ASA) Closed Claims Project database. The breathing circuit was the most common single source of injury (39%); nearly all damaging events were related to misconnects or disconnects. A misconnect was defined as a

TABLE 4-1 Essential safety features on a modern anesthesia workstation.

Essential Features	Purpose
Noninterchangeable gas-specific connections to pipeline inlets (DISS) ¹ with pressure gauges, filter, and check valve	Prevent incorrect pipeline attachments; detect failure, depletion, or fluctuation
Pin index safety system for cylinders with pressure gauges, and at least one oxygen cylinder	Prevent incorrect cylinder attachments; provide backup gas supply; detect depletion
Low oxygen pressure alarm	Detect oxygen supply failure at the common gas inlet
Minimum oxygen/nitrous oxide ratio controller device (hypoxic guard)	Prevent delivery of less than 21% oxygen
Oxygen failure safety device (shut-off or proportioning device)	Prevent administration of nitrous oxide or other gases when the oxygen supply fails
Oxygen must enter the common manifold downstream to other gases	Prevent hypoxia in event of proximal gas leak
Oxygen concentration monitor and alarm	Prevent administration of hypoxic gas mixtures in event of a low-pressure system leak; precisely regulate oxygen concentration
Automatically enabled essential alarms and monitors (eg, oxygen concentration)	Prevent use of the machine without essential monitors
Vaporizer interlock device	Prevent simultaneous administration of more than one volatile agent
Capnography and anesthetic gas measurement	Guide ventilation; prevent anesthetic overdose; help reduce awareness
Oxygen flush mechanism that does not pass through vaporizers	Rapidly refill or flush the breathing circuit
Breathing circuit pressure monitor and alarm	Prevent pulmonary barotrauma and detect sustained positive, high peak, and negative airway pressures
Exhaled volume monitor	Assess ventilation and prevent hypo- or hyperventilation
Pulse oximetry, blood pressure, and ECG monitoring	Provide minimal standard monitoring
Mechanical ventilator	Control alveolar ventilation more accurately and during muscle paralysis for prolonged periods
Backup battery	Provide temporary electrical power (>30 min) to monitors and alarms in event of power failure
Scavenger system	Prevent contamination of the operating room with waste anesthetic gases

¹DISS, diameter-index safety system.

nonfunctional and unconventional configuration of breathing circuit components or attachments. In decreasing frequency, other causes involved vaporizers (21%), ventilators (17%), and oxygen supply (11%). Other more basic components of the anesthesia machine (eg, valves) were responsible in only 7% of cases. All malpractice claims in the database that involved the anesthesia machine, oxygen supply tanks or lines, or ventilators occurred before 1990; since then claims involving breathing circuits and vaporizers have continued to occur.

The American National Standards Institute and subsequently the ASTM International (formerly the American Society for Testing and Materials, F1850–00) published standard specifications for anesthesia machines and their components. **Table 4–1** lists essential features of a modern anesthesia workstation. Changes in equipment design have been directed at minimizing the probability of breathing circuit misconnects and disconnects and automating machine checks. Because of the durability and functional longevity of anesthesia machines, the ASA has developed guidelines for determining anesthesia machine obsolescence (**Table 4–2**). This

chapter is an introduction to anesthesia machine design, function, and use.

OVERVIEW

2 In its most basic form, the anesthesia machine receives medical gases from a gas supply, controls the flow and reduces the pressure of desired gases to a safe level, vaporizes volatile anesthetics into the final gas mixture, and delivers the gases to a breathing circuit connected to the patient's airway (**Figures 4–2** and **4–3**). A mechanical ventilator attaches to the breathing circuit but can be excluded with a switch during spontaneous or manual (bag) ventilation. An auxiliary oxygen supply and suction regulator are also usually built into the workstation. In addition to standard safety features (**Table 4–1**) top-of-the-line anesthesia machines have additional safety features, enhancements, and built-in computer processors that integrate and monitor all components, perform automated machine checkouts,

TABLE 4–2 Unacceptable/undesirable features of older anesthesia machines.¹

Unacceptable features

1. Flowmeter-controlled vaporizer (eg, copper kettle, Vernitrol)
2. More than one flow control valve for a single gas
3. Vaporizer with a rotary dial that increases concentration with clockwise rotation
4. Connections in the scavenging system that are the same size as breathing circuit connections

Undesirable features

1. Adjustable pressure-limiting (APL) valve that is not isolated during mechanical ventilation
2. Oxygen flow control knob that is not fluted or larger than other flow control knobs
3. Oxygen flush control that is unprotected from accidental activation
4. Lack of main On/Off switch for electrical power to integral monitors and alarms
5. Lack of antidisconnect device on the fresh gas hose (common gas outlet)
6. Lack of airway pressure alarms

¹Data from ASA Guidelines for determining Anesthesia Machine Obsolescence.

and provide options such as automated record-keeping and networking external monitors and hospital information systems (Figure 4-4). Some machines are designed specifically for mobility, magnetic resonance imaging (MRI) compatibility or compactness.

GAS SUPPLY

Most machines have gas inlets for oxygen, nitrous oxide, and air. Compact models often lack air inlets, whereas other machines may have a fourth inlet for helium, heliox, carbon dioxide, or nitric oxide.

Separate inlets are provided for the primary pipeline gas supply that passes through the walls of health care facilities and the secondary cylinder gas supply. Machines therefore have two gas inlet pressure gauges for each gas: one for pipeline pressure and another for cylinder pressure.

Pipeline Inlets

Oxygen and nitrous oxide (and often air) are delivered from their central supply source to the operating room through a piping network. The tubing is color coded and connects to the anesthesia machine through a noninterchangeable **diameter-index**

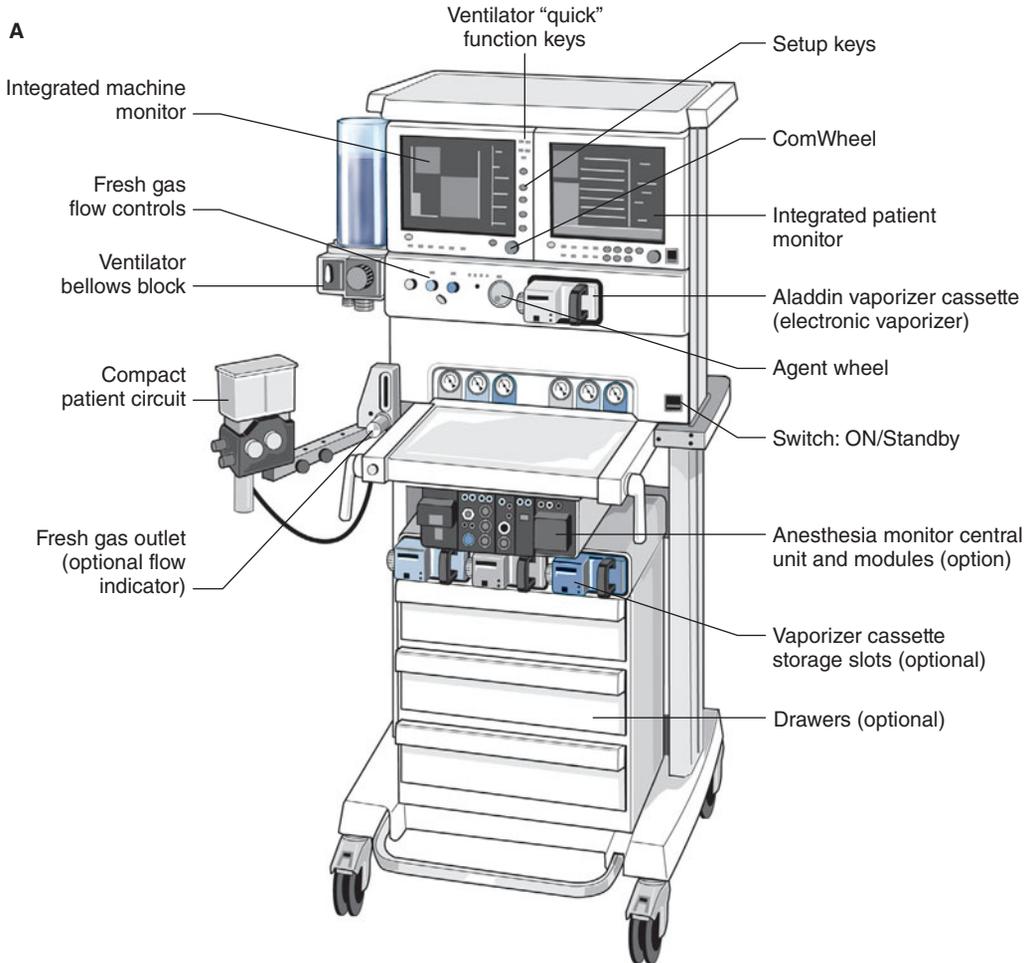

FIGURE 4-4 Highly sophisticated anesthesia machines with full integration options. **A:** Datex-Ohmeda S/5 ADU. (continued)

B

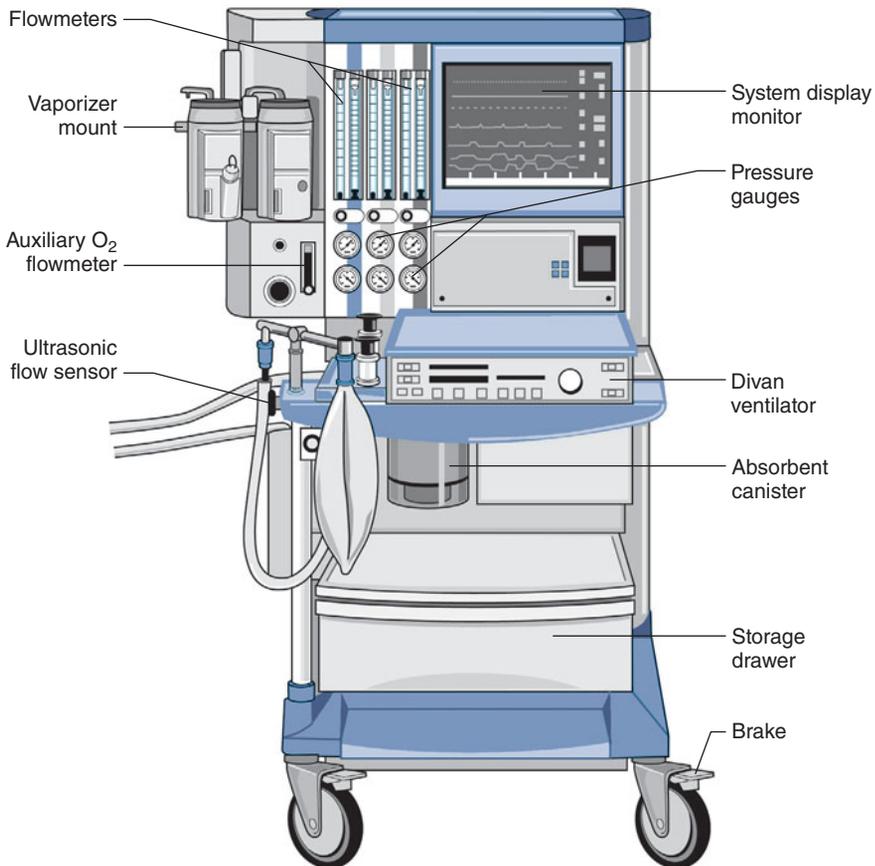

FIGURE 4-4 (continued) **B:** Dräger 6400.

safety system (DISS) fitting that prevents incorrect hose attachment. The noninterchangeability is achieved by making the bore diameter of the body and that of the connection nipple specific for each supplied gas. A filter helps trap debris from the wall supply and a one-way check valve prevents retrograde flow of gases into the pipeline supplies. It should be noted that most modern machines have an oxygen (pneumatic) power outlet that may be used to drive the ventilator or provide an auxiliary oxygen flowmeter. The DISS fittings for the oxygen inlet and the oxygen power outlet are identical and should not be mistakenly interchanged. The approximate pipeline pressure of gases delivered to the anesthesia machine is 50 psig.

Cylinder Inlets

Cylinders attach to the machine via hanger-yoke assemblies that utilize a **pin index safety system** to prevent accidental connection of a wrong gas cylinder. The yoke assembly includes index pins, a washer, a gas filter, and a check valve that prevents retrograde gas flow. The gas cylinders are also color-coded for specific gases to allow for easy identification. In North America the following color-coding scheme is used: oxygen = green, nitrous oxide = blue, carbon dioxide = gray, air = yellow, helium = brown, nitrogen = black. In the United Kingdom, white is used for oxygen and black and white for air. The E-cylinders attached to the anesthesia machine are

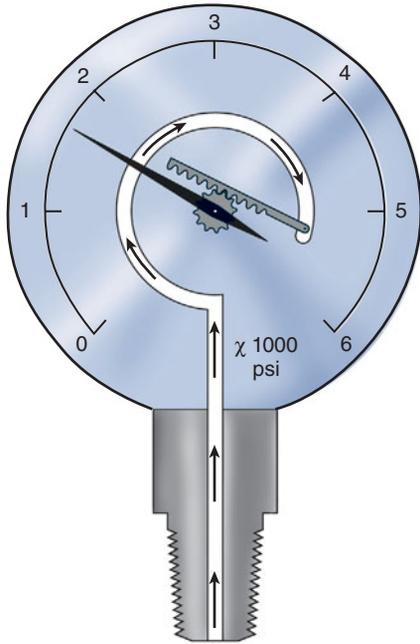

FIGURE 4-5 Bourdon pressure gauge.

a high-pressure source of medical gases and are generally used only as a back-up supply in case of pipeline failure. Pressure of gas supplied from the cylinder to the anesthesia machine is 45 psig. Some machines have two oxygen cylinders so that one cylinder can be used while the other is changed. At 20°C, a full cylinder contains 600 L of oxygen at a pressure of 1900 psig, and 1590 L of nitrous oxide at 745 psig. Cylinder pressure is usually measured by a Bourdon pressure gauge (Figure 4-5). A flexible tube within this gauge straightens when exposed to gas pressure, causing a gear mechanism to move a needle pointer.

FLOW CONTROL CIRCUITS

Pressure Regulators

Unlike the relatively constant pressure of the pipeline gas supply, the high and variable gas pressure in cylinders makes flow control difficult and potentially dangerous. To enhance safety and ensure optimal use of cylinder gases, machines utilize a pressure regulator to reduce the cylinder gas

pressure to 45–47 psig¹ before it enters the flow valve (Figure 4-6). This pressure, which is slightly lower than the pipeline supply, allows preferential use of the pipeline supply if a cylinder is left open (unless pipeline pressure drops below 45 psig). After passing through Bourdon pressure gauges and check valves, the pipeline gases share a common pathway with the cylinder gases. A high-pressure relief valve provided for each gas is set to open when the supply pressure exceeds the machine's maximum safety limit (95–110 psig), as might happen with a regulator failure on a cylinder. Some machines also use a second regulator to drop both pipeline and cylinder pressure further (two-stage pressure regulation). A second-stage pressure reduction may also be needed for an auxiliary oxygen flowmeter, the oxygen flush mechanism, or the drive gas to power a pneumatic ventilator.

Oxygen Supply Failure Protection Devices

3 Whereas the oxygen supply can pass directly to its flow control valve, nitrous oxide, air (in some machines), and other gases must first pass through safety devices before reaching their respective flow control valves. In other machines, air passes directly to its flow control valve; this allows administration of air even in the absence of oxygen. These devices permit the flow of other gases only if there is sufficient oxygen pressure in the safety device and help prevent accidental delivery of a hypoxic mixture in the event of oxygen supply failure. Thus in addition to supplying the oxygen flow control valve, oxygen from the common inlet pathway is used to pressurize safety devices, oxygen flush valves, and ventilator power outlets (in some models). Safety devices sense oxygen pressure via a small “piloting pressure” line that may be derived from the gas inlet or secondary regulator. In some anesthesia machine designs (eg, Datex-Ohmeda Excel), if the piloting pressure line falls below a threshold (eg, 20 psig), the shut-off valves close, preventing the administration of any other gases. The terms *fail-safe* and *nitrous cut-off* were previously used for the nitrous oxide shut-off valve.

¹Pressure unit conversions: 1 kiloPascal (kPa) = kg/m · s² = 1000 N/m² = 0.01 bar = 0.1013 atmospheres = 0.145 psig = 10.2 cm H₂O = 7.5 mm Hg.

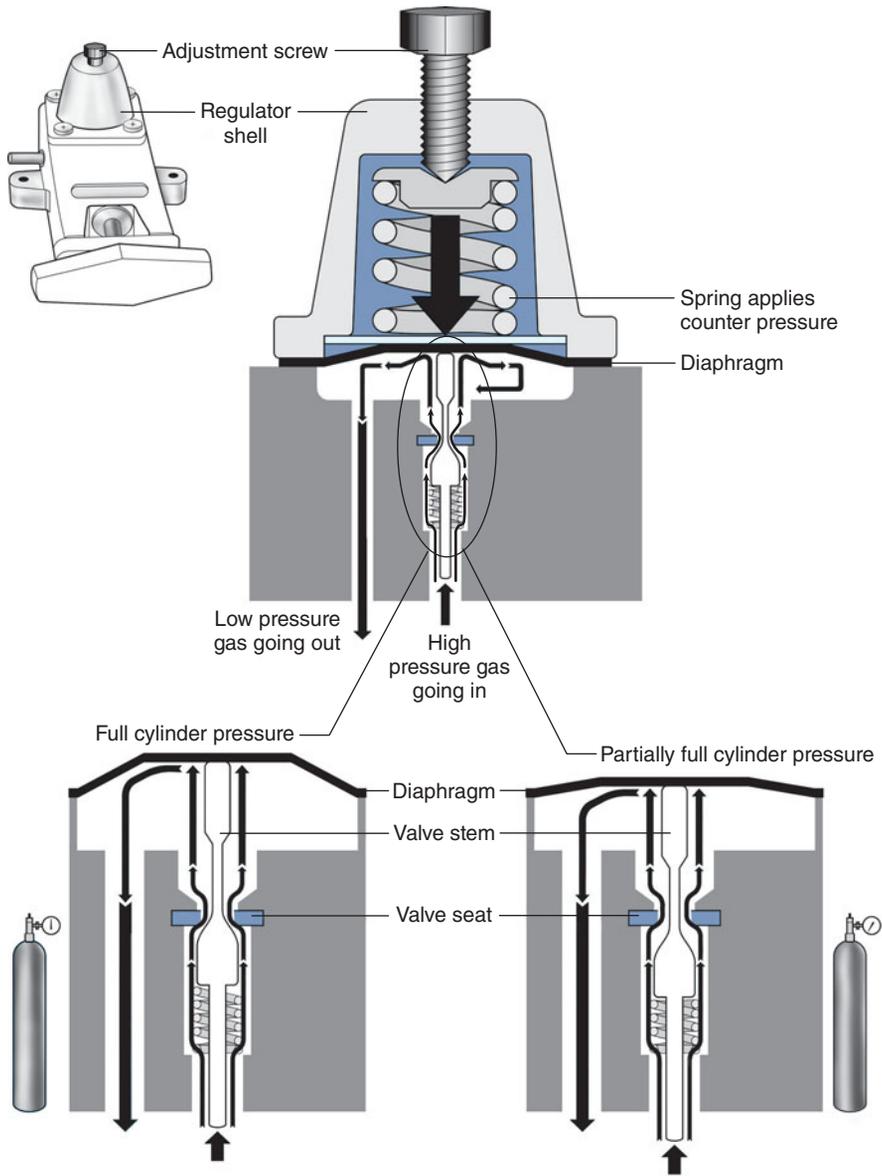

FIGURE 4-6 Cylinder inlet regulator.

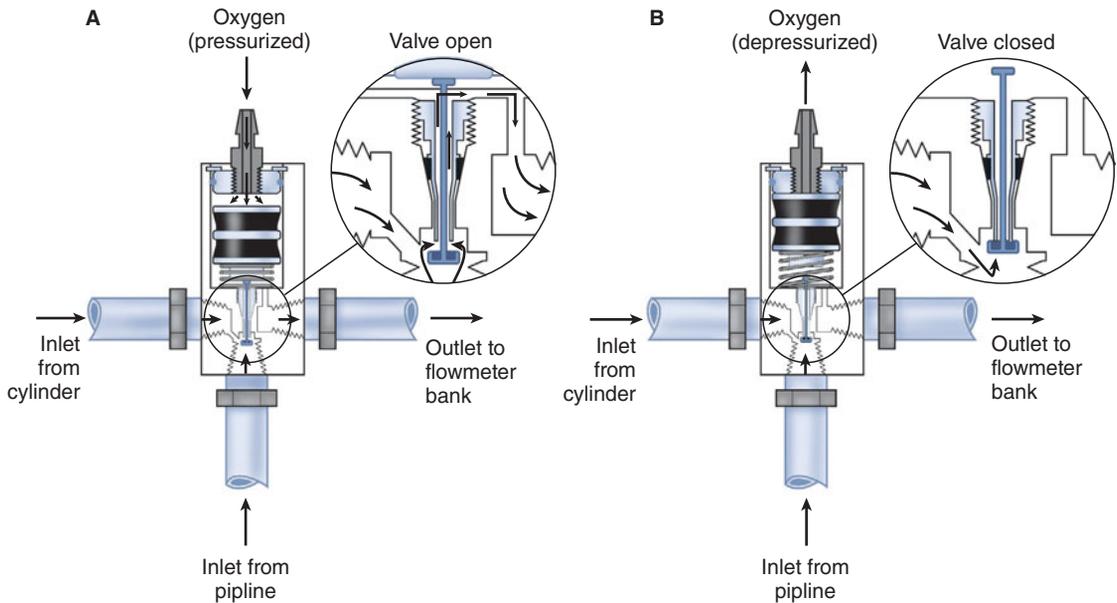

FIGURE 4-7 Dräger oxygen failure protection device (OFPD). **A:** Open. **B:** Closed.

Most modern (particularly Datex-Ohmeda) machines use a proportioning safety device instead of a threshold shut-off valve. These devices, called either an oxygen failure protection device (Dräger) or a balance regulator (Datex-Ohmeda), proportionately reduce the pressure of nitrous oxide and other gases except for air (Figures 4-7 and 4-8). They completely shut off nitrous oxide and other gas flow only below a set minimum oxygen pressure (eg, 0.5 psig for nitrous oxide and 10 psig for other gases).

All machines also have an oxygen supply low-pressure sensor that activates alarm sounds when inlet gas pressure drops below a threshold value (usually 20–30 psig). It must be emphasized that these safety devices do *not* protect against other possible causes of hypoxic accidents (eg, gas line misconnections), in which threshold pressure may be maintained by gases containing inadequate or no oxygen.

Flow Valves & Meters

Once the pressure has been reduced to a safe level, each gas must pass through flow control valves and is measured by flowmeters before mixing with other

gases, entering the active vaporizer, and exiting the machine's common gas outlet. **Gas lines proximal to flow valves are considered to be in the high-pressure circuit whereas those between the flow valves and the common gas outlet are considered part of the low-pressure circuit of the machine.** When the knob of the flow control valve is turned counterclockwise, a needle valve is disengaged from its seat, allowing gas to flow through the valve (Figure 4-9). Stops in the full-off and full-on positions prevent valve damage. Touch- and color-coded control knobs make it more difficult to turn the wrong gas off or on. As a safety feature the oxygen knob is usually fluted, larger, and protrudes farther than the other knobs. The oxygen flowmeter is positioned furthest to the right, downstream to the other gases; this arrangement helps to prevent hypoxia if there is leakage from a flowmeter positioned upstream.

Flow control knobs control gas entry into the flowmeters by adjustment via a needle valve. Flowmeters on anesthesia machines are classified as either constant-pressure variable-orifice (rotameter) or electronic. In constant-pressure variable-orifice flowmeters, an indicator ball, bobbin, or float is supported by the flow of gas through a tube (Thorpe

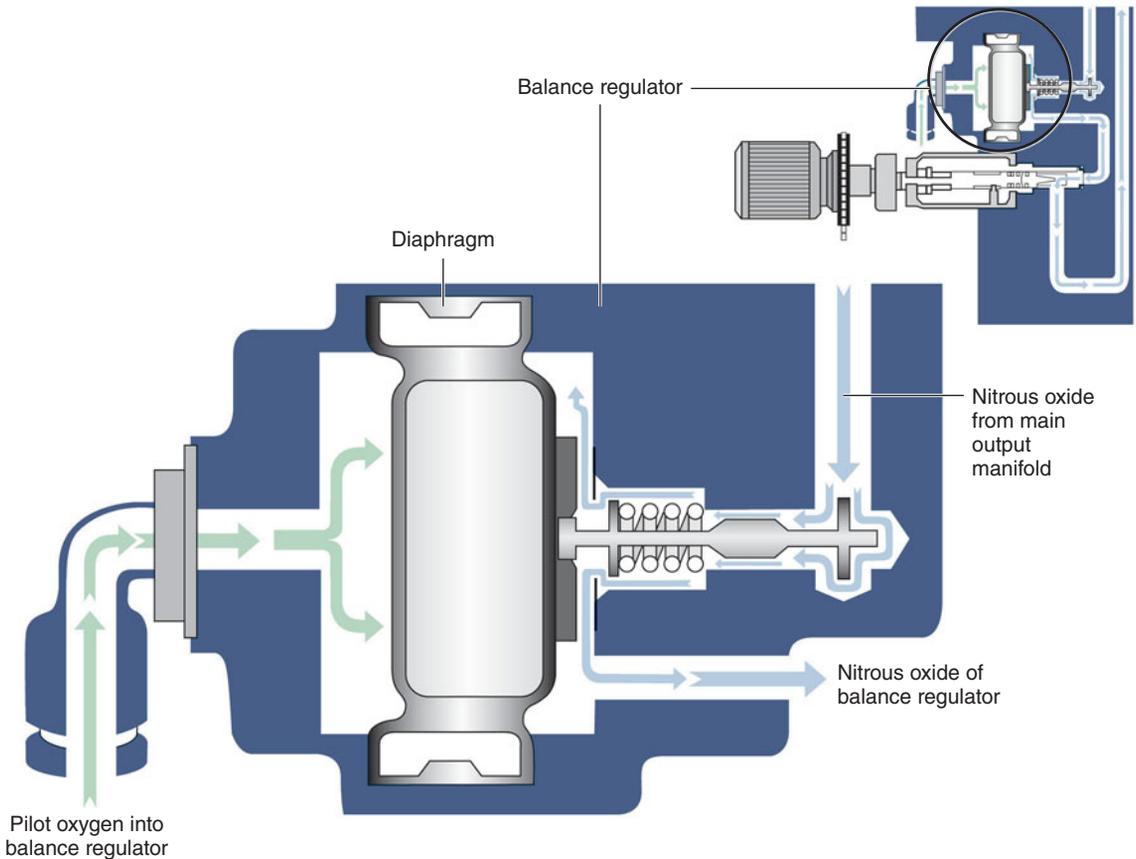

FIGURE 4-8 Datex-Ohmeda balance regulator.

tube) whose bore (orifice) is tapered. Near the bottom of the tube, where the diameter is small, a low flow of gas will create sufficient pressure under the float to raise it in the tube. As the float rises, the (variable) orifice of the tube widens, allowing more gas to pass around the float. The float will stop rising when its weight is just supported by the difference in pressure above and below it. If flow is increased, the pressure under the float increases, raising it higher in the tube until the pressure drop again just supports the float's weight. This pressure drop is constant regardless of the flow rate or the position in the tube and depends on the float weight and tube cross-sectional area.

Flowmeters are calibrated for specific gases, as the flow rate across a constriction depends on the

gas's viscosity at low laminar flows (Poiseuille's law) and its density at high turbulent flows. To minimize the effect of friction between them and the tube's wall, floats are designed to rotate constantly, which keeps them centered in the tube. Coating the tube's interior with a conductive substance grounds the system and reduces the effect of static electricity. Some flowmeters have two glass tubes, one for low flows and another for high flows (**Figure 4-10A**); the two tubes are in series and are still controlled by one valve. A dual taper design can allow a single flowmeter to read both high and low flows (**Figure 4-10B**). **Causes of flowmeter malfunction include debris in the flow tube, vertical tube misalignment, and sticking or concealment of a float at the top of a tube.**

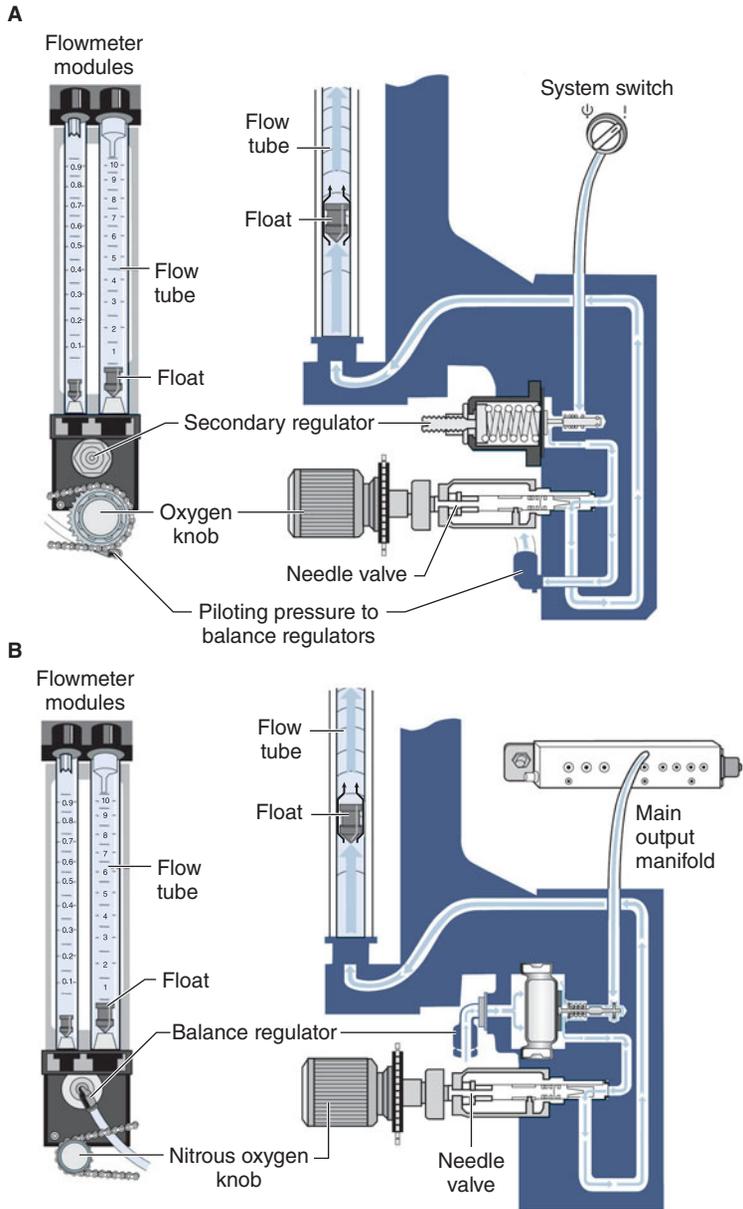

FIGURE 4-9 Gas flow-control needle valve (Datex-Ohmeda). **A:** Oxygen. **B:** Nitrous oxide. Note the secondary pressure regulator in the oxygen circuit and the balance regulator in the nitrous oxide circuit.

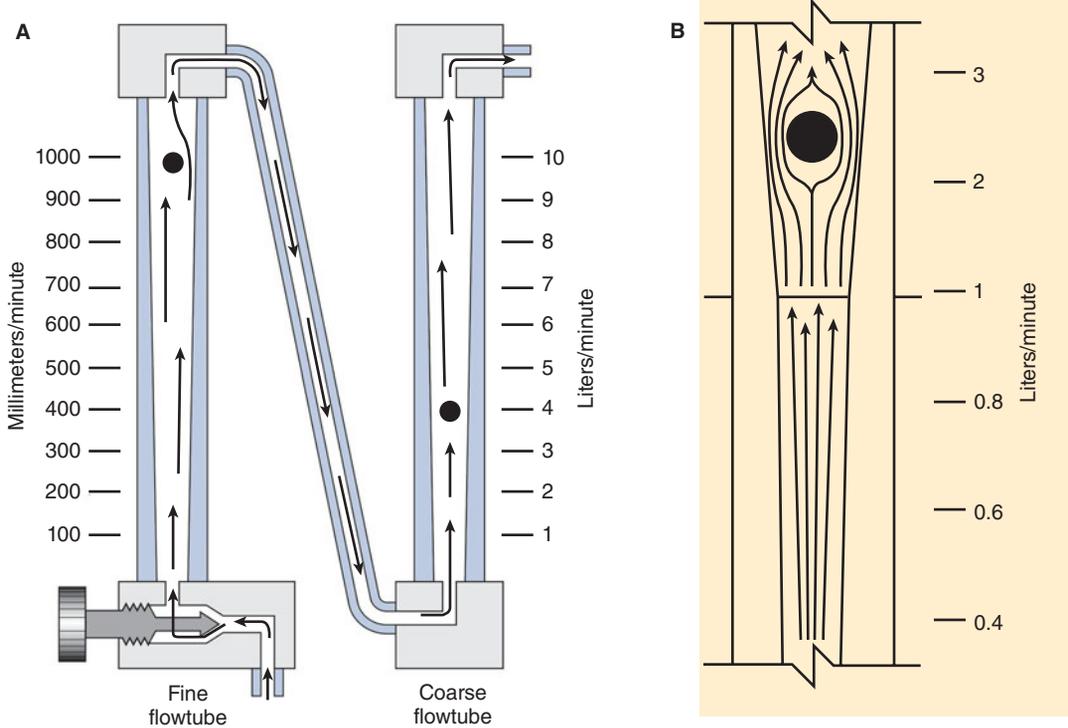

FIGURE 4-10 Constant-pressure variable orifice flowmeters (Thorpe type). **A:** Two tube design. **B:** Dual taper design.

Should a leak develop within or downstream from an oxygen flowmeter, a hypoxic gas mixture can be delivered to the patient (Figure 4-11). To reduce this risk, oxygen flowmeters are *always* positioned downstream to all other flowmeters (nearest to the vaporizer).

Some anesthesia machines have electronic flow control and measurement (Figure 4-12). In such instances, a back-up conventional (Thorpe) auxiliary oxygen flowmeter is provided. Other models have conventional flowmeters but electronic measurement of gas flow along with Thorpe tubes and

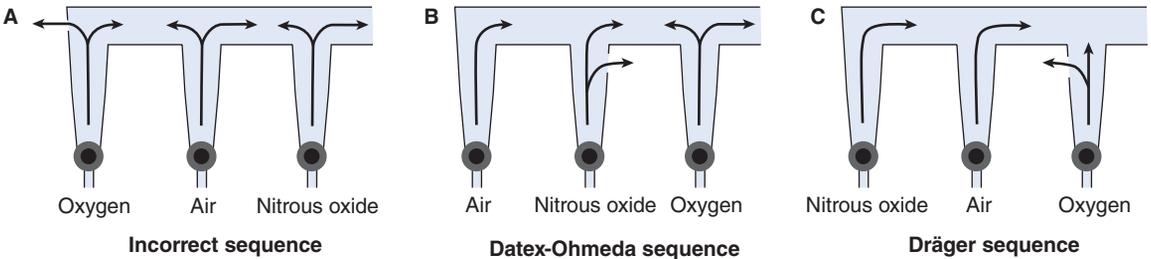

FIGURE 4-11 Sequence of flowmeters in a three-gas machine. **A:** An unsafe sequence. **B:** Typical Datex Ohmeda sequence. **C:** Typical Dräger sequence. Note that regardless of sequence a leak in the oxygen tube or further downstream can result in delivery of a hypoxic mixture.

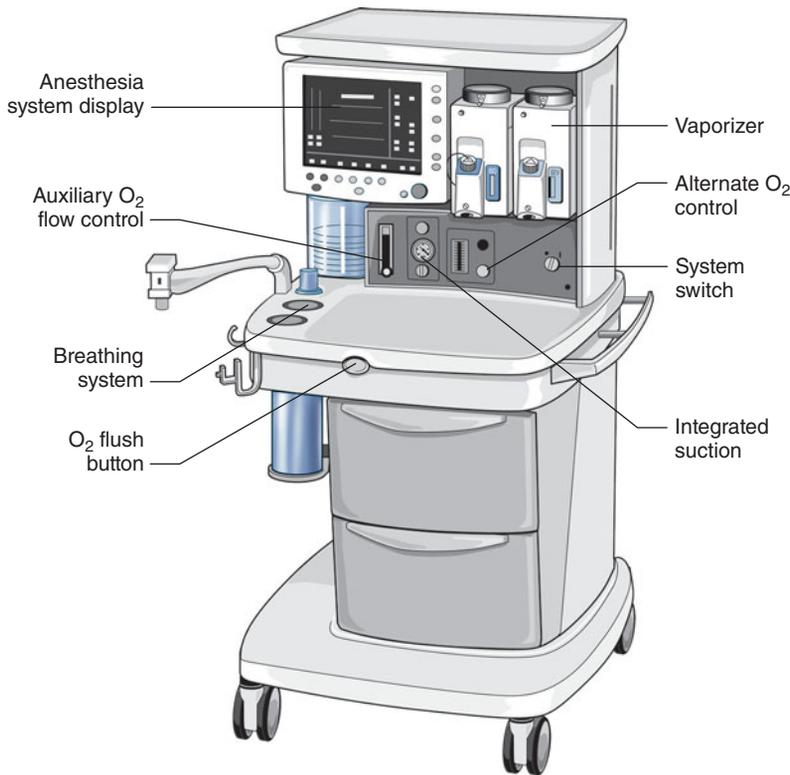

FIGURE 4-12 Datex-Ohmeda S/5 Avance with electronic flow control and measurement. Note the presence of only a single alternate flowmeter for oxygen to be used in a power failure.

digital or digital/graphic displays (Figure 4-13). The amount of pressure drop caused by a flow restrictor is the basis for measurement of gas flow rate in these systems. In these machines oxygen, nitrous oxide, and air each have a separate electronic flow measurement device in the flow control section before they are mixed together. Electronic flowmeters are essential components in workstations if gas flow rate data will be acquired automatically by computerized anesthesia recording systems.

A. Minimum Oxygen Flow

The oxygen flow valves are usually designed to deliver a minimum flow of 150 mL/min when the anesthesia machine is turned on. One method involves the use of a minimum flow resistor (Figure 4-14). This safety feature helps ensure that some oxygen enters the breathing circuit even if the operator forgets

to turn on the oxygen flow. Some machines are designed to deliver minimum flow or low-flow anesthesia (<1 L/min) and have minimum oxygen flows as low as 50 mL/min.

B. Oxygen/Nitrous Oxide Ratio Controller

4 Another safety feature of anesthesia machines is a linkage of the nitrous oxide gas flow to the oxygen gas flow; this arrangement helps ensure a minimum oxygen concentration of 25%. The oxygen/nitrous oxide ratio controller links the two flow valves either pneumatically or mechanically. To maintain the minimum oxygen concentration, the system (Link-25) in Datex-Ohmeda machines increases the flow of oxygen, whereas the oxygen ratio monitor controller (ORMC) in Dräger machines reduces the concentration of nitrous oxide. It should be noted that this safety device does

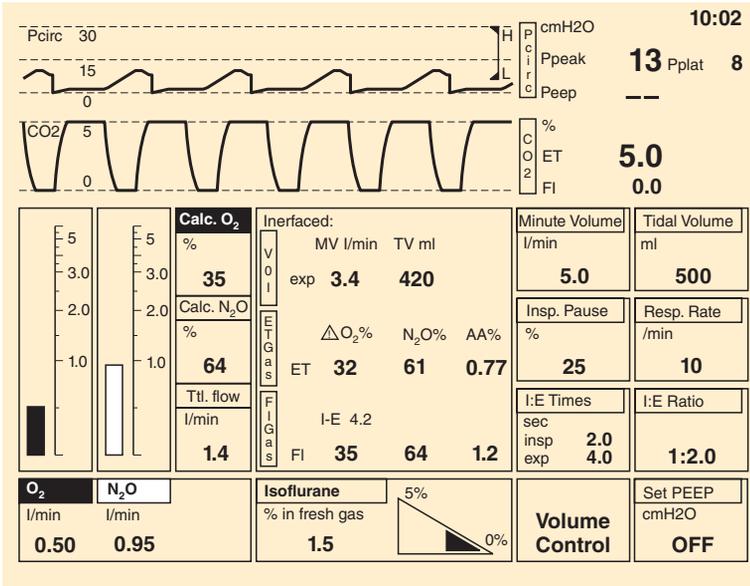

FIGURE 4-13 Graphic and digital flowmeter display of Datex-Ohmeda S/5 ADU.

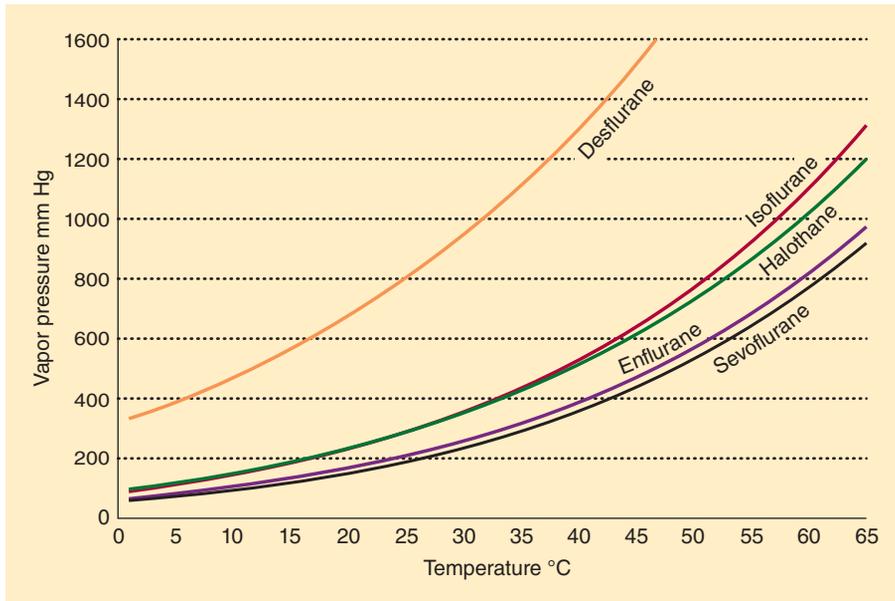

FIGURE 4-15 The vapor pressure of anesthetic gases.

not affect the flow of a third gas (eg, air, helium, or carbon dioxide).

Vaporizers

Volatile anesthetics (eg, halothane, isoflurane, desflurane, sevoflurane) must be vaporized before being delivered to the patient. Vaporizers have concentration-calibrated dials that precisely add volatile anesthetic agents to the combined gas flow from all flowmeters. They must be located between the flowmeters and the common gas outlet. Moreover, unless the machine accepts only one vaporizer at a time, all anesthesia machines should have an interlocking or exclusion device that prevents the concurrent use of more than one vaporizer.

A. Physics of Vaporization

At temperatures encountered in the operating room, the molecules of a volatile anesthetic in a closed container are distributed between the liquid and gaseous phases. The gas molecules bombard the walls of the container, creating the saturated vapor pressure of that agent. Vapor pressure depends on the characteristics of the volatile agent and the temperature. The greater the temperature, the greater the tendency for

the liquid molecules to escape into the gaseous phase and the greater the vapor pressure (Figure 4-15). Vaporization requires energy (the latent heat of vaporization), which results in a loss of heat from the liquid. As vaporization proceeds, temperature of the remaining liquid anesthetic drops and vapor pressure decreases unless heat is readily available to enter the system. Vaporizers contain a chamber in which a carrier gas becomes saturated with the volatile agent.

A liquid's boiling point is the temperature at which its vapor pressure is equal to the atmospheric pressure. As the atmospheric pressure decreases (as in higher altitudes), the boiling point also decreases. Anesthetic agents with low boiling points are more susceptible to variations in barometric pressure than agents with higher boiling points. Among the commonly used agents, desflurane has the lowest boiling point (22.8°C at 760 mm Hg).

B. Copper Kettle

The copper kettle vaporizer is no longer used in clinical anesthesia; however, understanding how it works provides invaluable insight into the delivery of volatile anesthetics (Figure 4-16). It is classified as a measured-flow vaporizer (or flowmeter-controlled

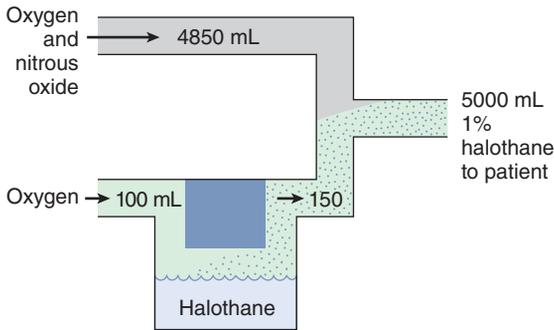

FIGURE 4-16 Schematic of a copper kettle vaporizer. Note that 50 mL/min of halothane vapor is added for each 100 mL/min oxygen flow that passes through the vaporizer.

vaporizer). In a copper kettle, the amount of carrier gas bubbled through the volatile anesthetic is controlled by a dedicated flowmeter. This valve is turned off when the vaporizer circuit is not in use. Copper is used as the construction metal because its relatively high specific heat (the quantity of heat required to raise the temperature of 1 g of substance by 1°C) and high thermal conductivity (the speed of heat conductance through a substance) enhance the vaporizer's ability to maintain a constant temperature. All the gas entering the vaporizer passes through the anesthetic liquid and becomes saturated with vapor. One milliliter of liquid anesthetic is the equivalent of approximately 200 mL of anesthetic vapor. Because the vapor pressure of volatile anesthetics is greater than the partial pressure required for anesthesia, the saturated gas leaving a copper kettle has to be diluted before it reaches the patient.

For example, the vapor pressure of halothane is 243 mm Hg at 20°C, so the concentration of halothane exiting a copper kettle at 1 atmosphere would be 243/760, or 32%. If 100 mL of oxygen enters the kettle, roughly 150 mL of gas exits (the initial 100 mL of oxygen plus 50 mL of saturated halothane vapor), one-third of which would be saturated halothane vapor. To deliver a 1% concentration of halothane (MAC 0.75%), the 50 mL of halothane vapor and 100 mL of carrier gas that left the copper kettle have to be diluted within a total of 5000 mL of fresh gas flow. Thus, every 100 mL of oxygen passing through a halothane vaporizer translates into a 1%

increase in concentration if total gas flow into the breathing circuit is 5 L/min. Therefore when total flow is fixed, flow through the vaporizer determines the ultimate concentration of anesthetic. Isoflurane has an almost identical vapor pressure, so the same relationship between copper kettle flow, total gas flow, and anesthetic concentration exists. However, if total gas flow changes without an adjustment in copper kettle flow (eg, exhaustion of a nitrous oxide cylinder), the delivered volatile anesthetic concentration rises rapidly to potentially dangerous levels.

C. Modern Conventional Vaporizers

5 All modern vaporizers are agent specific and temperature corrected, capable of delivering a constant concentration of agent regardless of temperature changes or flow through the vaporizer. Turning a single calibrated control knob counterclockwise to the desired percentage diverts an appropriate small fraction of the total gas flow into the carrier gas, which flows over the liquid anesthetic in a vaporizing chamber, leaving the balance to exit the vaporizer unchanged (**Figure 4-17**). Because some of the entering gas is never exposed to anesthetic liquid, this type of agent-specific vaporizer is also known as a variable-bypass vaporizer.

Temperature compensation is achieved by a strip composed of two different metals welded together. The metal strips expand and contract differently in response to temperature changes. When the temperature decreases, differential contraction causes the strip to bend allowing more gas to pass through the vaporizer. Such bimetallic strips are also used in home thermostats. As the temperature rises differential expansion causes the strip to bend the other way restricting gas flow into the vaporizer. Altering total fresh gas flow rates within a wide range does not significantly affect anesthetic concentration because the same proportion of gas is exposed to the liquid. However, the real output of an agent would be lower than the dial setting at extremely high flow (>15 L/min); the converse is true when the flow rate is less than 250 mL/min. Changing the gas composition from 100% oxygen to 70% nitrous oxide may transiently decrease volatile anesthetic concentration due to the greater solubility of nitrous oxide in volatile agents.

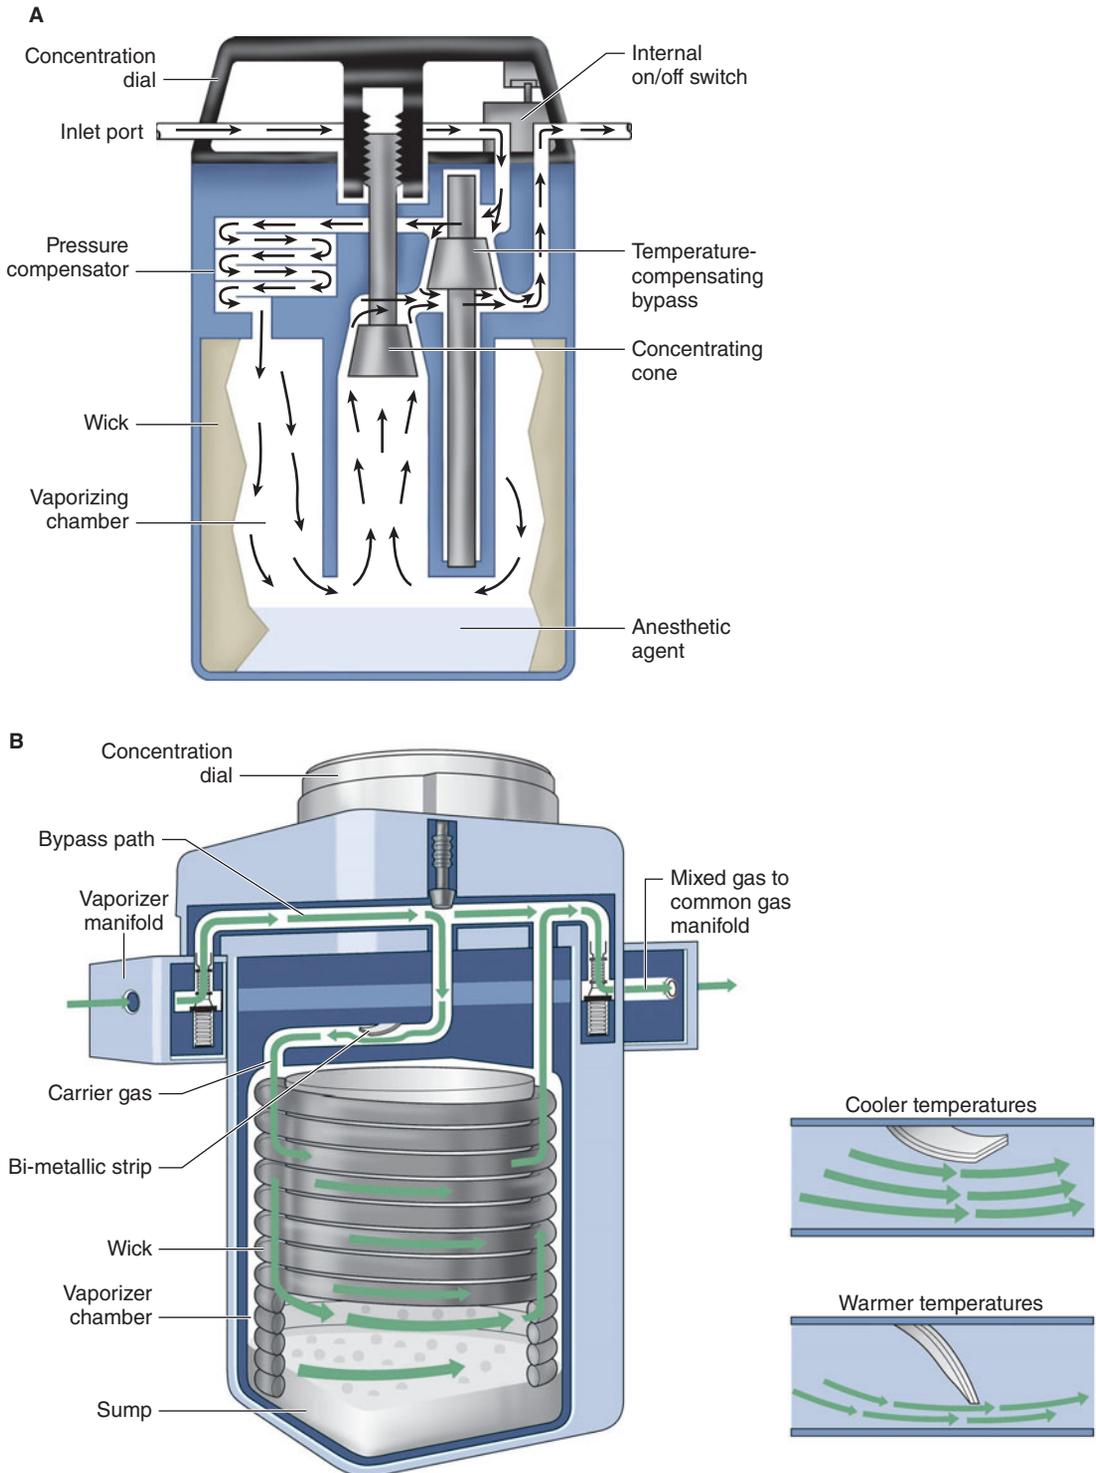

FIGURE 4-17 Schematic of agent-specific variable-bypass vaporizers. **A:** Dräger Vapor 19.n. **B:** Datex-Ohmeda Tec 7.

Given that these vaporizers are agent specific, filling them with the incorrect anesthetic should be avoided. For example, unintentionally filling a sevoflurane-specific vaporizer with halothane could lead to an anesthetic overdose. First, halothane's higher vapor pressure (243 mm Hg versus 157 mm Hg) will cause a 40% greater amount of anesthetic vapor to be released. Second, halothane is more than twice as potent as sevoflurane (MAC 0.75 versus 2.0). Conversely, filling a halothane vaporizer with sevoflurane will cause an anesthetic underdosage. Modern vaporizers offer agent-specific keyed filling ports to prevent filling with an incorrect agent.

Excessive tilting of older vaporizers (Tec 4, Tec 5, and Vapor 19.n) during transport may flood the bypass area and lead to dangerously high anesthetic concentrations. In the event of tilting and spillage, high flow of oxygen with the vaporizer turned off should be used to vaporize and flush the liquid anesthetic from the bypass area. Fluctuations in pressure from positive-pressure ventilation in older anesthesia machines may cause a transient reversal of flow through the vaporizer, unpredictably changing agent delivery. This "pumping effect" is more pronounced with low gas flows. A one-way check valve between the vaporizers and the oxygen flush valve (Datex-Ohmeda) together with some design modifications in newer units limit the occurrence of some of these problems. Variable bypass vaporizers compensate for changes in ambient pressures (ie, altitude changes maintaining relative anesthetic gas partial pressure).

D. Electronic Vaporizers

Electronically controlled vaporizers must be utilized for desflurane and are used for all volatile anesthetics in some sophisticated anesthesia machines.

1. Desflurane vaporizer—Desflurane's vapor pressure is so high that at sea level it almost boils at room temperature (Figure 4-15). **This high volatility, coupled with a potency only one-fifth that of other volatile agents, presents unique delivery problems.** First, the vaporization required for general anesthesia produces a cooling effect that would overwhelm the ability of conventional vaporizers to maintain a constant temperature. Second, because it vaporizes so extensively, a tremendously high fresh gas flow would be necessary to dilute the carrier gas

to clinically relevant concentrations. These problems have been addressed by the development of special desflurane vaporizers. A reservoir containing desflurane (desflurane sump) is electrically heated to 39°C (significantly higher than its boiling point) creating a vapor pressure of 2 atmospheres. Unlike a variable-bypass vaporizer, no fresh gas flows through the desflurane sump. Rather, pure desflurane vapor joins the fresh gas mixture before exiting the vaporizer. The amount of desflurane vapor released from the sump depends on the concentration selected by turning the control dial and the fresh gas flow rate. Although the Tec 6 Plus maintains a constant desflurane concentration over a wide range of fresh gas flow rates, it cannot automatically compensate for changes in elevation. Decreased ambient pressure (eg, high elevation) does not affect the concentration of agent delivered, but decreases the partial pressure of the agent. Thus, at high elevations, the anesthesiologist must manually increase the concentration control.

2. Aladin cassette vaporizer—This vaporizer is designed for use with the Datex-Ohmeda S/5 ADU and Aisys machines. Gas flow from the flow control is divided into bypass flow and liquid chamber flow (Figure 4-18). The latter is conducted into an agent-specific, color-coded, cassette (Aladin cassette) in which the volatile anesthetic is vaporized. The machine accepts only one cassette at a time and recognizes the cassette through magnetic labeling. The cassette does not contain any bypass flow channels; therefore, unlike traditional vaporizers, liquid anesthetic cannot escape during handling and the cassette can be carried in any position. After leaving the cassette, the now anesthetic-saturated liquid chamber flow reunites with the bypass flow before exiting the fresh gas outlet. A flow restrictor valve near the bypass flow helps to adjust the amount of fresh gas that flows to the cassette. Adjusting the ratio between the bypass flow and liquid chamber flow changes the concentration of volatile anesthetic agent delivered to the patient. In practice, the clinician changes the concentration by turning the agent wheel, which operates a digital potentiometer. Software sets the desired fresh gas agent concentration according to the number of output pulses from the agent wheel. Sensors in the cassette measure pressure and temperature, thus determining agent concentration in the gas leaving the cassette. Correct liquid chamber flow is

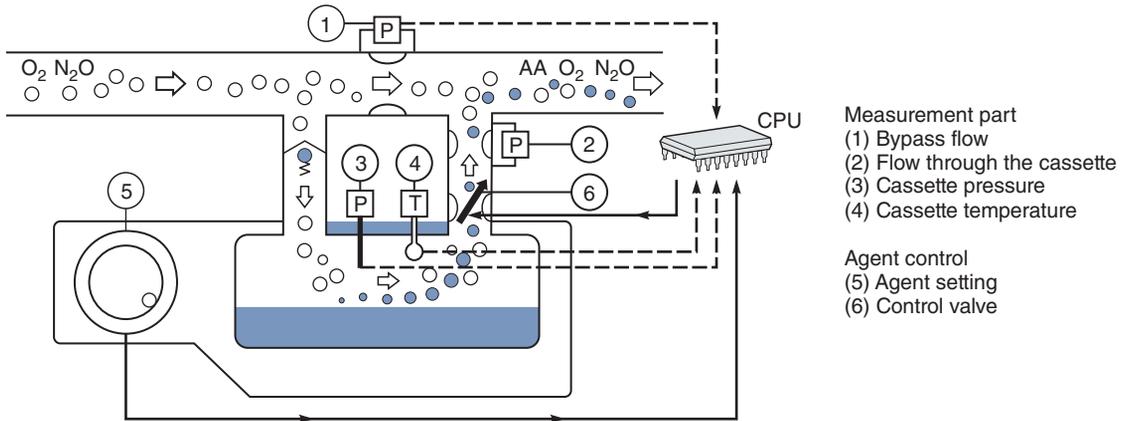

FIGURE 4-18 Schematic of the electronic Datex-Ohmeda Aladin vaporizer.

calculated based on desired fresh gas concentration and determined cassette gas concentration.

Common (Fresh) Gas Outlet

In contrast to the multiple gas inlets, the anesthesia machine has only one common gas outlet that supplies gas to the breathing circuit. The term *fresh gas outlet* is also often used because of its critical role in adding new gas of fixed and known composition to the circle system. Unlike older models, some newer anesthesia machines measure and report common outlet gas flows (Datex-Ohmeda S/5 ADU and Narkomed 6400). An antidisconnect retaining device is used to prevent accidental detachment of the gas outlet hose that connects the machine to the breathing circuit.

The oxygen flush valve provides a high flow (35–75 L/min) of oxygen directly to the common gas outlet, bypassing the flowmeters and vaporizers. It is used to rapidly refill or flush the breathing circuit, but because the oxygen may be supplied at a line pressure of 45–55 psig, there is a real potential of lung barotrauma. For this reason, the flush valve must be used cautiously whenever a patient is connected to the breathing circuit. Moreover, inappropriate use of the flush valve (or a situation of stuck valve) may result in backflow of gases into the low-pressure circuit, causing dilution of inhaled anesthetic concentration. Some machines use a second-stage regulator to drop the oxygen flush pressure to a lower level.

A protective rim around the flush button limits the possibility of unintentional activation. Anesthesia machines (eg, Datex-Ohmeda Aestiva/5) may have an optional auxiliary common gas outlet that is activated with a dedicated switch. It is primarily used for performing the low-pressure circuit leak test (see Anesthesia Machine Checkout List).

THE BREATHING CIRCUIT

The breathing system most commonly used with anesthesia machines is the circle system ([Figure 4-19](#)); a Bain circuit is occasionally used. The components and use of the circle system were previously discussed. It is important to note that gas composition at the common gas outlet can be controlled precisely and rapidly by adjustments in flowmeters and vaporizers. In contrast, gas composition, especially volatile anesthetic concentration, in the breathing circuit is significantly affected by other factors, including anesthetic uptake in the patient's lungs, minute ventilation, total fresh gas flow, volume of the breathing circuit, and the presence of gas leaks. Use of high gas flow rates during induction and emergence decreases the effects of such variables and can diminish the magnitude of discrepancies between fresh gas outlet and circle system anesthetic concentrations. Measurement of inspired and expired anesthetic gas concentration also greatly facilitates anesthetic management.

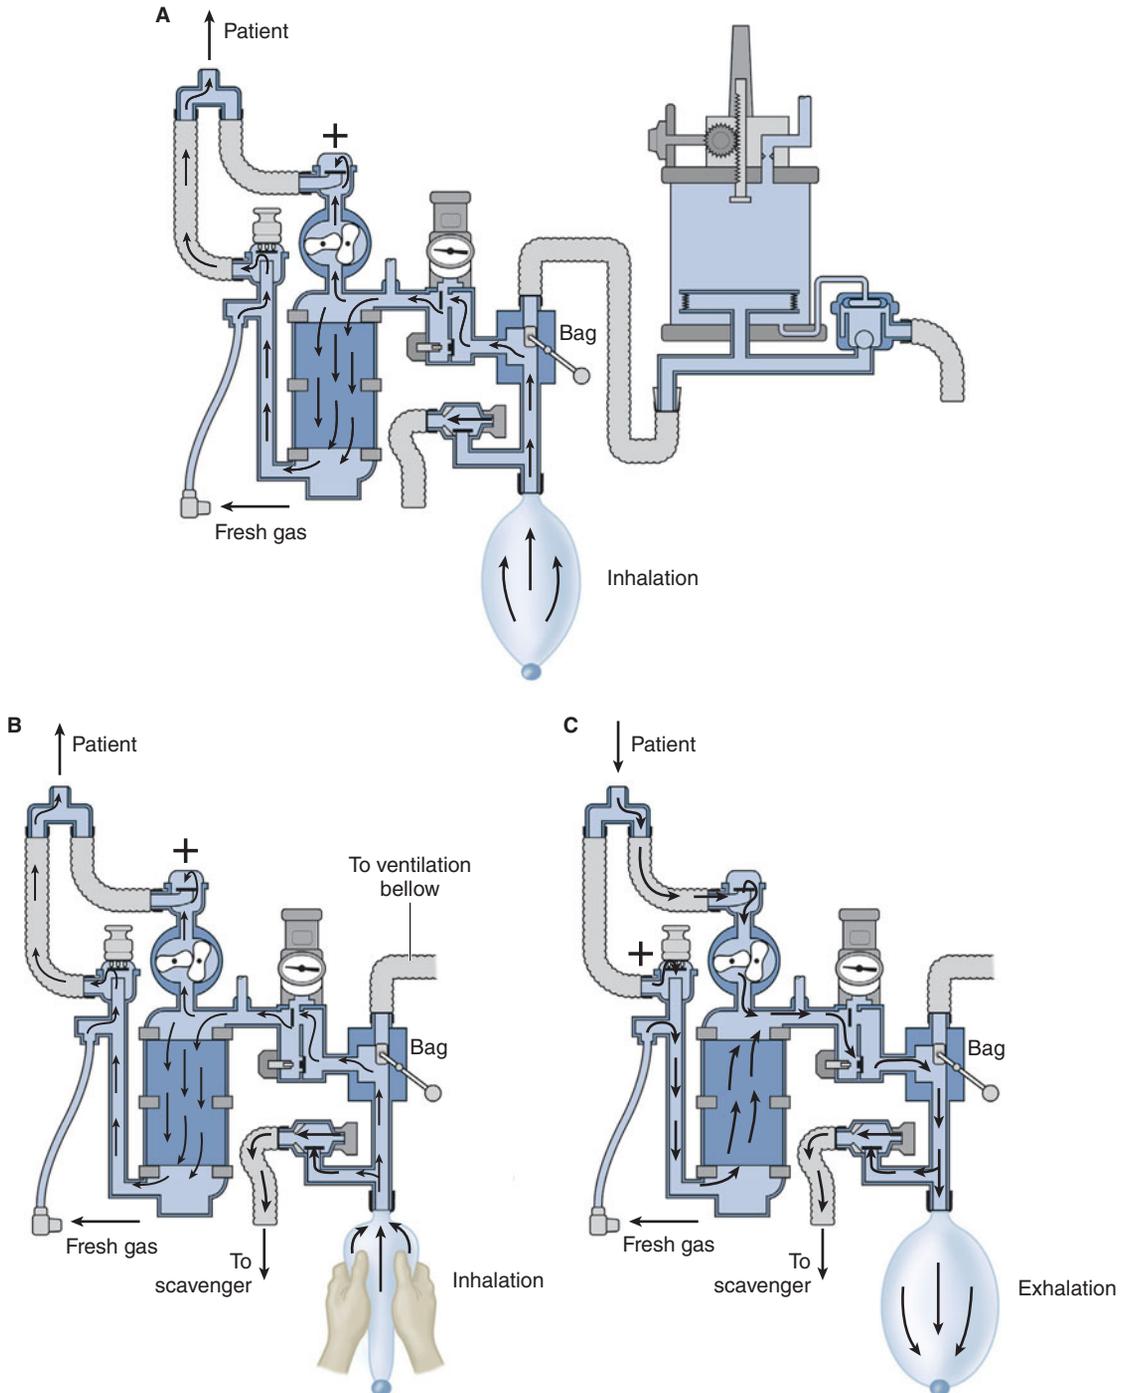

FIGURE 4-19 Diagram of a typical breathing circuit (Dräger Narkomed). Note gas flow during (A) spontaneous inspiration, (B) manual inspiration ("bagging"), and (C) exhalation (spontaneous or bag ventilation).

In most machines the common gas outlet is attached to the breathing circuit just past the exhalation valve to prevent artificially high exhaled tidal volume measurements. When spirometry measurements are made at the Y-connector, fresh gas flow can enter the circuit on the patient side of the inspiratory valve. The latter enhances CO₂ elimination and may help reduce desiccation of the CO₂ absorbent.

Newer anesthesia machines have integrated internalized breathing circuit components (Figure 4-20). The advantages of these designs include reduced probability of breathing circuit misconnects, disconnects, kinks, and leaks. The smaller volume of compact machines can also help conserve gas flow and volatile anesthetics and allow faster

changes in breathing circuit gas concentration. Internal heating of manifolds can reduce precipitation of moisture.

Oxygen Analyzers

General anesthesia should not be administered without an oxygen analyzer in the breathing circuit. **Three types of oxygen analyzers are available: polarographic (Clark electrode), galvanic (fuel cell), and paramagnetic.** The first two techniques utilize electrochemical sensors that contain cathode and anode electrodes embedded in an electrolyte gel separated from the sample gas by an oxygen-permeable membrane (usually Teflon). As oxygen reacts with the electrodes, a current is generated that is proportional

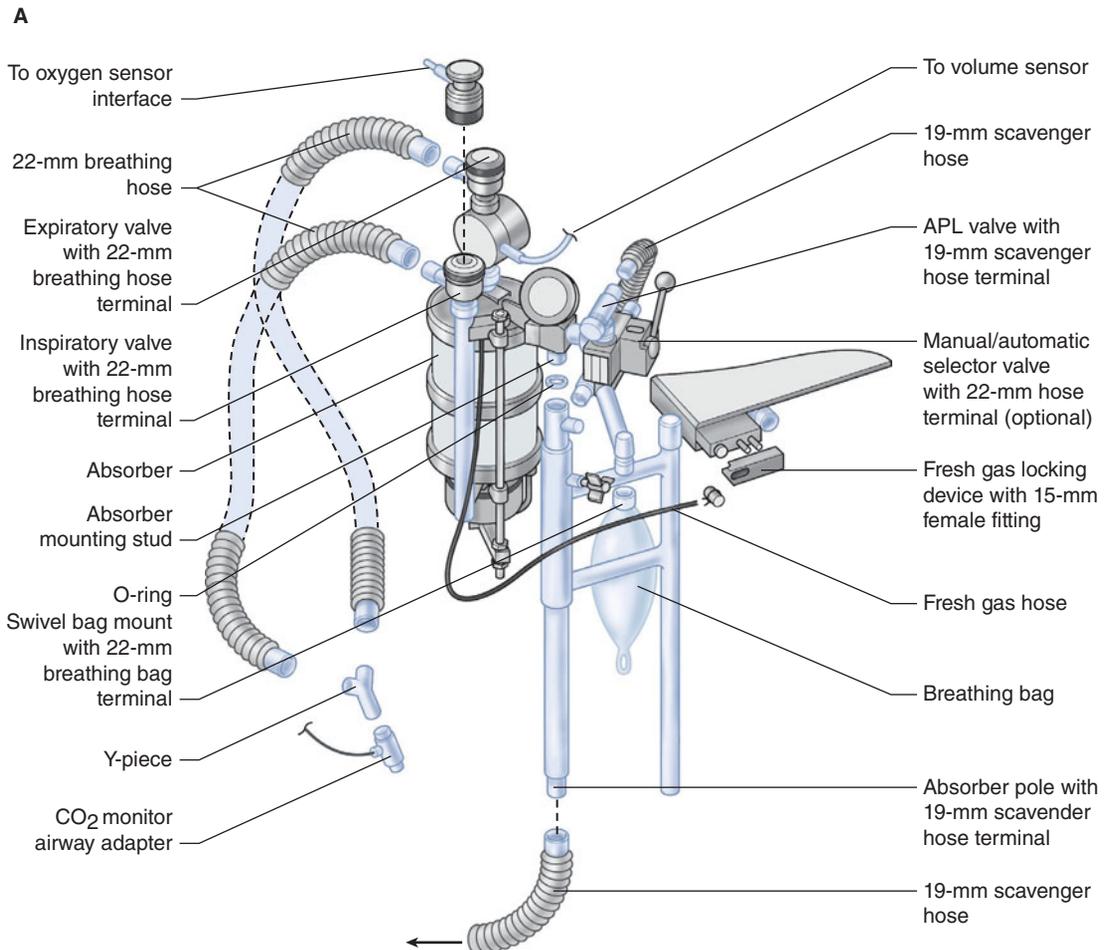

FIGURE 4-20 Breathing circuit design. **A:** Conventional external components. (continued)

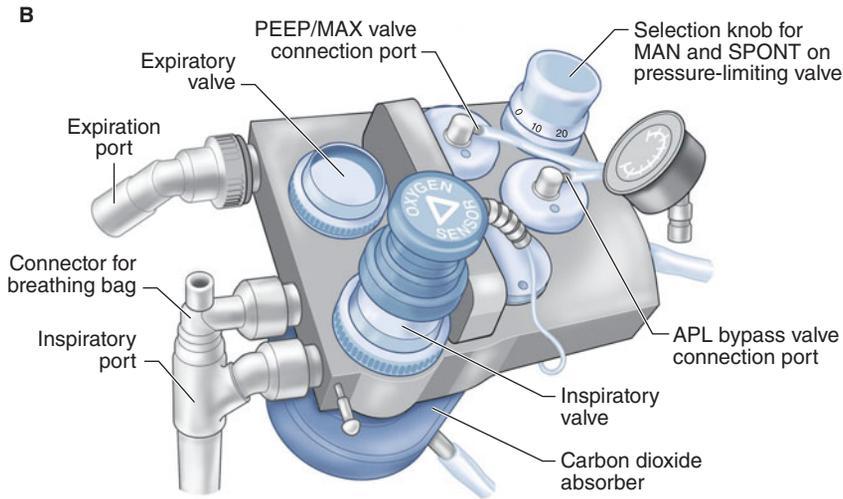

FIGURE 4-20 (continued) **B:** Compact design that reduces external connections and circuit volume (Dräger Fabius G5).

to the oxygen partial pressure in the sample gas. The galvanic and polarographic sensors differ in the composition of their electrodes and electrolyte gels. The components of the galvanic cell are capable of providing enough chemical energy so that the reaction does not require an external power source.

Although the initial cost of paramagnetic sensors is greater than that of electrochemical sensors, paramagnetic devices are self-calibrating and have no consumable parts. In addition, their response time is fast enough to differentiate between inspired and expired oxygen concentrations.

All oxygen analyzers should have a low-level alarm that is automatically activated by turning on the anesthesia machine. The sensor should be placed into the inspiratory or expiratory limb of the circle system's breathing circuit—but *not* into the fresh gas line. As a result of the patient's oxygen consumption, the expiratory limb has a slightly lower oxygen partial pressure than the inspiratory limb, particularly at low fresh gas flows. The increased humidity of expired gas does not significantly affect most modern sensors.

Spirometers

Spirometers, also called respirometers, are used to measure exhaled tidal volume in the breathing circuit on all anesthesia machines, typically near the exhalation valve. Some anesthesia machines also

measure the inspiratory tidal volume just past the inspiratory valve or the actual delivered and exhaled tidal volumes at the Y-connector that attaches to the patient's airway.

A common method employs a rotating vane of low mass in the expiratory limb in front of the expiratory valve of the circle system (vane anemometer or Wright respirometer, [Figure 4-21A](#)).

The flow of gas across vanes within the respirometer causes their rotation, which is measured electronically, photoelectrically, or mechanically. In another variation using this turbine principle, the volumeter or displacement meter is designed to measure the movement of discrete quantities of gas over time ([Figure 4-21B](#)).

Changes in exhaled tidal volumes usually represent changes in ventilator settings, but can also be due to circuit leaks, disconnections, or ventilator malfunction. These spirometers are prone to errors caused by inertia, friction, and water condensation. For example, Wright respirometers under-read at low flow rates and over-read at high flow rates. Furthermore, the measurement of exhaled tidal volumes at this location in the expiratory limb includes gas that had been lost to the circuit (and not delivered to the patient; discussed below). The difference between the volume of gas delivered to the circuit and the volume of gas actually reaching the patient becomes very significant with long

compliant breathing tubes, rapid respiratory rates, and high airway pressures. These problems are at least partially overcome by measuring the tidal volume at the Y-connector to the patient's airway.

A hot-wire anemometer utilizes a fine platinum wire, electrically heated at a constant temperature, inside the gas flow. The cooling effect of increasing gas flow on the wire electrode causes a change in electrical resistance. In a constant-resistance anemometer, gas flow is determined from the current needed to maintain a constant wire temperature (and resistance). Disadvantages include an inability to detect reverse flow, less accuracy at higher flow rates, and the possibility that the heated wire may be a potential ignition source for fire in the breathing manifold.

Ultrasonic flow sensors rely on discontinuities in gas flow generated by turbulent eddies in the flow stream. Upstream and downstream ultrasonic beams, generated from piezoelectric crystals, are transmitted at an angle to the gas stream. The Doppler frequency shift in the beams is proportional to the flow velocities in the breathing circuit. Major advantages include the absence of moving parts and greater accuracy due to the device's independence from gas density.

Machines with variable-orifice flowmeters usually employ two sensors (Figure 4-21C). One measures flow at the inspiratory port of the breathing system and the other measures flow at the expiratory port. These sensors use a change in internal diameter to generate a pressure drop that is proportional to the flow through the sensor. Clear tubes connect the sensors to differential pressure transducers inside the anesthesia machine (Datex-Ohmeda 7900 SmartVent). The changes in gas flows during the inspiratory and expiratory phases help the ventilator to adjust and provide a constant tidal volume. However, due to excessive condensation sensors can fail when used with heated humidified circuits.

A pneumotachograph is a fixed-orifice flowmeter that can function as a spirometer. A parallel bundle of small-diameter tubes in chamber (Fleisch pneumotachograph) or mesh screen provides a slight resistance to airflow. The pressure drop across this resistance is sensed by a differential pressure transducer and is proportional to the flow rate. Integration

of flow rate over time yields tidal volume. Moreover, analysis of pressure, volume, and time relationships can yield potentially valuable information about airway and lung mechanics. Modifications have been required to overcome inaccuracies due to water condensation and temperature changes. One modification employs two pressure-sensing lines in a Pitot tube at the Y-connection (Figure 4-21D). Gas flowing through the Pitot tube (flow sensor tube) creates a pressure difference between the flow sensor lines. This pressure differential is used to measure flow, flow direction, and airway pressure. Respiratory gases are continuously sampled to correct the flow reading for changes in density and viscosity.

Circuit Pressure

A pressure gauge or electronic sensor is always used to measure breathing-circuit pressure somewhere between the expiratory and inspiratory unidirectional valves; the exact location depends on the model of anesthesia machine. Breathing-circuit pressure usually reflects airway pressure if it is measured as close to the patient's airway as possible. The most accurate measurements of both inspiratory and expiratory pressures can be obtained from the Y-connection (eg, D-lite and Pedi-lite sensors).

6 A rise in airway pressure may signal worsening pulmonary compliance, an increase in tidal volume, or an obstruction in the breathing circuit, tracheal tube, or the patient's airway. A drop in pressure may indicate an improvement in compliance, a decrease in tidal volume, or a leak in the circuit. If circuit pressure is being measured at the CO₂ absorber, however, it will not always mirror the pressure in the patient's airway. For example, clamping the expiratory limb of the breathing tubes during exhalation will prevent the patient's breath from exiting the lungs. Despite this buildup in airway pressure, a pressure gauge at the absorber will read zero because of the intervening one-way valve.

Some machines have incorporated auditory feedback for pressure changes during ventilator use.

Adjustable Pressure-Limiting Valve

The adjustable pressure-limiting (APL) valve, sometimes referred to as the pressure relief or pop-off valve, is usually fully open during spontaneous

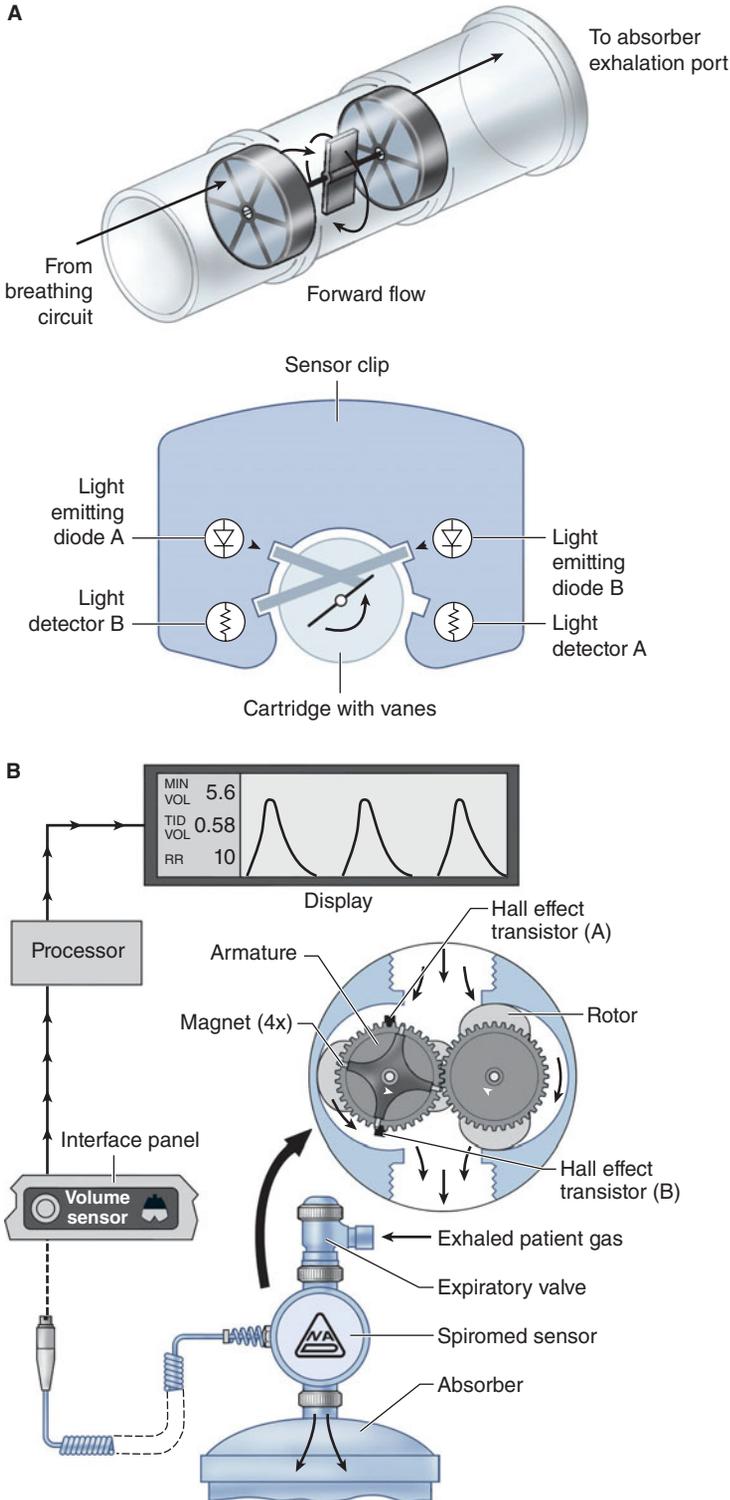

FIGURE 4-21 Spirometer designs. **A:** Vane anemometer (Datex-Ohmeda). **B:** Volumeter (Dräger).

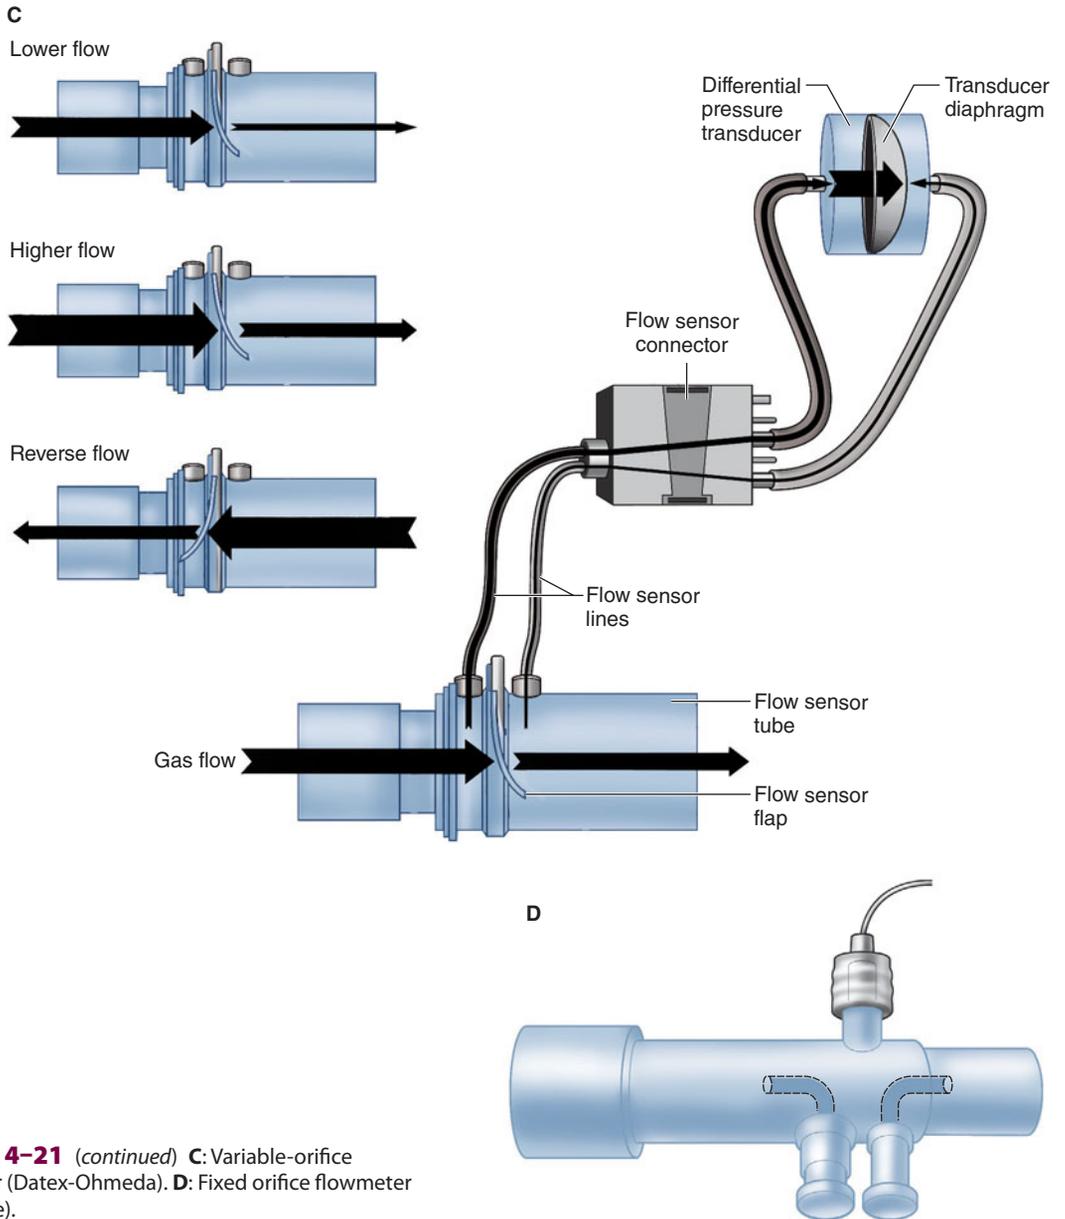

FIGURE 4-21 (continued) **C:** Variable-orifice flowmeter (Datex-Ohmeda). **D:** Fixed orifice flowmeter (Pitot tube).

ventilation but must be partially closed during manual or assisted bag ventilation. The APL valve often requires fine adjustments. If it is not closed sufficiently excessive loss of circuit volume due to leaks prevents manual ventilation. At the same time if it is closed too much or is fully closed a progressive rise in pressure could result in pulmonary barotrauma (eg, pneumothorax) or hemodynamic compromise, or both. As an added safety feature, the APL valves on modern machines act as true pressure-limiting devices that can never be completely closed; the upper limit is usually 70–80 cm H₂O.

Humidifiers

Absolute humidity is defined as the weight of water vapor in 1 L of gas (ie, mg/L). Relative humidity is the ratio of the actual mass of water present in a volume of gas to the maximum amount of water possible at a particular temperature. At 37°C and 100% relative humidity, absolute humidity is 44 mg/L, whereas at room temperature (21°C and 100% humidity) it is 18 mg/L. Inhaled gases in the operating room are normally administered at room temperature with little or no humidification. Gases must therefore be warmed to body temperature and saturated with water by the upper respiratory tract. Tracheal intubation and high fresh gas flows bypass this normal humidification system and expose the lower airways to dry (<10 mg H₂O/L), room temperature gases.

Prolonged humidification of gases by the lower respiratory tract leads to dehydration of mucosa, altered ciliary function, and, if excessively prolonged, could potentially lead to inspissation of secretions, atelectasis, and even ventilation/perfusion mismatching, particularly in patients with underlying lung disease. Body heat is also lost as gases are warmed and even more importantly as water is vaporized to humidify the dry gases. The heat of vaporization for water is 560 cal/g of water vaporized. Fortunately, this heat loss accounts for about only 5–10% of total intraoperative heat loss, is not significant for a short procedure (<1 h), and usually can easily be compensated for with a forced-air warming blanket. Humidification and heating of inspiratory gases may be most important for small pediatric patients and older patients with severe underlying lung pathology, eg, cystic fibrosis.

A. Passive Humidifiers

Humidifiers added to the breathing circuit minimize water and heat loss. The simplest designs are condenser humidifiers or heat and moisture exchanger (HME) units (Figure 4–22). These passive devices do not add heat or vapor but rather contain a hygroscopic material that traps exhaled humidification and heat, which is released upon subsequent inhalation. Depending on the design, they may substantially increase apparatus dead space (more than 60 mL³), which can cause significant rebreathing in pediatric patients. They can also increase breathing-circuit resistance and the work of breathing during spontaneous respirations. Excessive saturation of an HME with water or secretions can obstruct the breathing circuit. Some condenser humidifiers also act as effective filters that may protect the breathing circuit and anesthesia machine from bacterial or viral cross-contamination. This may be particularly important when ventilating patients with respiratory infections or compromised immune systems.

B. Active Humidifiers

Active humidifiers are more effective than passive ones in preserving moisture and heat. Active humidifiers add water to gas by passing the gas over a water chamber (passover humidifier) or through a saturated wick (wick humidifier), bubbling it through water (bubble-through humidifier), or mixing it with vaporized water (vapor-phase humidifier). Because increasing temperature increases the capacity of a gas to hold water vapor, heated humidifiers with thermostatically controlled elements are most effective.

The hazards of heated humidifiers include thermal lung injury (inhaled gas temperature should be monitored and should not exceed 41°C), nosocomial infection, increased airway resistance from excess water condensation in the breathing circuit, interference with flowmeter function, and an increased likelihood of circuit disconnection. These humidifiers are particularly valuable with children as they help prevent both hypothermia and the plugging of small tracheal tubes by dried secretions. Of course, any design that increases airway dead space should be avoided in pediatric patients. Unlike passive humidifiers, active humidifiers do not filter respiratory gases.

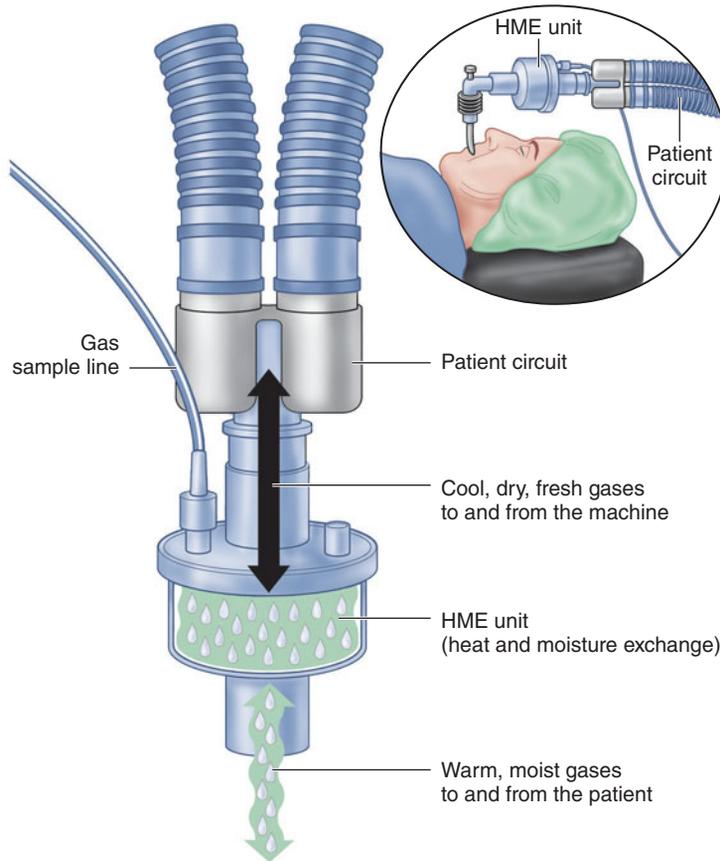

FIGURE 4-22 Heat and moisture exchanger (HME) functions as an “artificial nose” that attaches between the tracheal tube and the right-angle connector of the breathing circuit.

VENTILATORS

Ventilators are used extensively in the operating room (OR) and the intensive care unit (ICU). All modern anesthesia machines are equipped with a ventilator. Historically OR ventilators were simpler and more compact than their ICU counterparts. This distinction has become blurred due to advances in technology together with an increasing need for “ICU-type” ventilators as more critically ill patients come to the OR. The ventilators on some modern machines are just as sophisticated as those in the ICU and have almost the same capabilities. After a general discussion of basic ventilator principles, this section reviews the use of ventilators in conjunction with anesthesia machines.

Overview

Ventilators generate gas flow by creating a pressure gradient between the proximal airway and the alveoli. Older units relied on the generation of negative pressure around (and inside) the chest (eg, iron lungs), whereas modern ventilators generate positive pressure and gas flow in the upper airway.

Ventilator function is best described in relation to the four phases of the ventilatory cycle: inspiration, the transition from inspiration to expiration, expiration, and the transition from expiration to inspiration. Although several classification schemes exist, the most common is based on inspiratory phase characteristics and the method of cycling from inspiration to expiration.

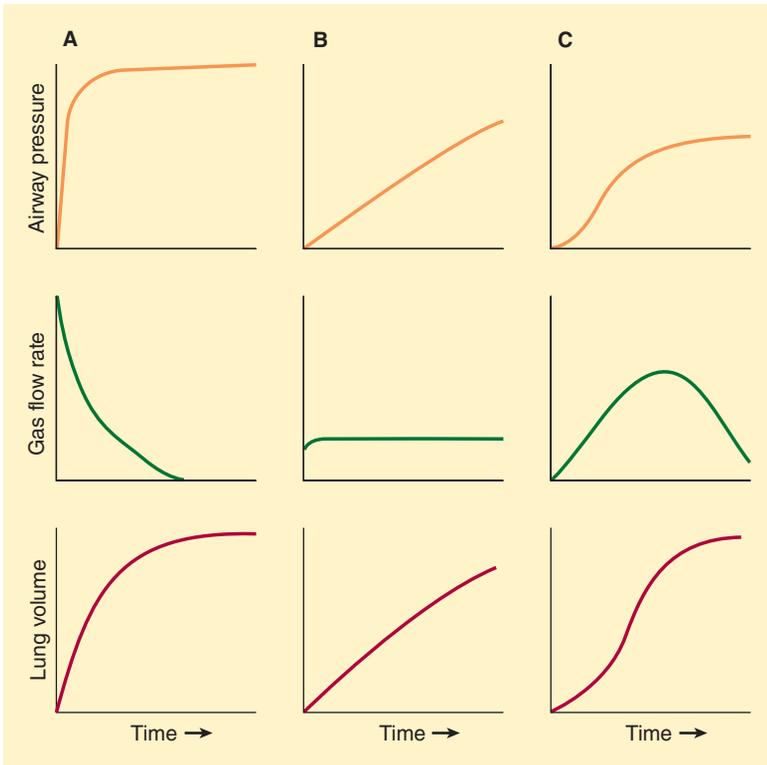

FIGURE 4-23 Pressure, volume, and flow profiles of different types of ventilators. **A:** Constant pressure. **B:** Constant flow. **C:** Nonconstant generator.

Other classification categories may include power source (eg, pneumatic-high pressure, pneumatic-Venturi, or electric), design (single-circuit system, double-circuit system, rotary piston, linear piston), and control mechanisms (eg, electronic timer or microprocessor).

A. Inspiratory Phase

During inspiration, ventilators generate tidal volumes by producing gas flow along a pressure gradient. The machine generates either a constant pressure (constant-pressure generators) or constant gas flow rate (constant-flow generators) during inspiration, regardless of changes in lung mechanics (Figure 4-23). Nonconstant generators produce pressures or gas flow rates that vary during the cycle but remain consistent from breath to breath. For instance, a ventilator that generates a flow pattern resembling a half cycle of a sine wave (eg, rotary piston ventilator) would be classified as a

nonconstant-flow generator. An increase in airway resistance or a decrease in lung compliance would increase peak inspiratory pressure but would not alter the flow rate generated by this type of ventilator (Figure 4-24).

B. Transition Phase from Inspiration to Expiration

Termination of the inspiratory phase can be triggered by a preset limit of time (fixed duration), a set inspiratory pressure that must be reached, or a predetermined tidal volume that must be delivered. Time-cycled ventilators allow tidal volume and peak inspiratory pressure to vary depending on lung compliance. Tidal volume is adjusted by setting inspiratory duration and inspiratory flow rate. Pressure-cycled ventilators will not cycle from the inspiratory phase to the expiratory phase until a preset pressure is reached. If a large circuit leak decreases peak pressures significantly,

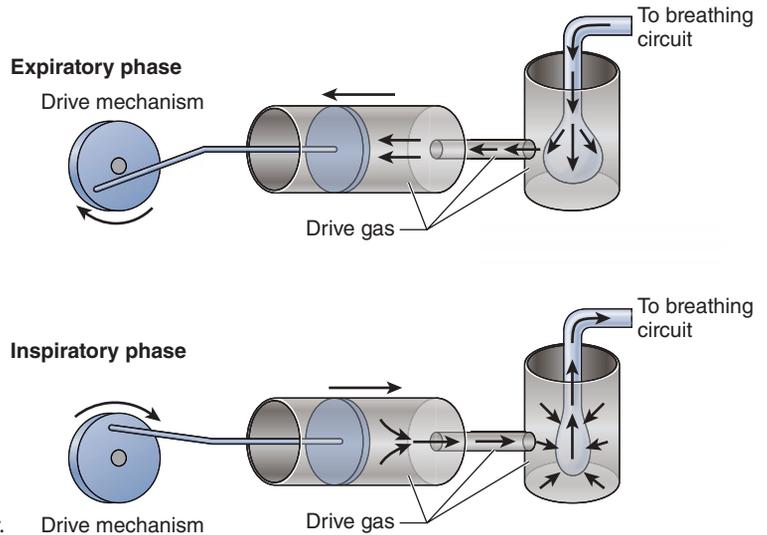

FIGURE 4-24 Rotary piston ventilator.

a pressure-cycled ventilator may remain in the inspiratory phase indefinitely. On the other hand, a small leak may not markedly decrease tidal volume, because cycling will be delayed until the pressure limit is met. Volume-cycled ventilators vary inspiratory duration and pressure to deliver a preset volume. In reality, modern ventilators overcome the many shortcomings of classic ventilator designs by incorporating secondary cycling parameters or other limiting mechanisms. For example, time-cycled and volume-cycled ventilators usually incorporate a pressure-limiting feature that terminates inspiration when a preset, adjustable safety pressure limit is reached. Similarly a volume-preset control that limits the excursion of the bellows allows a time-cycled ventilator to function somewhat like a volume-cycled ventilator, depending on the selected ventilator rate and inspiratory flow rate.

C. Expiratory Phase

The expiratory phase of ventilators normally reduces airway pressure to atmospheric levels or some preset value of positive end-expiratory pressure (PEEP). Exhalation is therefore passive. Flow out of the lungs is determined primarily by airway resistance and lung compliance. Expired gases fill up the bellows;

they are then relieved to the scavenging system. PEEP is usually created with an adjustable spring valve mechanism or pneumatic pressurization of the exhalation (spill) valve.

D. Transition Phase from Expiration to Inspiration

Transition into the next inspiratory phase may be based on a preset time interval or a change in pressure. The behavior of the ventilator during this phase together with the type of cycling from inspiration to expiration determines ventilator mode.

During controlled ventilation, the most basic mode of all ventilators, the next breath always occurs after a preset time interval. Thus tidal volume and rate are fixed in volume-controlled ventilation, whereas peak inspiratory pressure is fixed in pressure-controlled ventilation. Controlled ventilation modes are not designed for spontaneous breathing. In the volume-control mode, the ventilator adjusts gas flow rate and inspiratory time based on the set ventilatory rate and I:E ratio (**Figure 4-25A**). In the pressure-control mode, inspiratory time is also based on the set ventilator rate and inspiratory-to-expiratory (I:E) ratio, but gas flow is adjusted to maintain a constant inspiratory pressure (**Figure 4-25B**).

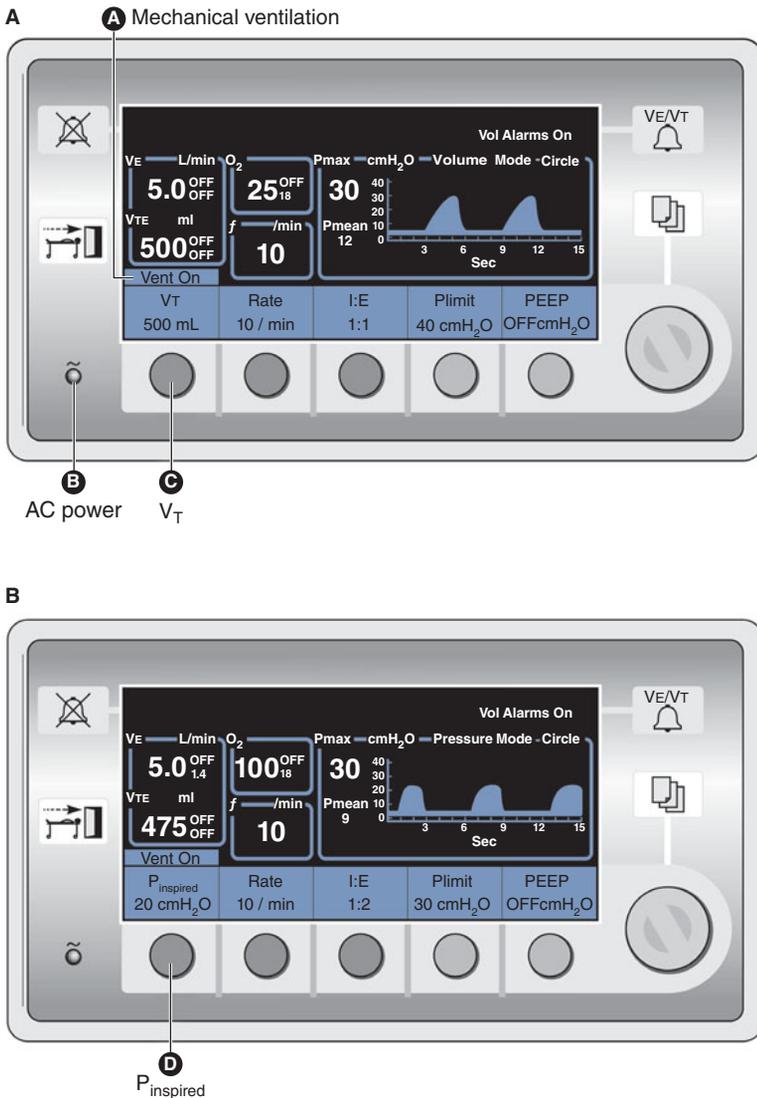

FIGURE 4-25 Ventilator controls (Datex-Ohmeda). **A:** Volume control mode. **B:** Pressure control mode.

In contrast, intermittent mandatory ventilation (IMV) allows patients to breathe spontaneously between controlled breaths. Synchronized intermittent mandatory ventilation (SIMV) is a further refinement that helps prevent “fighting the ventilator” and “breath stacking”; whenever possible, the ventilator tries to time the mandatory mechanical breaths with the drops in airway pressure below the end-expiratory pressure that occur as the patient initiates a spontaneous breath.

Ventilator Circuit Design

7 Traditionally ventilators on anesthesia machines have a double-circuit system design and are pneumatically powered and electronically controlled (Figure 4-26). Newer machines also incorporate microprocessor control that relies on sophisticated pressure and flow sensors. This feature allows multiple ventilatory modes, electronic PEEP, tidal volume modulation, and enhanced safety

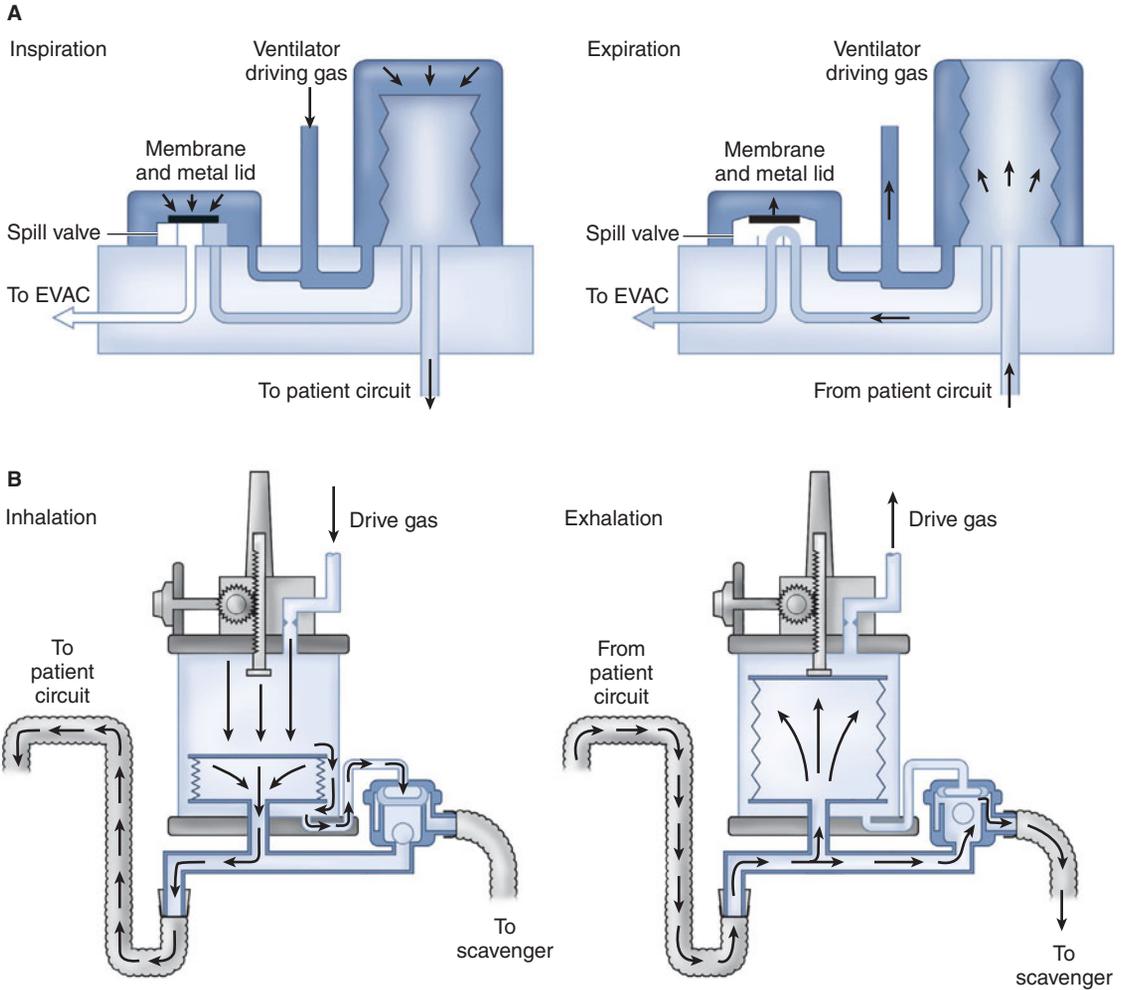

FIGURE 4-26 Double-circuit pneumatic ventilator design. **A:** Datex-Ohmeda. **B:** Dräger.

features. Some anesthesia machines have ventilators that use a single-circuit piston design (Figure 4-24).

A. Double-Circuit System Ventilators

In a double-circuit system design, tidal volume is delivered from a bellows assembly that consists of a bellows in a clear rigid plastic enclosure (Figure 4-26). A standing (ascending) bellows is preferred as it readily draws attention to a circuit disconnection by collapsing. Hanging (descending) bellows are rarely used and must not be weighted;

older ventilators with weighted hanging bellows continue to fill by gravity despite a disconnection in the breathing circuit.

The bellows in a double-circuit design ventilator takes the place of the breathing bag in the anesthesia circuit. Pressurized oxygen or air from the ventilator power outlet (45–50 psig) is routed to the space between the inside wall of the plastic enclosure and the outside wall of the bellows. Pressurization of the plastic enclosure compresses the pleated bellows inside, forcing the gas inside into the breathing

circuit and patient. In contrast, during exhalation, the bellows ascend as pressure inside the plastic enclosure drops and the bellows fill up with the exhaled gas. A ventilator flow control valve regulates drive gas flow into the pressurizing chamber. This valve is controlled by ventilator settings in the control box (Figure 4–26). Ventilators with microprocessors also utilize feedback from flow and pressure sensors. If oxygen is used for pneumatic power it will be consumed at a rate at least equal to minute ventilation. Thus, if oxygen fresh gas flow is 2 L/min and a ventilator is delivering 6 L/min to the circuit, a total of at least 8 L/min of oxygen is being consumed. This should be kept in mind if the hospital's medical gas system fails and cylinder oxygen is required. Some anesthesia machines reduce oxygen consumption by incorporating a Venturi device that draws in room air to provide air/oxygen pneumatic power. Newer machines may offer the option of using compressed air for pneumatic power. A leak in the ventilator bellows can transmit high gas pressure to the patient's airway, potentially resulting in pulmonary barotrauma. **This may be indicated by a higher than expected rise in inspired oxygen concentration (if oxygen is the sole pressurizing gas).** Some machine ventilators have a built-in drive gas regulator that reduces the drive pressure (eg, to 25 psig) for added safety.

Double-circuit design ventilators also incorporate a free breathing valve that allows outside air to enter the rigid drive chamber and the bellows to collapse if the patient generates negative pressure by taking spontaneous breaths during mechanical ventilation.

B. Piston Ventilators

In a piston design, the ventilator substitutes an electrically driven piston for the bellows (Figure 4–24); the ventilator requires either minimal or no pneumatic (oxygen) power. The major advantage of **8** a piston ventilator is its ability to deliver accurate tidal volumes to patients with very poor lung compliance and to very small patients. During volume-controlled ventilation the piston moves at a constant velocity whereas during pressure-controlled ventilation the piston moves with

decreasing velocity. As with the bellows, the piston fills with gas from the breathing circuit. To prevent generation of significant negative pressure during the downstroke of the piston the circle system configuration has to be modified (Figure 4–27). The ventilator must also incorporate a negative-pressure relief valve or be capable of terminating the piston's downstroke if negative pressure is detected. Introduction of a negative-pressure relief valve to the breathing circuit may introduce the risk of air entrainment and the potential for dilution of oxygen and volatile anesthetic concentrations if the patient breathes during mechanical ventilation and low fresh gas flows.

C. Spill Valve

Whenever a ventilator is used on an anesthesia machine, the circle system's APL valve must be functionally removed or isolated from the circuit. A bag/ventilator switch typically accomplishes this. When the switch is turned to "bag" the ventilator is excluded and spontaneous/manual (bag) ventilation is possible. When it is turned to "ventilator," the breathing bag and the APL are excluded from the breathing circuit. The APL valve may be automatically excluded in some newer anesthesia machines when the ventilator is turned on. The ventilator contains its own pressure-relief (pop-off) valve, called the spill valve, which is pneumatically closed during inspiration so that positive pressure can be generated (Figure 4–26). During exhalation, the pressurizing gas is vented out and the ventilator spill valve is no longer closed. The ventilator bellows or piston refill during expiration; when the bellows is completely filled, the increase in circle system pressure causes the excess gas to be directed to the scavenging system through the spill valve. Sticking of this valve can result in abnormally elevated airway pressure during exhalation.

Pressure & Volume Monitoring

Peak inspiratory pressure is the highest circuit pressure generated during an inspiratory cycle, and provides an indication of dynamic compliance. Plateau pressure is the pressure measured during an inspiratory pause (a time of no gas flow), and mirrors static compliance. During

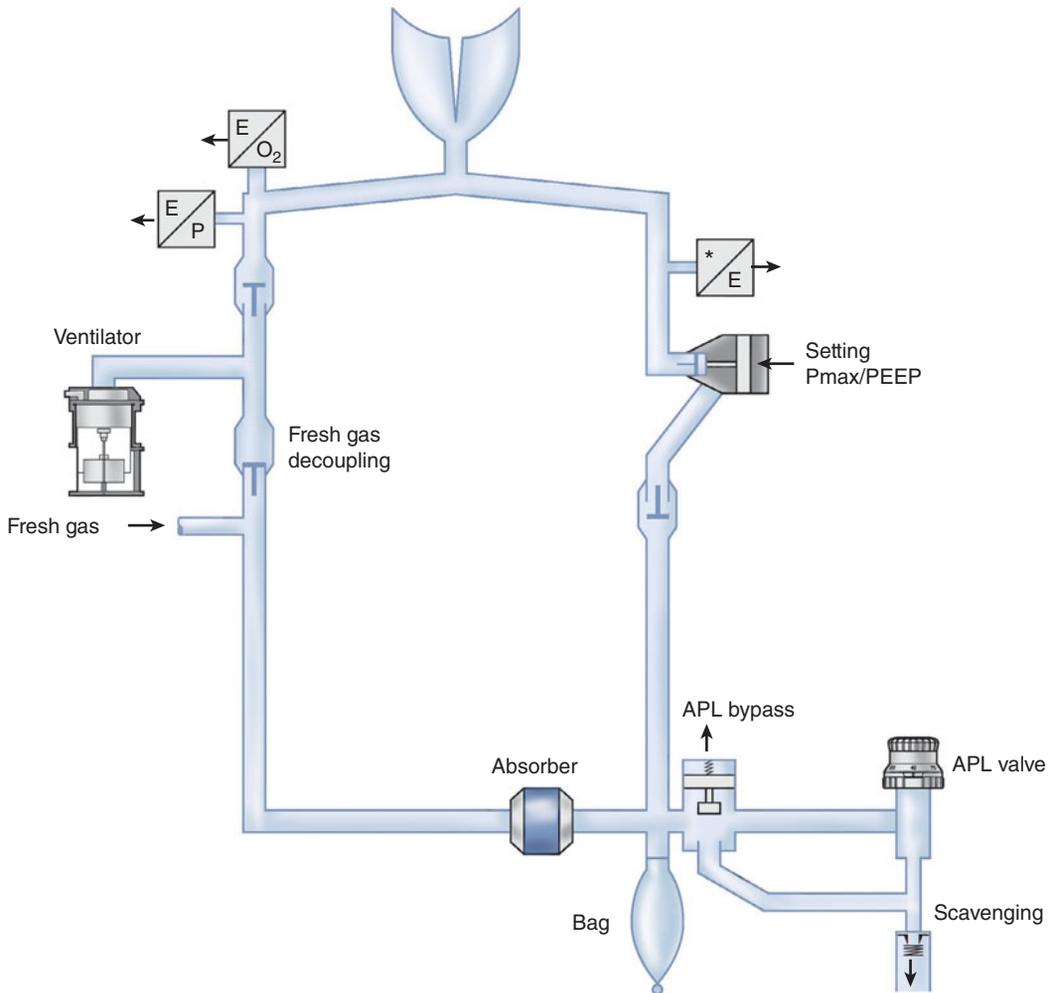

FIGURE 4-27 Modified circle system for a piston ventilator (Dräger Fabius GS).

normal ventilation of a patient without lung disease, peak inspiratory pressure is equal to or only slightly greater than plateau pressure. An increase in both peak inspiratory pressure and plateau pressure implies an increase in tidal volume or a decrease in pulmonary compliance. An increase in peak inspiratory pressure without any change in plateau pressure signals an increase in airway resistance or inspiratory gas flow rate (Table 4-3). Thus, the shape of the breathing-circuit pressure waveform can provide important airway information. Many anesthesia

machines graphically display breathing-circuit pressure (Figure 4-28). Airway secretions or kinking of the tracheal tube can be easily ruled out with the use of a suction catheter. Flexible fiberoptic bronchoscopy will usually provide a definitive diagnosis.

Ventilator Alarms

Alarms are an integral part of all modern anesthesia ventilators. Whenever a ventilator is used **9** “disconnect alarms” must be passively activated. Anesthesia workstations should have at least

TABLE 4-3 Causes of increased peak inspiratory pressure (PIP), with or without an increased plateau pressure (PP).

Increased PIP and PP
Increased tidal volume
Decreased pulmonary compliance
Pulmonary edema
Trendelenburg position
Pleural effusion
Ascites
Abdominal packing
Peritoneal gas insufflation
Tension pneumothorax
Endobronchial intubation
Increased PIP and Unchanged PP
Increased inspiratory gas flow rate
Increased airway resistance
Kinked endotracheal tube
Bronchospasm
Secretions
Foreign body aspiration
Airway compression
Endotracheal tube cuff herniation

three disconnect alarms: low peak inspiratory pressure, low exhaled tidal volume, and low exhaled carbon dioxide. The first is always built into the ventilator whereas the latter two may be in separate modules. A small leak or partial breathing-circuit disconnection may be detected by subtle decreases in peak inspiratory pressure, exhaled volume, or end-tidal carbon dioxide before alarm thresholds are reached. Other built-in ventilator alarms include high peak inspiratory pressure, high PEEP, sustained high airway pressure, negative pressure, and low oxygen-supply pressure. Most modern anesthesia ventilators also have integrated spirometers and oxygen analyzers that provide additional alarms.

Problems Associated with Anesthesia Ventilators

A. Ventilator–Fresh Gas Flow Coupling

10 From the previous discussion, it is important to appreciate that because the ventilator's spill valve is closed during inspiration, fresh gas flow from the machine's common gas outlet normally contributes to the tidal volume delivered to the patient. For example, if the fresh gas flow is 6 L/min, the I:E ratio

is 1:2, and the respiratory rate is 10 breaths/min, each tidal volume will include an extra 200 mL in addition to the ventilator's output:

$$\frac{(6000 \text{ mL/min}) (33\%)}{10 \text{ breaths/min}} \approx 200 \text{ mL/breath}$$

Thus, increasing fresh gas flow increases tidal volume, minute ventilation, and peak inspiratory pressure. To avoid problems with ventilator–fresh gas flow coupling, airway pressure and exhaled tidal volume must be monitored closely and excessive fresh gas flows must be avoided.

B. Excessive Positive Pressure

Intermittent or sustained high inspiratory pressures (>30 mm Hg) during positive-pressure ventilation increase the risk of pulmonary barotrauma (eg, pneumothorax) or hemodynamic compromise, or both, during anesthesia. Excessively high pressures may arise from incorrect settings on the ventilator, ventilator malfunction, fresh gas flow coupling (above), or activation of the oxygen flush during the **11** inspiratory phase of the ventilator. Use of the oxygen flush valve during the inspiratory cycle of a ventilator *must be avoided* because the ventilator spill valve will be closed and the APL valve is excluded; the surge of oxygen (600–1200 mL/s) and circuit pressure will be transferred to the patient's lungs.

In addition to a high-pressure alarm, all ventilators have a built-in automatic or APL valve. The mechanism of pressure limiting may be as simple as a threshold valve that opens at a certain pressure or electronic sensing that abruptly terminates the ventilator inspiratory phase.

C. Tidal Volume Discrepancies

12 Large discrepancies between the set and actual tidal volume that the patient receives are often observed in the operating room during volume control ventilation. Causes include breathing-circuit compliance, gas compression, ventilator–fresh gas flow coupling (above), and leaks in the anesthesia machine, the breathing circuit, or the patient's airway.

The compliance for standard adult breathing circuits is about 5 mL/cm H₂O. Thus, if peak

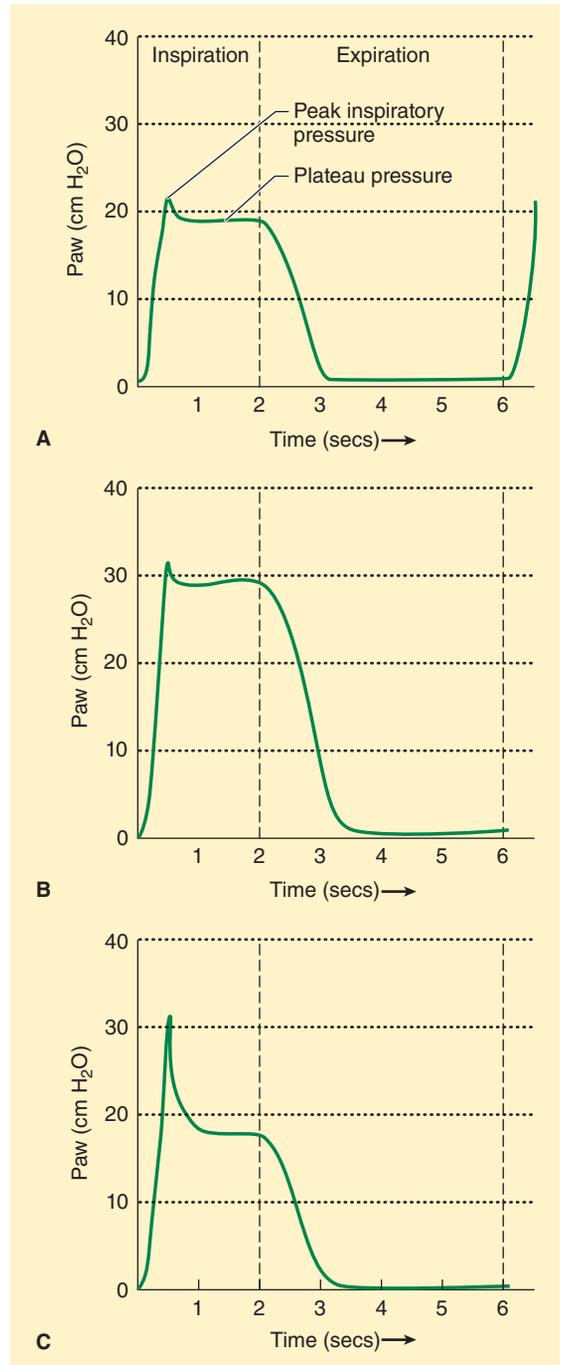

FIGURE 4-28 Airway pressures (Paw) can be diagrammatically presented as a function of time. **A:** In normal persons, the peak inspiratory pressure is equal to or slightly greater than the plateau pressure. **B:** An increase in peak inspiratory pressure and plateau pressure (the difference between the two remains almost constant) can be due to an increase in tidal volume or a decrease in pulmonary compliance. **C:** An increase in peak inspiratory pressure with little change in plateau pressure signals an increase in inspiratory flow rate or an increase in airway resistance.

inspiratory pressure is 20 cm H₂O, about 100 mL of set tidal volume is lost to expanding the circuit. For this reason breathing circuits for pediatric patients are designed to be much stiffer, with compliances as small as 1.5–2.5 mL/cm H₂O.

Compression losses, normally about 3%, are due to gas compression within the ventilator bellows and may be dependent on breathing-circuit volume. Thus if tidal volume is 500 mL another 15 mL of the set tidal gas may be lost. Gas sampling for capnography and anesthetic gas measurements represent additional losses in the form of gas leaks unless the sampled gas is returned to the breathing circuit, as occurs in some machines.

Accurate detection of tidal volume discrepancies is dependent on where the spirometer is placed. Sophisticated ventilators measure both inspiratory and expiratory tidal volumes. It is important to note that unless the spirometer is placed at the Y-connector in the breathing circuit, compliance and compression losses will not be apparent.

Several mechanisms have been built into newer anesthesia machines to reduce tidal volume discrepancies. During the initial electronic self-checkout, some machines measure total system compliance and subsequently use this measurement to adjust the excursion of the ventilator bellows or piston; leaks may also be measured but are usually not compensated. The actual method of tidal volume compensation or modulation varies according to manufacturer and model. In one design a flow sensor measures the tidal volume delivered at the inspiratory valve for the first few breaths and adjusts subsequent metered drive gas flow volumes to compensate for tidal volume losses (feedback adjustment). Another design continually measures fresh gas and vaporizer flow and subtracts this amount from the metered drive gas flow (preemptive adjustment). Alternately, machines that use electronic control of gas flow can decouple fresh gas flow from the tidal volume by delivery of fresh gas flow only during exhalation. Lastly, the inspiratory phase of the ventilator–fresh gas flow may be diverted through a decoupling valve into the breathing bag, which is excluded from the circle system during ventilation. During exhalation the decoupling valve opens, allowing the fresh gas that was temporarily stored in the bag to enter the breathing circuit.

WASTE-GAS SCAVENGERS

13 Waste-gas scavengers dispose of gases that have been vented from the breathing circuit by the APL valve and ventilator spill valve. Pollution of the operating room environment with anesthetic gases may pose a health hazard to surgical personnel. Although it is difficult to define safe levels of exposure, the National Institute for Occupational Safety and Health (NIOSH) recommends limiting the room concentration of nitrous oxide to 25 ppm and halogenated agents to 2 ppm (0.5 ppm if nitrous oxide is also being used) in time-integrated samples. Reduction to these trace levels is possible only with properly functioning waste-gas scavenging systems.

To avoid the buildup of pressure, excess gas volume is vented through the APL valve in the breathing circuit and the ventilator spill valve. Both valves should be connected to hoses (transfer tubing) leading to the scavenging interface, which may be inside the machine or an external attachment (**Figure 4–29**). The pressure immediately downstream to the interface should be kept between 0.5 and +3.5 cm H₂O during normal operating conditions. The scavenging interface may be described as either open or closed.

An open interface is open to the outside atmosphere and usually requires no pressure relief valves. In contrast, a closed interface is closed to the outside atmosphere and requires negative- and positive-pressure relief valves that protect the patient from the negative pressure of the vacuum system and positive pressure from an obstruction in the disposal tubing, respectively. The outlet of the scavenging system may be a direct line to the outside via a ventilation duct beyond any point of recirculation (passive scavenging) or a connection to the hospital's vacuum system (active scavenging). A chamber or reservoir bag accepts waste-gas overflow when the capacity of the vacuum is exceeded. The vacuum control valve on an active system should be adjusted to allow the evacuation of 10–15 L of waste gas per minute. This rate is adequate for periods of high fresh gas flow (ie, induction and emergence) yet minimizes the risk of transmitting negative pressure to the breathing circuit during lower flow conditions

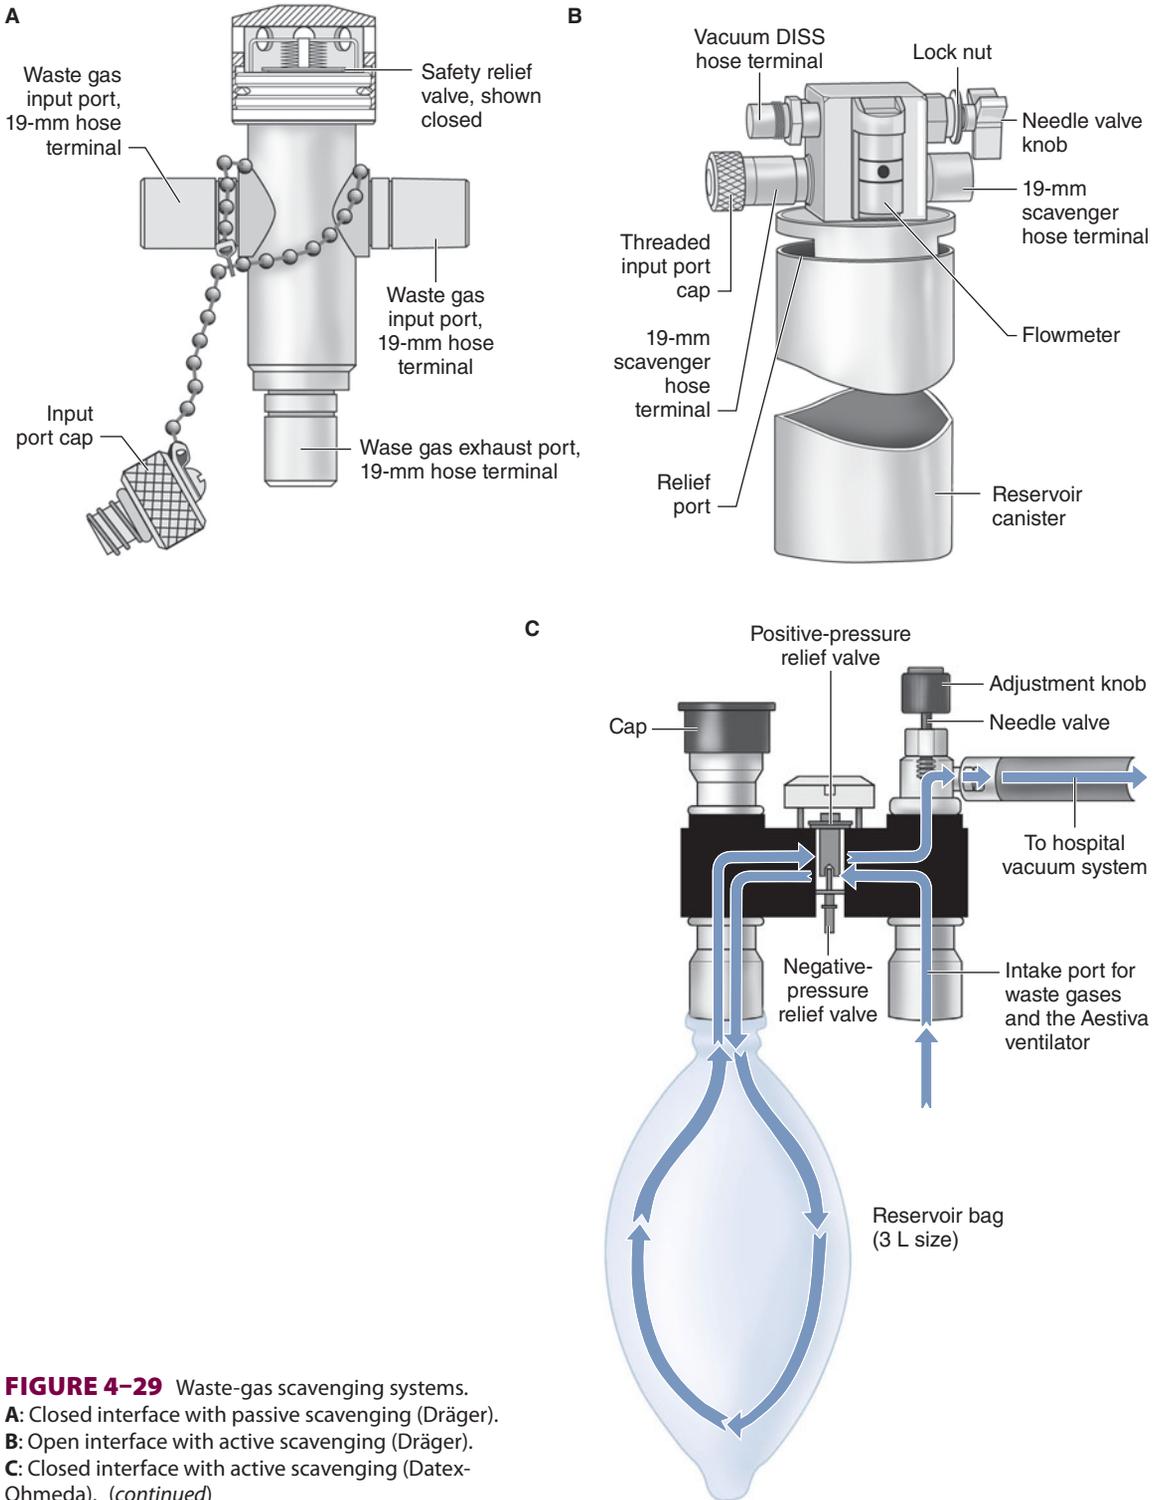

FIGURE 4-29 Waste-gas scavenging systems.
A: Closed interface with passive scavenging (Dräger).
B: Open interface with active scavenging (Dräger).
C: Closed interface with active scavenging (Datex-Ohmeda). (continued)

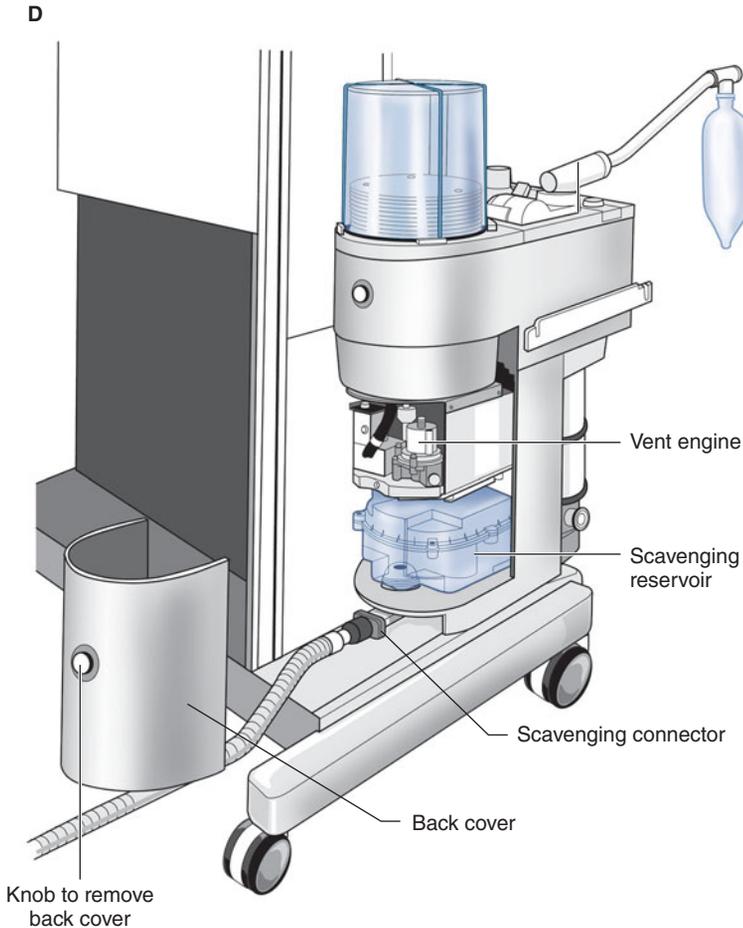

FIGURE 4-29 (continued) **D:** Built-in scavenging system that can be either active or passive; the active scavenging option has an open interface whereas the passive scavenging option has a closed interface with positive- and negative-pressure relief valves (Datex-Ohmeda).

(maintenance). Unless used correctly the risk of occupational exposure for health care providers is higher with an open interface. Some machines may come with both active and passive scavenger systems.

ANESTHESIA MACHINE CHECKOUT LIST

Misuse or malfunction of anesthesia gas delivery equipment can cause major morbidity or mortality.

14 A routine inspection of anesthesia equipment before each use increases operator familiarity and confirms proper functioning. The U.S. Food and Drug Administration (FDA) has made available a generic checkout procedure for anesthesia gas

machines and breathing systems (**Table 4-4**). This procedure should be modified as necessary, depending on the specific equipment being used and the manufacturer's recommendations. Note that although the entire checkout does not need to be repeated between cases on the same day, the conscientious use of a checkout list is mandatory before each anesthetic procedure. A mandatory check-off procedure increases the likelihood of detecting anesthesia machine faults. Some anesthesia machines provide an automated system check that requires a variable amount of human intervention. These system checks may include nitrous oxide delivery (hypoxic mixture prevention), agent delivery, mechanical and manual ventilation, pipeline pressures, scavenging, breathing circuit compliance, and gas leakage.

TABLE 4-4 Anesthesia apparatus checkout recommendations.^{1,2}

This checkout, or a reasonable equivalent, should be conducted before administration of anesthesia. These recommendations are valid only for an anesthesia system that conforms to current and relevant standards and includes an ascending bellows ventilator and at least the following monitors: capnograph, pulse oximeter, oxygen analyzer, respiratory volume monitor (spirometer), and breathing-system pressure monitor with high- and low-pressure alarms. Users are encouraged to modify this guideline to accommodate differences in equipment design and variations in local clinical practice. Such local modifications should have appropriate peer review. Users should refer to the appropriate operator manuals for specific procedures and precautions.

Emergency Ventilation Equipment

- *1. Verify backup ventilation equipment is available and functioning

High-Pressure System

- *2. Check O₂ cylinder supply
 - a. Open O₂ cylinder and verify at least half full (about 1000 psig).
 - b. Close cylinder
- *3. Check central pipeline supplies; check that hoses are connected and pipeline gauges read about 50 psig.

Low-Pressure System

- *4. Check initial status of low-pressure system
 - a. Close flow control valves and turn vaporizers off.
 - b. Check fill level and tighten vaporizers' filler caps.
- *5. Perform leak check of machine low-pressure system
 - a. Verify that the machine master switch and flow control valves are off.
 - b. Attach suction bulb to common (fresh) gas outlet.
 - c. Squeeze bulb repeatedly until fully collapsed.
 - d. Verify bulb stays *fully* collapsed for at least 10 seconds.
 - e. Open one vaporizer at a time and repeat steps c and d.
 - f. Remove suction bulb, and reconnect fresh gas hose.
- *6. Turn on machine master switch and all other necessary electrical equipment.
- *7. Test flowmeters
 - a. Adjust flow of all gases through their full range, checking for smooth operation of floats and undamaged flowtubes.
 - b. Attempt to create a hypoxic O₂/N₂O mixture and verify correct changes in flow and/or alarm.

Scavenging System

- *8. Adjust and check scavenging system
 - a. Ensure proper connections between the scavenging system and both APL (pop-off) valve and ventilator relief valve.
 - b. Adjust waste-gas vacuum (if possible).
 - c. Fully open APL valve and occlude Y-piece.
 - d. With minimum O₂ flow, allow scavenger reservoir bag to collapse completely and verify that absorber pressure gauge reads about zero.
 - e. With the O₂ flush activated, allow scavenger reservoir bag to distend fully, and then verify that absorber pressure gauge reads <10 cm H₂O.

Breathing System

- *9. Calibrate O₂ monitor
 - a. Ensure monitor reads 21% in room air.
 - b. Verify low-O₂ alarm is enabled and functioning.
 - c. Reinstall sensor in circuit and flush breathing system with O₂.
 - d. Verify that monitor now reads greater than 90%.
- 10. Check initial status breathing system
 - a. Set selector switch to Bag mode.
 - b. Check that breathing circuit is complete, undamaged, and unobstructed.
 - c. Verify that CO₂ absorbent is adequate.
 - d. Install breathing-circuit accessory equipment (eg, humidifier, PEEP valve) to be used during the case.
- 11. Perform leak check of the breathing system
 - a. Set all gas flows to zero (or minimum).
 - b. Close APL (pop-off) valve and occlude Y-piece.
 - c. Pressurize breathing system to about 30 cm H₂O with O₂ flush.
 - d. Ensure that pressure remains fixed for at least 10 seconds.
 - e. Open APL (pop-off) valve and ensure that pressure decreases.

Manual and Automatic Ventilation Systems

- 12. Test ventilation systems and unidirectional valves
 - a. Place a second breathing bag on Y-piece.
 - b. Set appropriate ventilator parameters for next patient.
 - c. Switch to automatic-ventilation (ventilator) mode.
 - d. Turn ventilator on and fill bellows and breathing bag with O₂ flush.
 - e. Set O₂ flow to minimum, other gas flows to zero.
 - f. Verify that during inspiration bellows deliver appropriate tidal volume and that during expiration bellows fill completely.
 - g. Set fresh gas flow to about 5 L min⁻¹.
 - h. Verify that the ventilator bellows and simulated lungs fill and empty appropriately without sustained pressure at end expiration.
 - i. Check for proper action of unidirectional valves.
 - j. Exercise breathing circuit accessories to ensure proper function.
 - k. Turn ventilator off and switch to manual ventilation (Bag/APL) mode.
 - l. Ventilate manually and ensure inflation and deflation of artificial lungs and appropriate feel of system resistance and compliance.
 - m. Remove second breathing bag from Y-piece.

(continued)

TABLE 4-4 Anesthesia apparatus checkout recommendations.^{1,2} (continued)

<i>Monitors</i>	<i>Final Position</i>
13. Check, calibrate, and/or set alarm limits of all monitors: capnograph, pulse oximeter, O ₂ analyzer, respiratory-volume monitor (spirometer), pressure monitor with high and low airway-pressure alarms.	14. Check final status of machine <ol style="list-style-type: none"> a. Vaporizers off b. APL valve open c. Selector switch to Bag mode d. All flowmeters to zero (or minimum) e. Patient suction level adequate f. Breathing system ready to use

¹Data from <http://www.fda.gov/cdrh/humfac/anesckot.html>.

²APL, adjust pressure-limiting; PEEP, positive end-expiratory pressure.

*If an anesthesia provider uses the same machine in successive cases, these steps need not be repeated, or they can be abbreviated after the initial checkout.

CASE DISCUSSION

Detection of a Leak

After induction of general anesthesia and intubation of a 70-kg man for elective surgery, a standing bellows ventilator is set to deliver a tidal volume of 500 mL at a rate of 10 breaths/min. Within a few minutes, the anesthesiologist notices that the bellows fails to rise to the top of its clear plastic enclosure during expiration. Shortly thereafter, the disconnect alarm is triggered.

Why has the ventilator bellows fallen and the disconnect alarm sounded?

Fresh gas flow into the breathing circuit is inadequate to maintain the circuit volume required for positive-pressure ventilation. In a situation in which there is no fresh gas flow, the volume in the breathing circuit will slowly fall because of the constant uptake of oxygen by the patient (metabolic oxygen consumption) and absorption of expired CO₂. An absence of fresh gas flow could be due to exhaustion of the hospital's oxygen supply (remember the function of the fail-safe valve) or failure to turn on the anesthesia machine's flow control valves. These possibilities can be ruled out by examining the oxygen Bourdon pressure gauge and the flowmeters. A more likely explanation is a gas leak that exceeds the rate of fresh gas flow. Leaks are particularly important in closed-circuit anesthesia.

How can the size of the leak be estimated?

When the rate of fresh gas inflow equals the rate of gas outflow, the circuit's volume will be

maintained. Therefore, the size of the leak can be estimated by increasing fresh gas flows until there is no change in the height of the bellows from one expiration to the next. If the bellows collapse despite a high rate of fresh gas inflow, a complete circuit disconnection should be considered. The site of the disconnection must be determined immediately and repaired to prevent hypoxia and hypercapnia. A resuscitation bag can be used to ventilate the patient if there is a delay in correcting the situation.

Where are the most likely locations of a breathing-circuit disconnection or leak?

Frank disconnections occur most frequently between the right-angle connector and the tracheal tube, whereas leaks are most commonly traced to the base plate of the CO₂ absorber. In the intubated patient, leaks often occur in the trachea around an uncuffed tracheal tube or an inadequately filled cuff. There are numerous potential sites of disconnection or leak within the anesthesia machine and the breathing circuit, however. Every addition to the breathing circuit, such as a humidifier, increases the likelihood of a leak.

How can these leaks be detected?

Leaks usually occur before the fresh gas outlet (ie, within the anesthesia machine) or after the fresh gas inlet (ie, within the breathing circuit). Large leaks within the anesthesia machine are less common and can be ruled out by a simple test. Pinching the tubing that connects the machine's fresh gas outlet to the circuit's fresh gas inlet creates a back pressure that obstructs the forward

flow of fresh gas from the anesthesia machine. This is indicated by a drop in the height of the flowmeter floats. When the fresh gas tubing is released, the floats should briskly rebound and settle at their original height. If there is a substantial leak within the machine, obstructing the fresh gas tubing will not result in any back pressure, and the floats will not drop. A more sensitive test for detecting small leaks that occur before the fresh gas outlet involves attaching a suction bulb at the outlet as described in step 5 of Table 4–4. Correcting a leak within the machine usually requires removing it from service.

Leaks within a breathing circuit not connected to a patient are readily detected by closing the APL valve, occluding the Y-piece, and activating the oxygen flush until the circuit reaches a pressure of 20–30 cm H₂O. A gradual decline in circuit pressure indicates a leak within the breathing circuit (Table 4–4, step 11).

How are leaks in the breathing circuit located?

Any connection within the breathing circuit is a potential site of a gas leak. A quick survey of the circuit may reveal a loosely attached breathing tube or a cracked oxygen analyzer adaptor. Less obvious causes include detachment of the tubing used by the disconnect alarm to monitor circuit pressures, an open APL valve, or an improperly adjusted scavenging unit. Leaks can usually be identified audibly or by applying a soap solution to suspect connections and looking for bubble formation.

Leaks within the anesthesia machine and breathing circuit are usually detectable if the machine and circuit have undergone an established checkout procedure. For example, steps 5 and 11 of the FDA recommendations (Table 4–4) will reveal most significant leaks.

Cardiovascular Monitoring

KEY CONCEPTS

- 1 The central venous pressure catheter's tip should not be allowed to migrate into the heart chambers.
- 2 Although the pulmonary artery catheter can be used to guide goal-directed hemodynamic therapy to ensure organ perfusion in shock states, other less invasive methods to determine hemodynamic performance are available, including transpulmonary thermodilution cardiac output measurements and pulse contour analyses of the arterial pressure waveform.
- 3 Relative contraindications to pulmonary artery catheterization include left bundle-branch block (because of the concern about complete heart block) and conditions associated with greatly increased risk of arrhythmias, such as Wolff–Parkinson–White syndrome.
- 4 Pulmonary artery pressure should be continuously monitored to detect an overwedged position indicative of catheter migration.
- 5 Accurate measurements of cardiac output depend on rapid and smooth injection, precisely known injectant temperature and volume, correct entry of the calibration factors for the specific type of pulmonary artery catheter into the cardiac output computer, and avoidance of measurements during electrocautery.

Vigilant perioperative monitoring of the cardiovascular system is one of the primary duties of anesthesia providers. This chapter focuses on the specific monitoring devices and techniques used by anesthesiologists to monitor cardiac function and circulation in healthy and nonhealthy patients alike.

ARTERIAL BLOOD PRESSURE

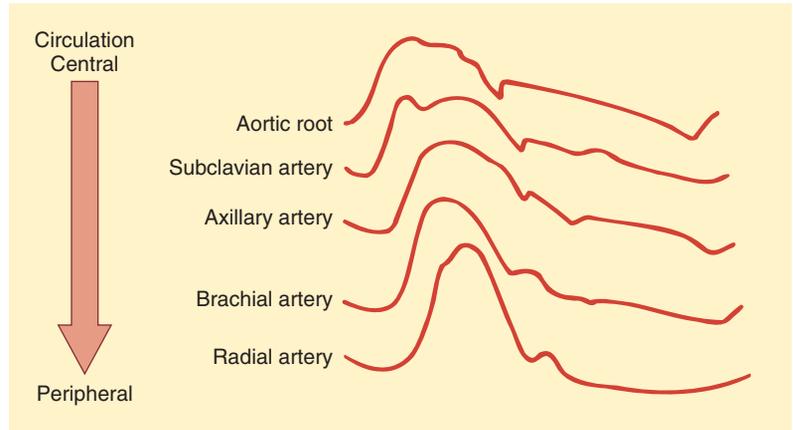

The rhythmic contraction of the left ventricle, ejecting blood into the vascular system, results in pulsatile arterial pressures. The peak pressure generated during systolic contraction (in the absence of aortic valve stenosis) approximates the systolic arterial

blood pressure (SBP); the lowest arterial pressure during diastolic relaxation is the diastolic blood pressure (DBP). Pulse pressure is the difference between the systolic and diastolic pressures. The time-weighted average of arterial pressures during a pulse cycle is the **mean arterial pressure (MAP)**. MAP can be estimated by application of the following formula:

$$\text{MAP} = \frac{(\text{SBP}) + 2(\text{DBP})}{3}$$

Arterial blood pressure is greatly affected by where the pressure is measured. **As a pulse moves peripherally through the arterial tree, wave reflection distorts the pressure waveform, leading to**

FIGURE 5-1 Changes in configuration as a waveform moves peripherally. (Reproduced, with permission, from Shah N, Bedford RF: Invasive and noninvasive blood pressuring monitoring. In: *Clinical Monitoring: Practical Applications in Anesthesia and Critical Care Medicine*. Lake CL, Hines RL, Blitt CD [editors]. WB Saunders, Philadelphia, 2001.)

an exaggeration of systolic and pulse pressures (Figure 5-1). For example, radial artery systolic pressure is usually greater than aortic systolic pressure because of its more distal location. In contrast, radial artery systolic pressures often underestimate more “central” pressures following hypothermic cardiopulmonary bypass because of changes in hand vascular resistance. Vasodilating drugs may accentuate this discrepancy. The level of the sampling site relative to the heart affects the measurement of blood pressure because of the effect of gravity (Figure 5-2). In patients with severe peripheral vascular disease, there may be a significant difference in blood pressure measurements among the extremities. The higher value should be used in these patients.

Because noninvasive (palpation, Doppler, auscultation, oscillometry, plethysmography) and invasive (arterial cannulation) methods of blood pressure determination differ greatly, they are discussed separately.

1. Noninvasive Arterial Blood Pressure Monitoring

Indications

The use of any anesthetic, no matter how “trivial,” is an indication for arterial blood pressure measurement. The techniques and frequency of pressure determination depend on the patient’s condition and the type of surgical procedure. An oscillometric

blood pressure measurement every 3–5 min is adequate in most cases.

Contraindications

Although some method of blood pressure measurement is mandatory, techniques that rely on a blood pressure cuff are best avoided in extremities with vascular abnormalities (eg, dialysis shunts) or with intravenous lines. Rarely, it may prove impossible to monitor blood pressure in cases (eg, burns) in which there may be no accessible site from which the blood pressure can be safely recorded.

Techniques & Complications

A. Palpation

SBP can be determined by (1) locating a palpable peripheral pulse, (2) inflating a blood pressure cuff proximal to the pulse until flow is occluded, (3) releasing cuff pressure by 2 or 3 mm Hg per heartbeat, and (4) measuring the cuff pressure at which pulsations are again palpable. This method tends to underestimate systolic pressure, however, because of the insensitivity of touch and the delay between flow under the cuff and distal pulsations. Palpation does not provide a diastolic pressure or MAP. The equipment required is simple and inexpensive.

B. Doppler Probe

When a Doppler probe is substituted for the anesthesiologist’s finger, arterial blood pressure

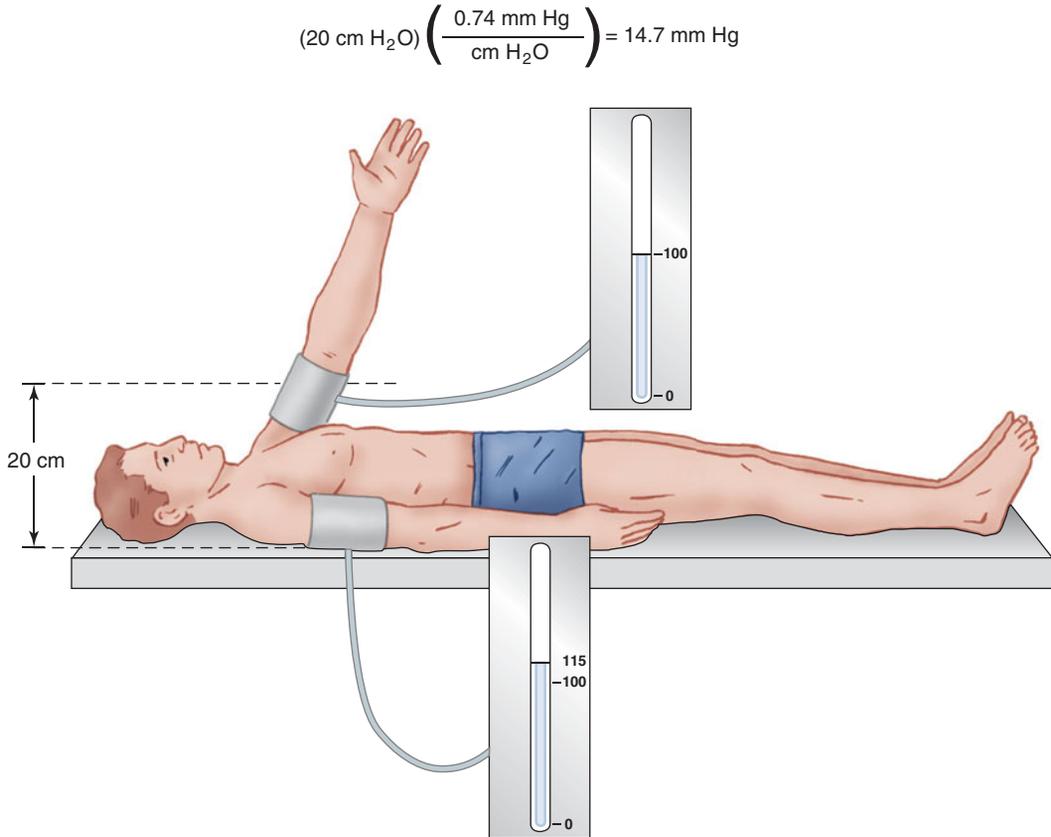

FIGURE 5-2 The difference in blood pressure (mm Hg) at two different sites of measurement equals the height of an interposed column of water (cm H₂O) multiplied by a conversion factor (1 cm H₂O = 0.74 mm Hg).

measurement becomes sensitive enough to be useful in obese patients, pediatric patients, and patients in shock (**Figure 5-3**). The **Doppler effect** is the shift in the frequency of sound waves when their source moves relative to the observer. For example, the pitch of a train's whistle increases as a train approaches and decreases as it departs. Similarly, the reflection of sound waves off of a moving object causes a frequency shift. A Doppler probe transmits an ultrasonic signal that is reflected by underlying tissue. As red blood cells move through an artery, a Doppler frequency shift will be detected by the probe. The difference between transmitted and received frequency causes the characteristic swishing sound, which indicates blood flow. Because air reflects ultrasound,

a coupling gel (but not corrosive electrode jelly) is applied between the probe and the skin. Positioning the probe directly above an artery is crucial, since the beam must pass through the vessel wall. Interference from probe movement or electrocautery is an annoying distraction. Note that only systolic pressures can be reliably determined with the Doppler technique.

A variation of Doppler technology uses a piezoelectric crystal to detect lateral arterial wall movement to the intermittent opening and closing of vessels between systolic and diastolic pressure. This instrument thus detects both systolic and diastolic pressures. The Doppler effect is routinely employed by perioperative echocardiographers to discern both the directionality and velocity of both blood flow

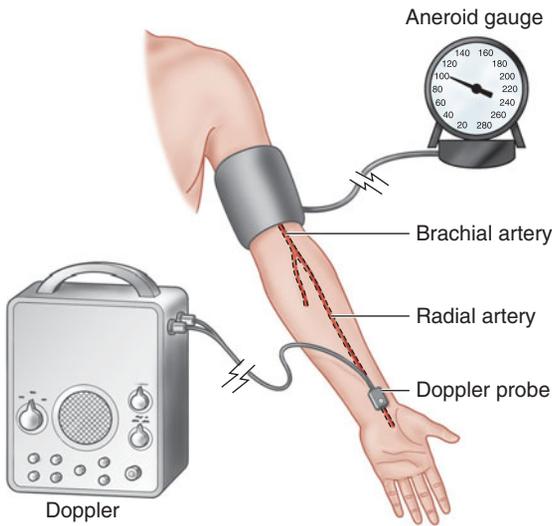

FIGURE 5-3 A Doppler probe secured over the radial artery will sense red blood cell movement as long as the blood pressure cuff is below systolic pressure. (Reproduced, with permission, from Parks Medical Electronics.)

within the heart and the movement of the heart's muscle tissue (tissue Doppler).

C. Auscultation

Inflation of a blood pressure cuff to a pressure between systolic and diastolic pressures will partially collapse an underlying artery, producing turbulent flow and the characteristic Korotkoff sounds. These sounds are audible through a stethoscope placed under—or just distal to—the distal third of the blood pressure cuff. The clinician measures pressure with an aneroid or mercury manometer.

Occasionally, Korotkoff sounds cannot be heard through part of the range from systolic to diastolic pressure. This auscultatory gap is most common in hypertensive patients and can lead to an inaccurate diastolic pressure measurement. Korotkoff sounds are often difficult to auscultate during episodes of hypotension or marked peripheral vasoconstriction. In these situations, the subsonic frequencies associated with the sounds can be detected by a microphone and amplified to indicate systolic and diastolic pressures. Motion artifact and electrocautery interference limit the usefulness of this method.

D. Oscillometry

Arterial pulsations cause oscillations in cuff pressure. These oscillations are small if the cuff is inflated above systolic pressure. When the cuff pressure decreases to systolic pressure, the pulsations are transmitted to the entire cuff, and the oscillations markedly increase. Maximal oscillation occurs at the MAP, after which oscillations decrease. Because some oscillations are present above and below arterial blood pressure, a mercury or aneroid manometer provides an inaccurate and unreliable measurement. Automated blood pressure monitors electronically measure the pressures at which the oscillation amplitudes change (Figure 5-4). A microprocessor derives systolic, mean, and diastolic pressures using an algorithm. Machines that require identical consecutive pulse waves for measurement confirmation may be unreliable during arrhythmias (eg, atrial fibrillation). Oscillometric monitors should not be used on patients on cardiopulmonary bypass. Nonetheless, the speed, accuracy, and versatility of oscillometric devices have greatly improved, and they have become the preferred noninvasive blood pressure monitors in the United States and worldwide.

E. Arterial Tonometry

Arterial tonometry measures beat-to-beat arterial blood pressure by sensing the pressure required to partially flatten a superficial artery that is supported by a bony structure (eg, radial artery). A tonometer consisting of several independent pressure transducers is applied to the skin overlying the artery (Figure 5-5). The contact stress between the transducer directly over the artery and the skin reflects intraluminal pressure. Continuous pulse recordings produce a tracing very similar to an invasive arterial blood pressure waveform. Limitations to this technology include sensitivity to movement artifact and the need for frequent calibration.

Clinical Considerations

Adequate oxygen delivery to vital organs must be maintained during anesthesia. Unfortunately, instruments to monitor specific organ perfusion and oxygenation are complex, expensive, and often unreliable, and, for that reason, an adequate arterial

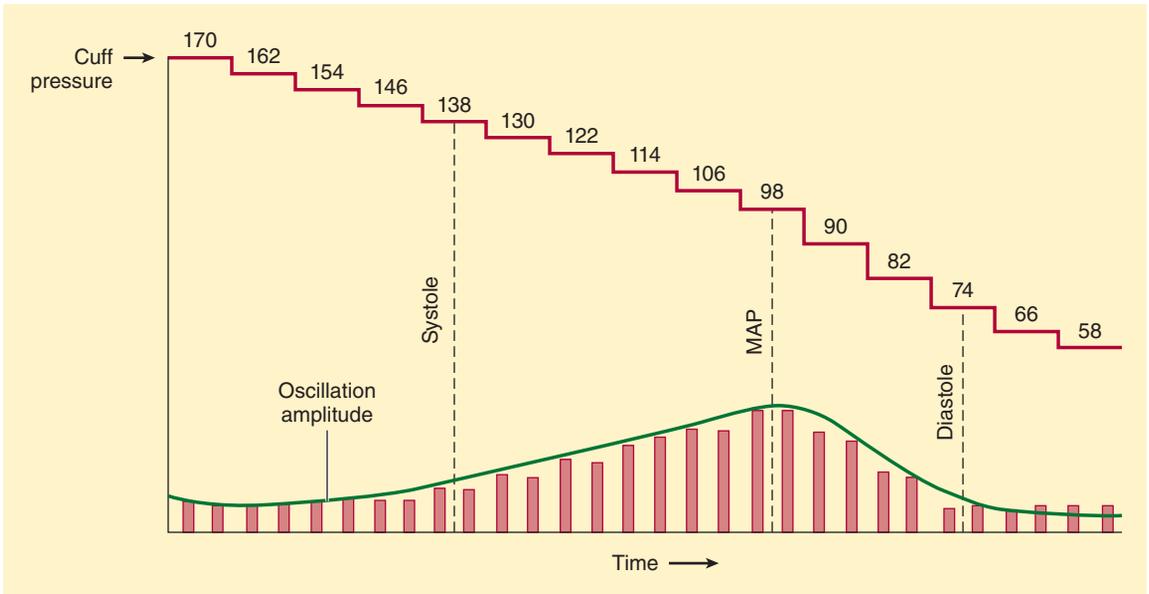

FIGURE 5-4 Oscillometric determination of blood pressure.

blood pressure is assumed to predict adequate organ blood flow. However, flow also depends on vascular resistance:

$$\text{Flow} = \frac{\text{Pressure}}{\text{Resistance}}$$

Even if the pressure is high, when the resistance is also high, flow can be low. Thus, arterial blood

pressure should be viewed as an indicator—but not a measure—of organ perfusion.

The accuracy of any method of blood pressure measurement that involves a blood pressure cuff depends on proper cuff size (Figure 5-6). The cuff's bladder should extend at least halfway around the extremity, and the width of the cuff should be 20% to 50% greater than the diameter of the extremity.

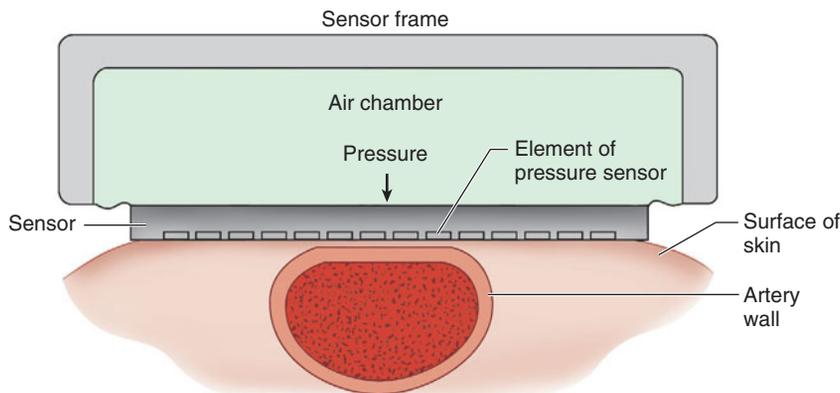

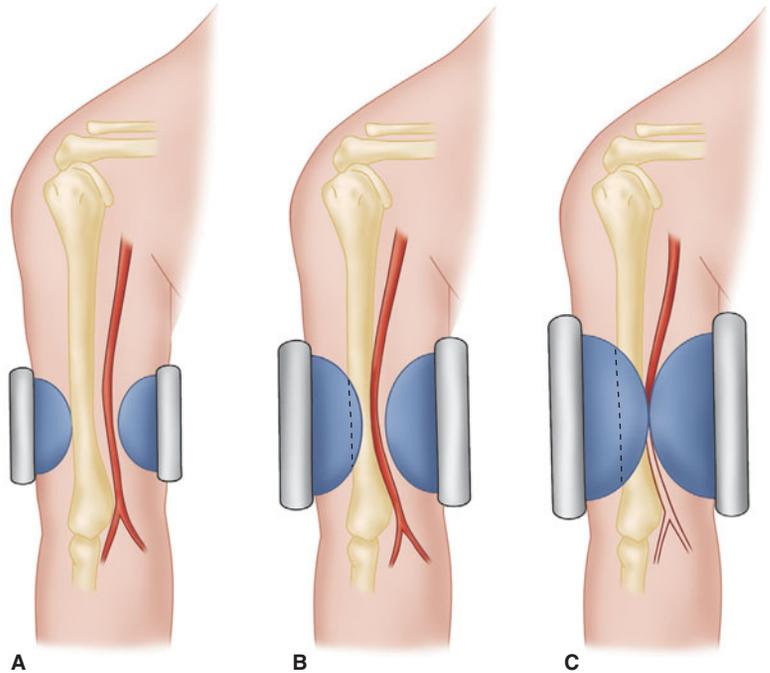

FIGURE 5-5 Tonometry is a method of continuous (beat-to-beat) arterial blood pressure determination. The sensors must be positioned directly over the artery.

FIGURE 5-6 Blood pressure cuff width influences the pressure readings. Three cuffs, all inflated to the same pressure, are shown. The narrowest cuff (A) will require more pressure, and the widest cuff (C) less pressure, to occlude the brachial artery for determination of systolic pressure. Too narrow a cuff may produce a large overestimation of systolic pressure. Whereas the wider cuff may underestimate the systolic pressure, the error with a cuff 20% too wide is not as significant as the error with a cuff 20% too narrow. (Reproduced, with permission, from Gravenstein JS, Paulus DA: *Clinical Monitoring Practice*, 2nd ed. Lippincott, Philadelphia, 1987.)

Automated blood pressure monitors, using one or a combination of the methods described above, are frequently used in anesthesiology. A self-contained air pump inflates the cuff at set intervals. Incorrect or too frequent use of these automated devices has resulted in nerve palsies and extensive extravasation of intravenously administered fluids. In case of equipment failure, an alternative method of blood pressure determination must be immediately available.

2. Invasive Arterial Blood Pressure Monitoring

Indications

Indications for invasive arterial blood pressure monitoring by catheterization of an artery include induced current or anticipated hypotension or wide blood pressure deviations, end-organ disease necessitating precise beat-to-beat blood pressure regulation, and the need for multiple arterial blood gas measurements.

Contraindications

If possible, catheterization should be avoided in smaller end arteries with inadequate collateral blood flow or in extremities where there is a suspicion of preexisting vascular insufficiency.

A. Selection of Artery for Cannulation

Several arteries are available for percutaneous catheterization.

1. The **radial artery** is commonly cannulated because of its superficial location and substantial collateral flow (in most patients the ulnar artery is larger than the radial and there are connections between the two via the palmar arches). Five percent of patients have incomplete palmar arches and lack adequate collateral blood flow. Allen's test is a simple, but not reliable, method for assessing the safety of radial artery cannulation. In this test, the patient exsanguinates his or her hand by making a fist. While the operator occludes

the radial and ulnar arteries with fingertip pressure, the patient relaxes the blanched hand. Collateral flow through the palmar arterial arch is confirmed by flushing of the thumb within 5 sec after pressure on the ulnar artery is released. Delayed return of normal color (5–10 s) indicates an equivocal test or insufficient collateral circulation (>10 s). The Allen's test is of such questionable utility that many practitioners routinely avoid it. Alternatively, blood flow distal to the radial artery occlusion can be detected by palpation, Doppler probe, plethysmography, or pulse oximetry. Unlike Allen's test, these methods of determining the adequacy of collateral circulation do not require patient cooperation.

2. **Ulnar artery** catheterization is usually more difficult than radial catheterization because of the ulnar artery's deeper and more tortuous course. Because of the risk of compromising blood flow to the hand, ulnar catheterization would not normally be considered if the ipsilateral radial artery has been punctured but unsuccessfully cannulated.
3. The **brachial artery** is large and easily identifiable in the antecubital fossa. Its proximity to the aorta provides less waveform distortion. However, being near the elbow predisposes brachial artery catheters to kinking.
4. The **femoral artery** is prone to atheroma formation and pseudoaneurysm, but often provides an excellent access. The femoral site has been associated with an increased incidence of infectious complications and arterial thrombosis. Aseptic necrosis of the head of the femur is a rare, but tragic, complication of femoral artery cannulation in children.
5. The **dorsalis pedis and posterior tibial arteries** are some distance from the aorta and therefore have the most distorted waveforms.
6. The **axillary artery** is surrounded by the axillary plexus, and nerve damage can result from a hematoma or traumatic cannulation. Air or thrombi can quickly gain access to the cerebral circulation during vigorous retrograde flushing of axillary artery catheters.

B. Technique of Radial Artery Cannulation

One technique of radial artery cannulation is illustrated in [Figure 5–7](#). Supination and extension of the wrist provide optimal exposure of the radial artery. The pressure–tubing–transducer system should be nearby and already flushed with saline to ensure easy and quick connection after cannulation. The radial pulse is palpated, and the artery's course is determined by lightly pressing the *tips* of the index and middle fingers of the anesthesiologist's nondominant hand over the area of maximal impulse or by use of ultrasound. Using aseptic technique, 1% lidocaine is infiltrated in the skin of awake patients, directly above the artery, with a small gauge needle. A larger gauge needle can then be used as a skin punch, facilitating entry of an 18-, 20-, or 22-gauge catheter over a needle through the skin at a 45° angle, directing it toward the point of palpation. Upon blood flashback, a guidewire may be advanced through the catheter into the artery and the catheter advanced over the guidewire. Alternatively, the needle is lowered to a 30° angle and advanced another 1–2 mm to make certain that the tip of the catheter is well into the vessel lumen. The catheter is advanced off the needle into the arterial lumen, after which the needle is withdrawn. Applying firm pressure over the artery proximal to the catheter tip, with the middle and ring fingertips, prevents blood from spurting from the catheter while the tubing is connected. Waterproof tape or suture can be used to hold the catheter in place.

C. Complications

Complications of intraarterial monitoring include hematoma, bleeding (particularly with catheter tubing disconnections), vasospasm, arterial thrombosis, embolization of air bubbles or thrombi, pseudoaneurysm formation, necrosis of skin overlying the catheter, nerve damage, infection, necrosis of extremities or digits, and unintentional intraarterial drug injection. Factors associated with an increased rate of complications include prolonged cannulation, hyperlipidemia, repeated insertion attempts, female gender, extracorporeal circulation, the use of larger catheters in smaller vessels, and the use of vasopressors. The risks are minimized when the ratio of catheter to artery size is small, saline is

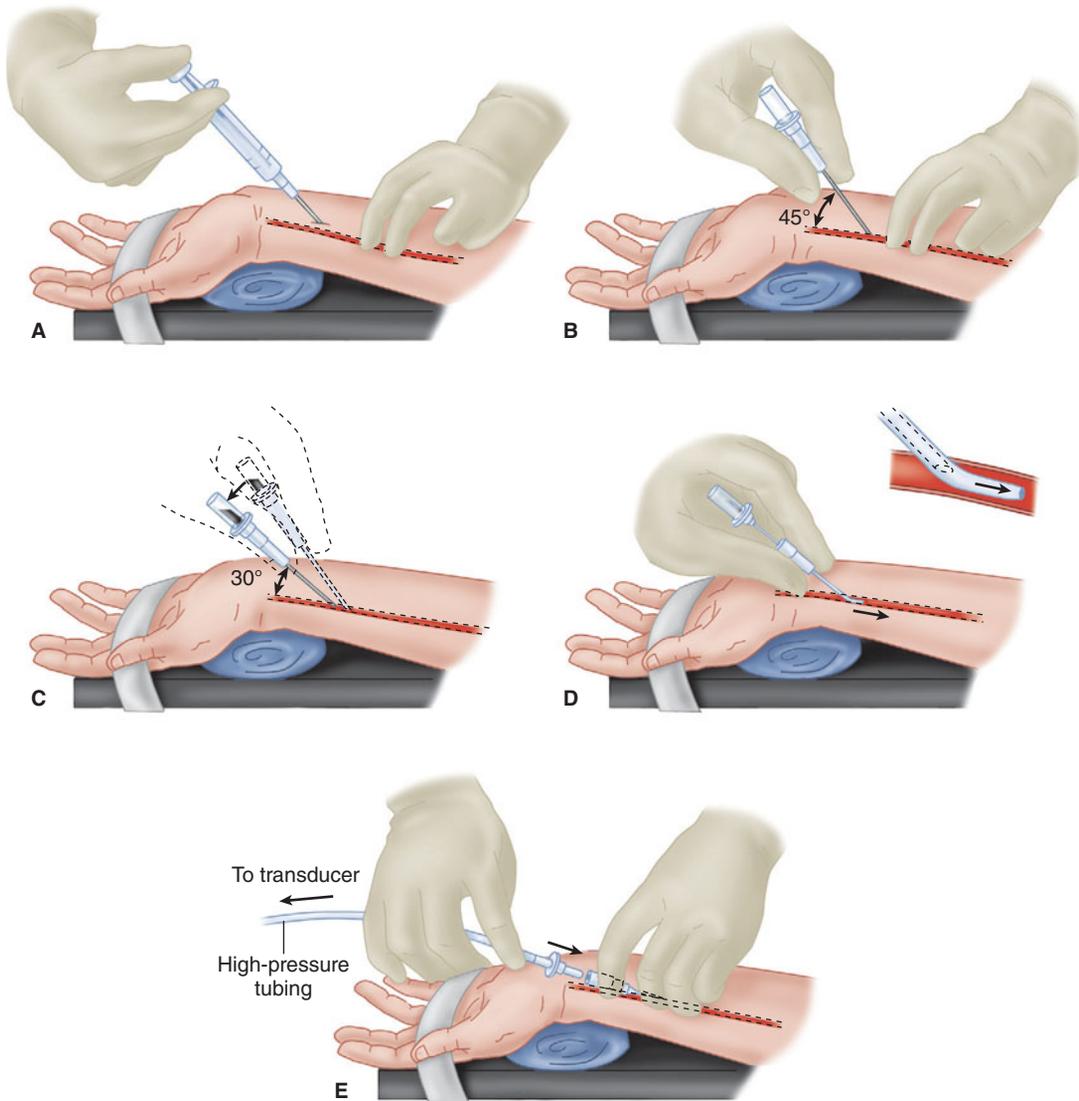

FIGURE 5-7 Cannulation of the radial artery. **A:** Proper positioning and palpation of the artery are crucial. After skin preparation, local anesthetic is infiltrated with a 25-gauge needle. **B:** A 20- or 22-gauge catheter is advanced through the skin at a 45° angle. **C:** Flashback of blood signals entry into the artery, and the catheter–

needle assembly is lowered to a 30° angle and advanced 1–2 mm to ensure an intraluminal catheter position. **D:** The catheter is advanced over the needle, which is withdrawn. **E:** Proximal pressure with middle and ring fingers prevents blood loss, while the arterial tubing Luer-lock connector is secured to the intraarterial catheter.

continuously infused through the catheter at a rate of 2–3 mL/hr, flushing of the catheter is limited, and meticulous attention is paid to aseptic technique. Adequacy of perfusion can be continually monitored during radial artery cannulation by placing a pulse oximeter on an ipsilateral finger.

Clinical Considerations

Because intraarterial cannulation allows continuous beat-to-beat blood pressure measurement, it is considered the optimal blood pressure monitoring technique. The quality of the transduced waveform, however, depends on the dynamic characteristics of

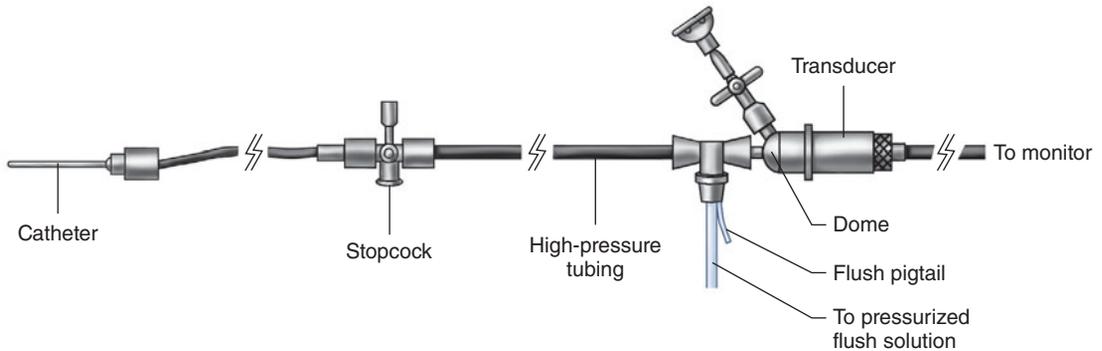

FIGURE 5-8 The catheter-tubing-transducer system.

the catheter-tubing-transducer system (Figure 5-8). False readings can lead to inappropriate therapeutic interventions.

A complex waveform, such as an arterial pulse wave, can be expressed as a summation of simple harmonic waves (according to the Fourier theorem). For accurate measurement of pressure, the catheter-tubing-transducer system must be capable of responding adequately to the highest frequency of the arterial waveform (Figure 5-9). Stated another way, the natural frequency of the measuring system must exceed the natural frequency of the arterial pulse (approximately 16–24 Hz).

Most transducers have frequencies of several hundred Hz (>200 Hz for disposable transducers).

The addition of tubing, stopcocks, and air in the line all decrease the frequency of the system. If the frequency response is too low, the system will be overdamped and will not faithfully reproduce the arterial waveform, underestimating the systolic pressure. Underdamping is also a serious problem, leading to overshoot and a falsely high SBP.

Catheter-tubing-transducer systems must also prevent **hyperresonance**, an artifact caused by reverberation of pressure waves within the system. A **damping coefficient** (β) of 0.6–0.7 is optimal. The natural frequency and damping coefficient can be determined by examining tracing oscillations after a high-pressure flush (Figure 5-10).

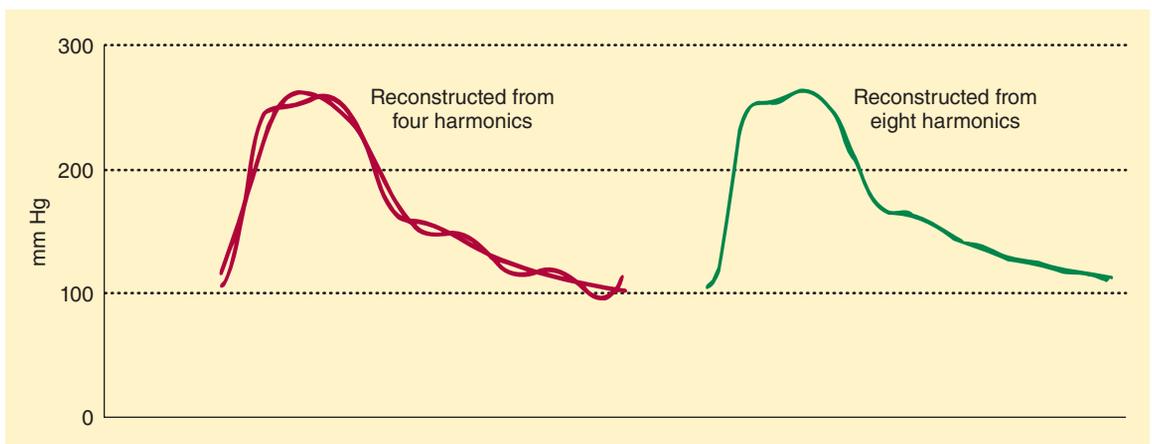

FIGURE 5-9 An original waveform overlays a four-harmonic reconstruction (left) and an eight-harmonic reconstruction (right). Note that the higher harmonic plot

more closely resembles the original waveform. (Reproduced, with permission, from Saidman LS, Smith WT: *Monitoring in Anesthesia*. Butterworth-Heinemann, 1985.)

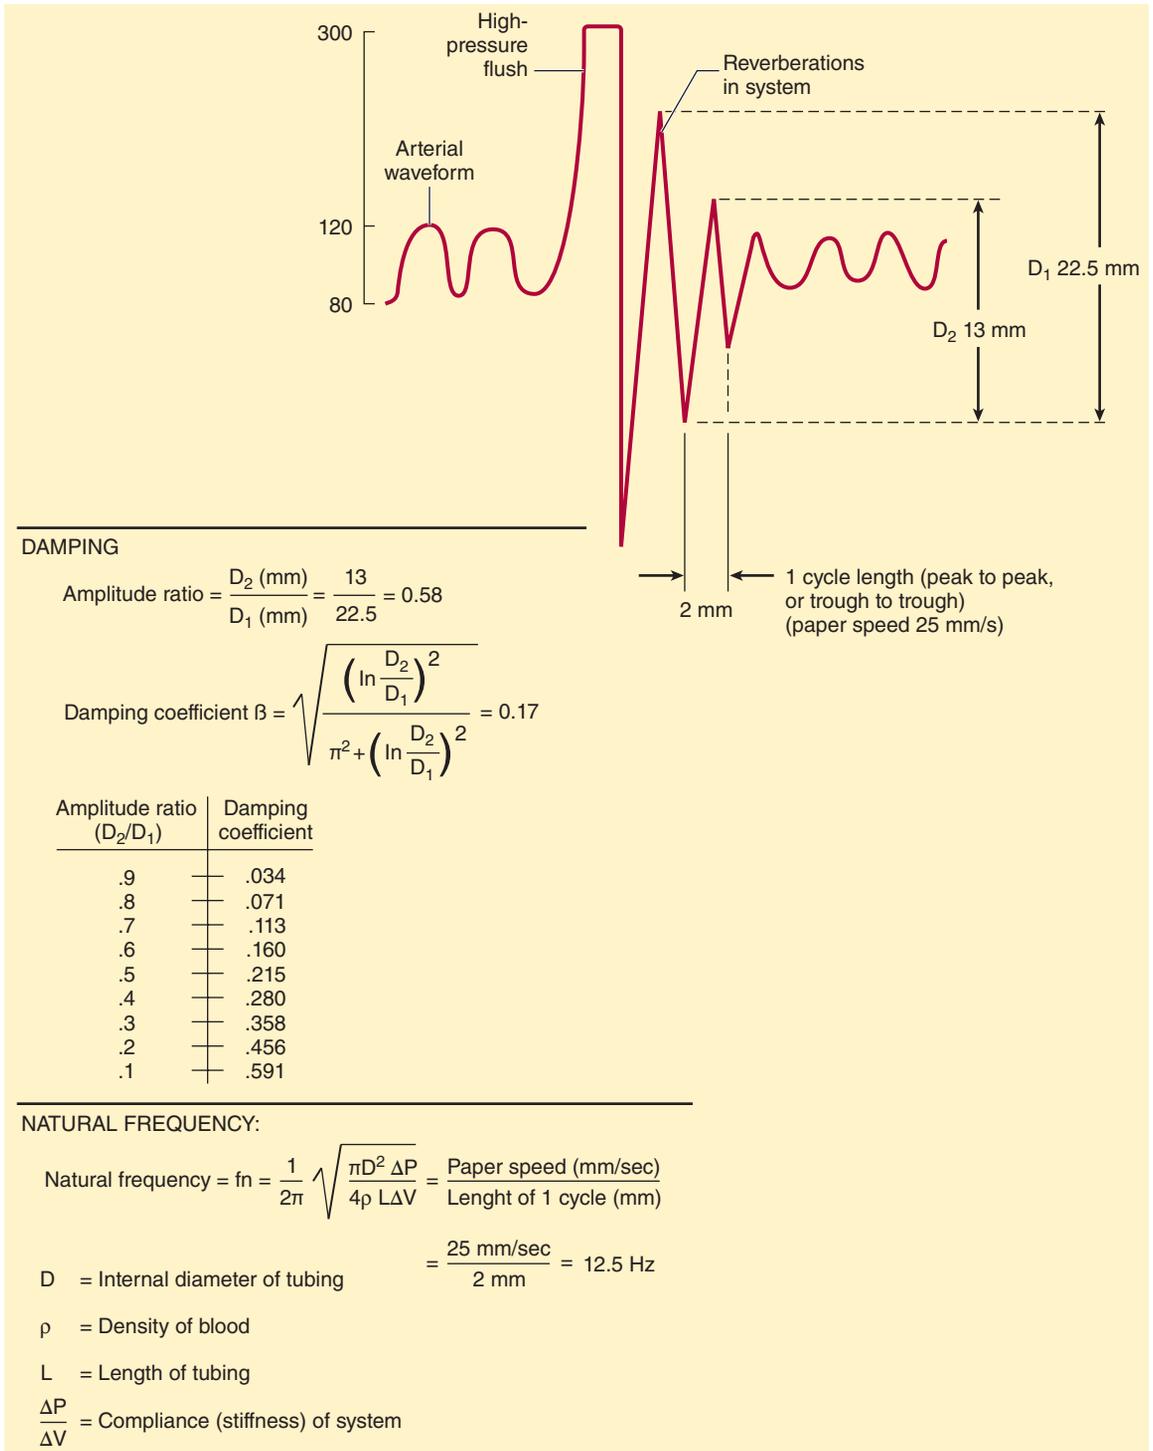

FIGURE 5-10 Damping and natural frequency of a transducer system can be determined by a high-pressure flush test.

System dynamics are improved by minimizing tubing length, eliminating unnecessary stopcocks, removing air bubbles, and using low-compliance tubing. Although smaller diameter catheters lower natural frequency, they improve underdamped systems and are less apt to result in vascular complications. If a large catheter totally occludes an artery, reflected waves can distort pressure measurements.

Pressure transducers have evolved from bulky, reusable instruments to miniaturized, disposable devices. Transducers contain a diaphragm that is distorted by an arterial pressure wave. The mechanical energy of a pressure wave is converted into an electric signal. Most transducers are resistance types that are based on the **strain gauge** principle: stretching a wire or silicone crystal changes its electrical resistance. The sensing elements are arranged as a “Wheatstone bridge” circuit so that the voltage output is proportionate to the pressure applied to the diaphragm (Figure 5-11).

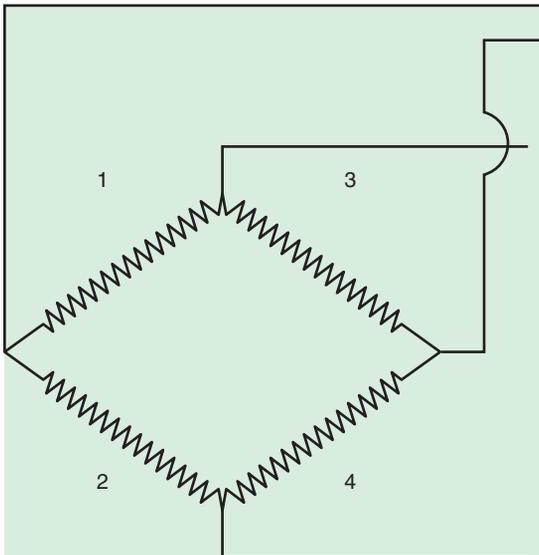

FIGURE 5-11 In the original strain gauge pressure transducers, a deformable diaphragm was connected to a Wheatstone bridge. When pressure was applied to the diaphragm, strain on two of the resistors (No. 2 and No. 3) increased, whereas strain on the other two (No. 1 and No. 4) decreased. The change in total resistance across the bridge was proportional to the change in blood pressure, allowing direct accurate measurement of intravascular blood pressure for the first time.

Transducer accuracy depends on correct calibration and zeroing procedures. A stopcock at the level of the desired point of measurement—usually the midaxillary line—is opened, and the zero trigger on the monitor is activated. If the patient’s position is altered by raising or lowering the operating table, the transducer must either be moved in tandem or zeroed to the new level of the midaxillary line. In a seated patient, the arterial pressure in the brain differs significantly from left ventricular pressure. In this circumstance, cerebral pressure is determined by setting the transducer to zero at the level of the ear, which approximates the circle of Willis. The transducer’s zero should be checked regularly, as some transducer measurements can “drift” over time.

External calibration of a transducer compares the transducer’s reading with a manometer, but modern transducers rarely require external calibration.

Digital readouts of systolic and diastolic pressures are a running average of the highest and lowest measurements within a certain time interval. Because motion or cautery artifacts can result in some very misleading numbers, the arterial waveform should always be monitored. The shape of the arterial wave provides clues to several hemodynamic variables. The rate of upstroke indicates contractility, the rate of downstroke indicates peripheral vascular resistance, and exaggerated variations in size during the respiratory cycle suggest hypovolemia. MAP is calculated by integrating the area under the pressure curve.

Intraarterial catheters also provide access for intermittent arterial blood gas sampling and analysis. The development of fiberoptic sensors that can be inserted through a 20-gauge arterial catheter enables continuous blood gas monitoring. Unfortunately, these sensors are quite expensive and are often inaccurate, so they are rarely used. Analysis of the arterial pressure waveform allows for estimation of cardiac output (CO) and other hemodynamic parameters. These devices are discussed in the section on CO monitoring.

ELECTROCARDIOGRAPHY

Indications & Contraindications

All patients should have intraoperative monitoring of their electrocardiogram (ECG). There are no contraindications.

Techniques & Complications

Lead selection determines the diagnostic sensitivity of the ECG. ECG leads are positioned on the chest and extremities to provide different perspectives of the electrical potentials generated by the heart. At the end of diastole, the atria contract, which provides the atrial contribution to CO, generating the “P” wave. Following atrial contraction, the ventricle is loaded awaiting systole. The QRS complex begins the electrical activity of systole following the 120–200 msec atrioventricular (AV) nodal delay. Depolarization of the ventricle proceeds from the AV node through the interventricular system via the His–Purkinje fibers. The normal QRS lasts approximately 120 msec, which can be prolonged in patients with cardiomyopathies and heart failure. The T wave represents repolarization as the heart prepares to contract again. Prolongation of the QT interval secondary to electrolyte imbalances or drug effects can potentially lead to life-threatening arrhythmias (les torsade de pointes).

The electrical axis of lead II is approximately 60° from the right arm to the left leg, which is parallel to the electrical axis of the atria, resulting in the largest P-wave voltages of any surface lead. This orientation enhances the diagnosis of arrhythmias and the detection of inferior wall ischemia. Lead V₅ lies over the fifth intercostal space at the anterior axillary line; this position is a good compromise for detecting anterior and lateral wall ischemia. A true V₅ lead is possible only on operating room ECGs with at least five lead wires, but a modified V₅ can be monitored by rearranging the standard three-limb lead placement (Figure 5-12). Ideally, because each lead provides unique information, leads II and V₅ should be monitored simultaneously. If only a single-channel machine is available, the preferred lead for monitoring depends on the location of any prior infarction or ischemia. Esophageal leads are even better than lead II for arrhythmia diagnosis, but have not yet gained general acceptance in the operating room.

Electrodes are placed on the patient's body to monitor the ECG (Figure 5-13). Conductive gel lowers the skin's electrical resistance, which can be further decreased by cleansing the site with alcohol. Needle electrodes are used only if the disks are unsuitable (eg, with an extensively burned patient).

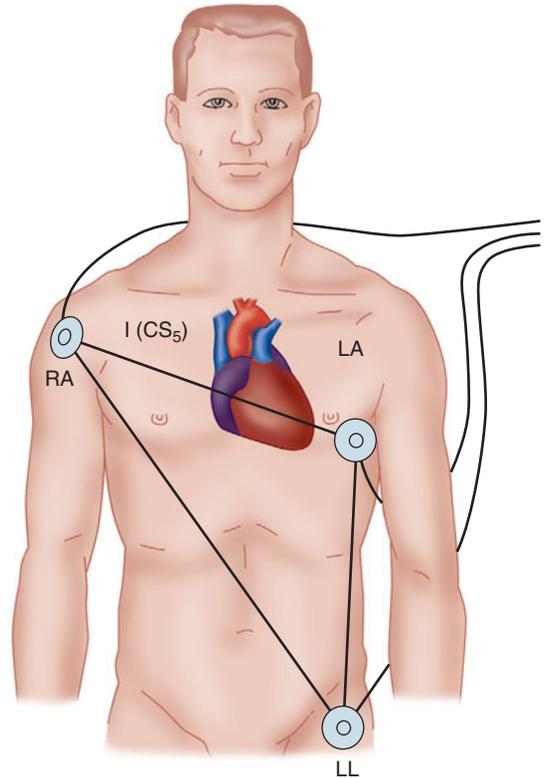

FIGURE 5-12 Rearranged three-limb lead placement. Anterior and lateral ischemia can be detected by placing the left arm lead (LA) at the V₅ position. When lead I is selected on the monitor, a modified V₅ lead (CS₅) is displayed. Lead II allows detection of arrhythmias and inferior wall ischemia. RA, right arm; LL, left leg.

Clinical Considerations

The ECG is a recording of the electrical potentials generated by myocardial cells. Its routine use allows arrhythmias, myocardial ischemia,

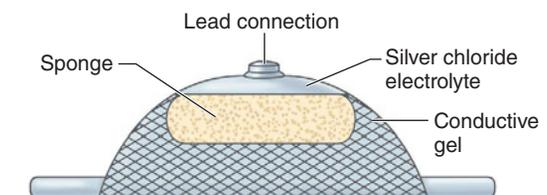

FIGURE 5-13 A cross-sectional view of a silver chloride electrode.

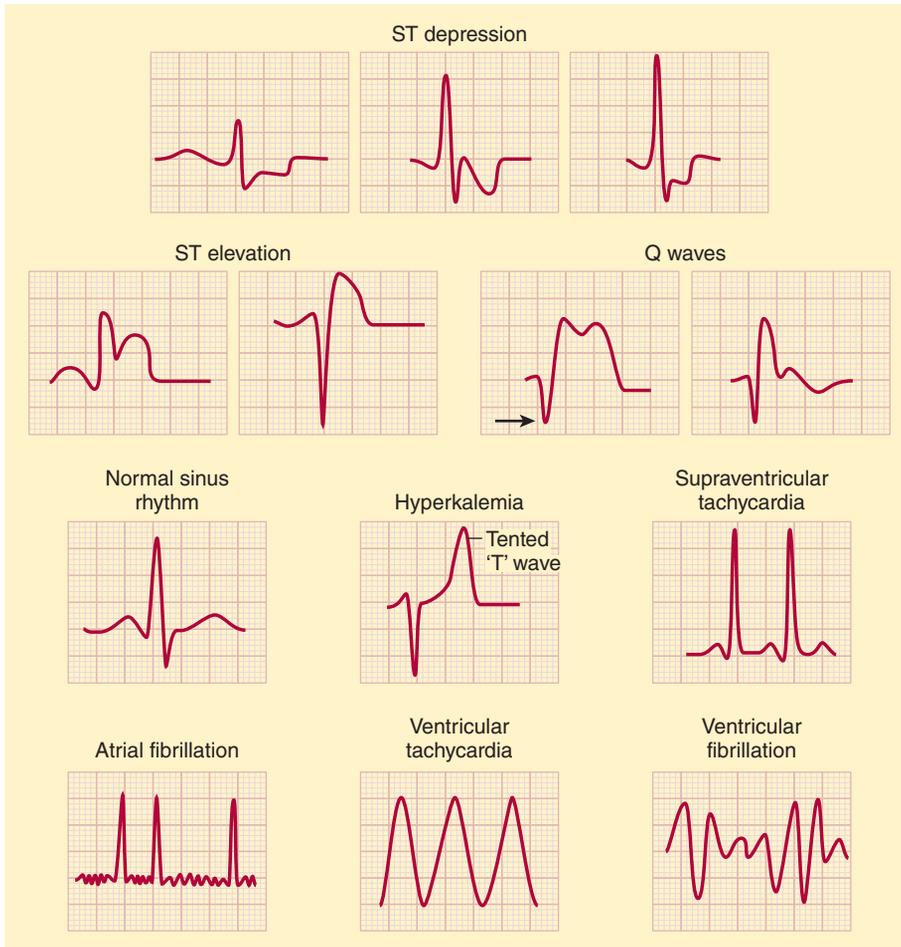

FIGURE 5-14 Common ECG findings during cardiac surgery. (Redrawn and reproduced, with permission, from Wasnick J, Hillel Z, Kramer D, et al: *Cardiac Anesthesia & Transesophageal Echocardiography*, McGraw-Hill, 2011.)

conduction abnormalities, pacemaker malfunction, and electrolyte disturbances to be detected (Figure 5-14). Because of the small voltage potentials being measured, artifacts remain a major problem. Patient or lead-wire movement, use of electrocautery, 60-cycle interference from nearby alternating current devices, and faulty electrodes can simulate arrhythmias. Monitoring filters incorporated into the amplifier to reduce “motion” artifacts will lead to distortion of the ST segment and may impede the diagnosis of ischemia. Digital readouts of the heart rate (HR) may be misleading because of monitor misinterpretation of artifacts or

large T waves—often seen in pediatric patients—as QRS complexes.

Depending on equipment availability, a pre-induction rhythm strip can be printed or frozen on the monitor’s screen to compare with intraoperative tracings. To interpret ST-segment changes properly, the ECG must be standardized so that a 1-mV signal results in a deflection of 10 mm on a standard strip monitor. Newer units continuously analyze ST segments for early detection of myocardial ischemia. Automated ST-segment analysis increases the sensitivity of ischemia detection, does not require additional physician skill or vigilance,

and may help diagnose intraoperative myocardial ischemia.

Commonly accepted criteria for diagnosing myocardial ischemia require that the ECG be recorded in “diagnostic mode” and include a flat or downsloping ST-segment depression exceeding 1 mm, 80 msec after the J point (the end of the QRS complex), particularly in conjunction with T-wave inversion. ST-segment elevation with peaked T waves can also represent ischemia. Wolff–Parkinson–White syndrome, bundle-branch blocks, extrinsic pacemaker capture, and digoxin therapy may preclude the use of ST-segment information. The audible beep associated with each QRS complex should be loud enough to detect rate and rhythm changes when the anesthesiologist’s visual attention is directed elsewhere. Some ECGs are capable of storing aberrant QRS complexes for further analysis, and some can even interpret and diagnose arrhythmias. The interference caused by electrocautery units, however, has limited the usefulness of automated arrhythmia analysis in the operating room.

CENTRAL VENOUS CATHETERIZATION

Indications

Central venous catheterization is indicated for monitoring central venous pressure (CVP), administration of fluid to treat hypovolemia and shock, infusion of caustic drugs and total parenteral nutrition, aspiration of air emboli, insertion of transcutaneous pacing leads, and gaining venous access in patients with poor peripheral veins. With specialized catheters, central venous catheterization can be used for continuous monitoring of central venous oxygen saturation.

Contraindications

Relative contraindications include tumors, clots, or tricuspid valve vegetations that could be dislodged or embolized during cannulation. Other contraindications relate to the cannulation site. For example, subclavian vein cannulation is relatively contraindicated in patients who are receiving anticoagulants (due to the inability to provide direct

compression in the event of an accidental arterial puncture). Some clinicians avoid central venous cannulation on the side of a previous carotid endarterectomy due to concerns about the possibility of unintentional carotid artery puncture. The presence of other central catheters or pacemaker leads may reduce the number of sites available for central line placement.

Techniques & Complications

Central venous cannulation involves introducing a catheter into a vein so that the catheter’s tip lies with the venous system within the thorax. Generally, the optimal location of the catheter tip is just superior to or at the junction of the superior vena cava and the right atrium. When the catheter tip is located within the thorax, inspiration will increase or decrease CVP, depending on whether ventilation is controlled or spontaneous. Measurement of CVP is made with a water column (cm H₂O), or, preferably, an electronic transducer (mm Hg). The pressure should be measured during end expiration.

Various sites can be used for cannulation (Figure 5–15 and Table 5–1). All cannulation sites have an increased risk of line-related infections the longer the catheter remains in place. Compared with other sites, the subclavian vein is associated with a greater risk of pneumothorax during insertion, but a reduced risk of other complications during prolonged cannulations (eg, in critically ill patients). The right internal jugular vein provides a combination of accessibility and safety. Left-sided internal jugular vein catheterization has an increased risk of pleural effusion and chylothorax. The external jugular veins can also be used as entry sites, but due to the acute angle at which they join the great veins of the chest, are associated with a slightly increased likelihood of failure to gain access to the central circulation than the internal jugular veins. Femoral veins can also be cannulated, but are associated with an increased risk of line-related sepsis. There are at least three cannulation techniques: a catheter over a needle (similar to peripheral catheterization), a catheter through a needle (requiring a large-bore needle stick), and a catheter over a guidewire (Seldinger’s technique; Figure 5–16). The overwhelming majority of central lines are placed using Seldinger’s technique.

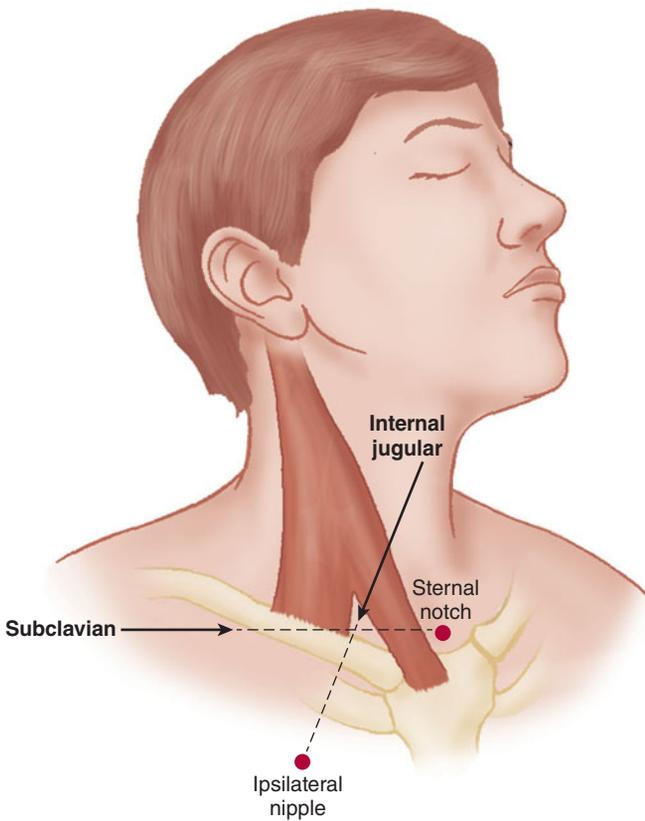

FIGURE 5-15 The subclavian and internal jugular veins are both used for central access perioperatively with the sternal notch and ipsilateral nipple in the direction of needle passage for each, respectively. (Redrawn and reproduced, with permission, from Wasnick J, Hillel Z, Kramer D, et al: *Cardiac Anesthesia & Transesophageal Echocardiography*, McGraw-Hill, 2011.)

The following scenario describes the placement of an internal jugular venous line. The patient is placed in the Trendelenburg position to decrease the risk of air embolism and to distend the internal jugular (or subclavian) vein. Venous catheterization requires full aseptic technique, including scrub, sterile gloves, gown, mask, hat, bactericidal skin

preparation (alcohol-based solutions are preferred), and sterile drapes. The two heads of the sternocleidomastoid muscle and the clavicle form the three sides of a triangle (Figure 5-16A). A 25-gauge needle is used to infiltrate the apex of the triangle with local anesthetic. The internal jugular vein can be located using ultrasound, and we strongly

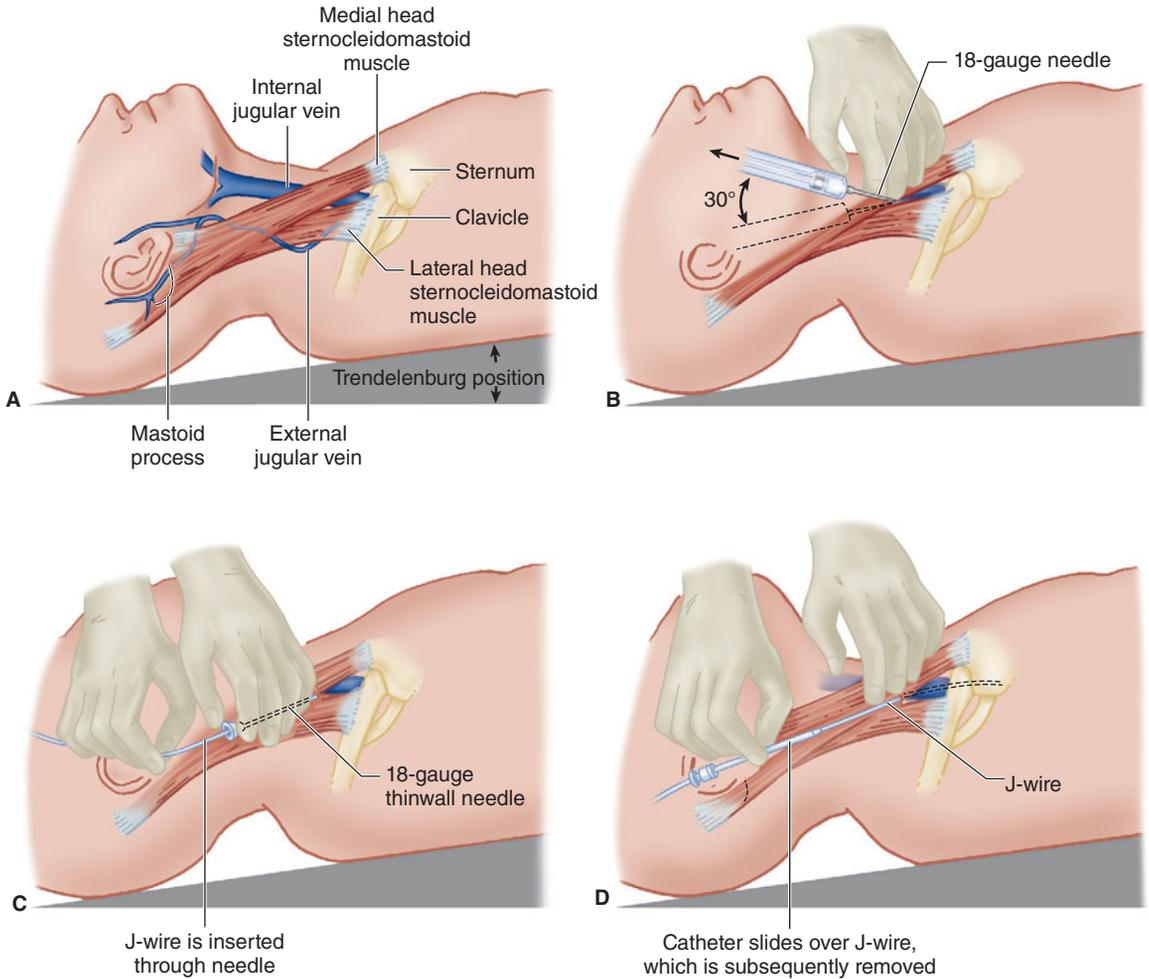

FIGURE 5-16 Right internal jugular cannulation with Seldinger's technique (see text).

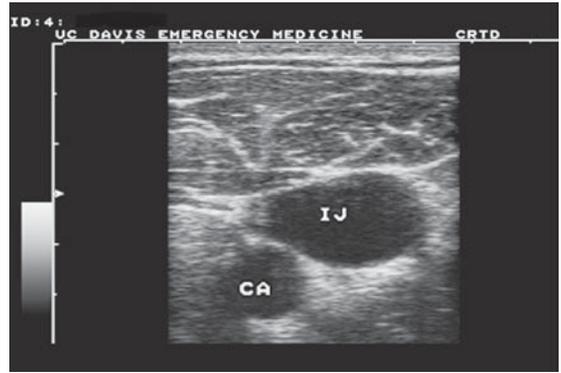

recommend that it be used whenever possible (Figure 5-17). Alternatively, it may be located by advancing the 25-gauge needle—or a 23-gauge needle in heavier patients—along the medial border of the lateral head of the sternocleidomastoid, toward the ipsilateral nipple, at an angle of 30° to the skin. Aspiration of venous blood confirms the vein's location. It is essential that the vein (and not the artery) be cannulated. Cannulation of the carotid artery can lead to hematoma, stroke, airway compromise, and possibly death. An 18-gauge thin-wall needle or an 18-gauge catheter over needle is advanced along the

same path as the locator needle (Figure 5-16B), and, with the latter apparatus, the needle is removed from the catheter once the catheter has been advanced into the vein. When free blood flow is achieved, a J wire with a 3-mm radius curvature is introduced after confirmation of vein puncture (Figure 5-16C). The needle (or catheter) is removed, and a dilator is advanced over the wire. The catheter is prepared for insertion by flushing all ports with saline, and all distal ports are “capped” or clamped, except the one through which the wire must pass. Next, the dilator is removed, and the final catheter is advanced over

A

B

internal jugular vein. (Reproduced, with permission, from Tintinalli JE, et al: *Tintinalli's Emergency Medicine: A Comprehensive Study Guide*, 7th edition, McGraw-Hill, 2011.)

the wire (Figure 5-16D). The guidewire is removed, with a thumb placed over the catheter hub to prevent aspiration of air until the intravenous catheter tubing is connected to it. The catheter is then secured, and a sterile dressing is applied. Correct location is confirmed with a chest radiograph.

1 The catheter's tip should not be allowed to migrate into the heart chambers. Fluid-administration sets should be changed frequently, per your medical center protocol.

The possibility of placement of the vein dilator or catheter into the carotid artery can be decreased by transducing the vessel's pressure waveform from the introducer needle (or catheter, if a catheter over needle has been used) before passing the wire (most simply accomplished by using a sterile intravenous extension tubing as a manometer). Alternatively, one may compare the blood's color or PaO_2 with an arterial sample. Blood color and pulsatility can be misleading or inconclusive, and more than one confirmation method should be used. In cases where transesophageal echocardiography (TEE) is used, the guide wire can be seen in the right atrium, confirming venous entry (Figure 5-18).

The risks of central venous cannulation include line infection, blood stream infection, air or thrombus embolism, arrhythmias (indicating that the catheter tip is in the right atrium or ventricle), hematoma, pneumothorax, hemothorax, hydrothorax,

chylothorax, cardiac perforation, cardiac tamponade, trauma to nearby nerves and arteries, and thrombosis.

Clinical Considerations

Normal cardiac function requires adequate ventricular filling by venous blood. CVP approximates right atrial pressure. Ventricular volumes are related to pressures through compliance. Highly compliant

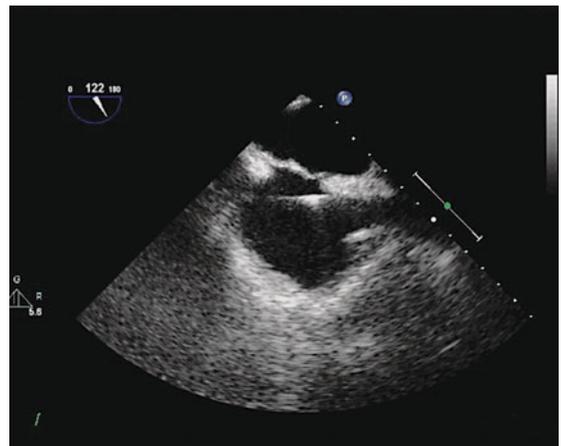

FIGURE 5-18 A wire is seen on this transesophageal echocardiography image of the right atrium.

ventricles accommodate volume with minimal changes in pressure. Noncompliant systems have larger swings in pressure with less volume changes. Consequently, an individual CVP measurement will reveal only limited information about ventricular volumes and filling. Although a very low CVP may indicate a volume-depleted patient, a moderate to high pressure reading may reflect either volume overload or poor ventricular compliance. Changes associated with volume loading coupled with other measures of hemodynamic performance (eg, blood pressure, HR, urine output) may be a better indicator of the patient's volume responsiveness. CVP measurements should always be considered within the context of the patient's overall clinical perspective.

The shape of the central venous waveform corresponds to the events of cardiac contraction (Figure 5-19): *a* waves from atrial contraction are absent in atrial fibrillation and are exaggerated in junctional rhythms ("cannon" *a* waves); *c* waves are due to tricuspid valve elevation during early ventricular contraction; *v* waves reflect venous return against a closed tricuspid valve; and the *x* and *y* descents are probably caused by the downward displacement of the tricuspid valve during systole and tricuspid valve opening during diastole.

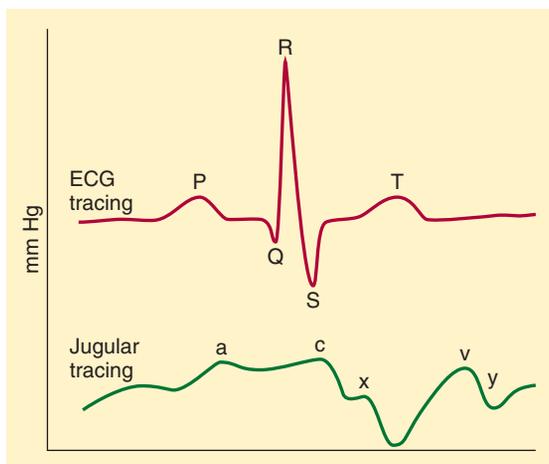

FIGURE 5-19 The upward waves (*a*, *c*, *v*) and the downward descents (*x*, *y*) of a central venous tracing in relation to the electrocardiogram (ECG).

PULMONARY ARTERY CATHETERIZATION

The pulmonary artery (PA) catheter (or Swan-Ganz catheter) was introduced into routine practice in operating rooms and intensive care units in the 1970s. It quickly became common for patients undergoing major surgery to be managed with PA catheterization. The catheter provides measurements of both CO and PA occlusion pressures and was used to guide hemodynamic therapy, especially when patients became unstable. Determination of the PA occlusion or wedge pressure permitted (in the absence of mitral stenosis) an estimation of the left ventricular end-diastolic pressure (LVEDP), and, depending upon ventricular compliance, an estimate of ventricular volume. Through its ability to perform measurements of CO, the patient's stroke volume (SV) was also determined.

$$\text{CO} = \text{SV} \times \text{HR}$$

$$\text{SV} = \text{CO}/\text{HR}$$

$$\text{Blood pressure} = \text{CO} \times \text{systemic vascular resistance (SVR)}$$

Consequently, hemodynamic monitoring with the PA catheter attempted to discern why a patient was unstable so that therapy could be directed at the underlying problem.

If the SVR is diminished, such as in states of vasodilatory shock (sepsis), the SV may increase. Conversely, a reduction in SV may be secondary to poor cardiac performance or hypovolemia. Determination of the "wedge" or pulmonary capillary occlusion pressure (PCOP) by inflating the catheter balloon estimates the LVEDP. A decreased SV in the setting of a low PCOP/ LVEDP indicates hypovolemia and the need for volume administration. A "full" heart, reflected by a high PCOP/ LVEDP and low SV, indicates the need for a positive inotropic drug. Conversely, a normal or increased SV in the setting of hypotension could be treated with the administration of vasoconstrictor drugs to restore SVR in a vasodilated patient.

Although patients can present concurrently with hypovolemia, sepsis, and heart failure, this basic treatment approach and the use of the

PA catheter to guide therapy became more or less synonymous with perioperative intensive care and cardiac anesthesia. However, numerous large observational studies have shown that patients managed with PA catheters had worse outcomes than similar patients who were managed without PA catheters. Other studies seem to indicate that although PA catheter-guided patient management may do no harm, it offers no specific benefits. Although the PA catheter can be used to guide goal-directed hemodynamic therapy to ensure organ perfusion in shock states, other less invasive methods to determine hemodynamic performance are available, including transpulmonary thermodilution CO measurements and pulse contour analyses of the arterial pressure waveform. Both methods permit calculation of the SV as a guide for hemodynamic management. Moreover, right atrial blood oxygen saturation, as opposed to mixed venous saturation (normal is 75%), can be used as an alternative measure to discern tissue oxygen extraction and the adequacy of tissue oxygen delivery.

Despite numerous reports of its questionable utility and the increasing number of alternative methods to determine hemodynamic parameters, the PA catheter is still employed perioperatively more often in the United States than elsewhere. Although echocardiography can readily inform hemodynamic decision-making through imaging the heart to determine if it is full, compressed, contracting, or empty echocardiography requires a trained individual to obtain and interpret the images. Alternative less invasive hemodynamic monitors have gained acceptance in Europe and may expand in the United States, further decreasing the use of PA catheters.

Until other alternatives are available, PA catheterization should be considered whenever cardiac index, preload, volume status, or the degree of mixed venous blood oxygenation need to be known. These measurements might prove particularly important in surgical patients at high risk for hemodynamic instability (eg, those who recently sustained myocardial infarction) or during surgical procedures associated with an increased incidence of hemodynamic complications (eg, thoracic aortic aneurysm repair).

Contraindications

3 Relative contraindications to pulmonary artery catheterization include left bundle-branch block (because of the concern about complete heart block) and conditions associated with a greatly increased risk of arrhythmias, such as Wolff–Parkinson–White syndrome. A catheter with pacing capability is better suited to these situations. A PA catheter may serve as a nidus of infection in bacteremic patients or thrombus formation in patients prone to hypercoagulation.

Techniques & Complications

Although various PA catheters are available, the most popular design integrates five lumens into a 7.5 FR catheter, 110-cm long, with a polyvinylchloride body (Figure 5–20). The lumens house the

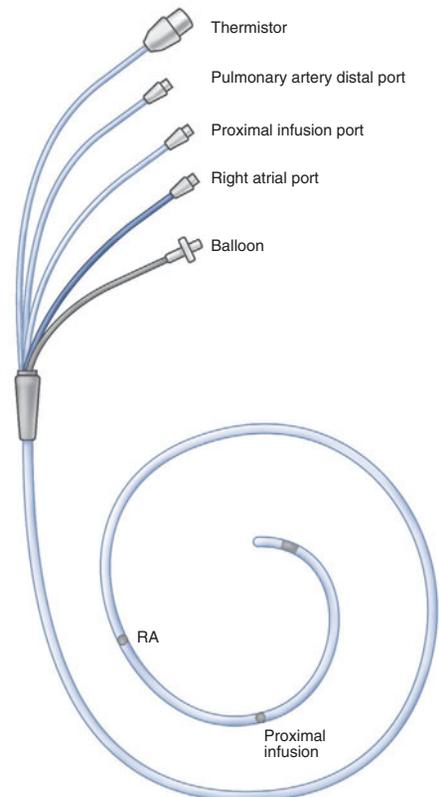

FIGURE 5–20 Balloon-tipped pulmonary artery flotation catheter (Swan–Ganz catheter). RA, right atrium.

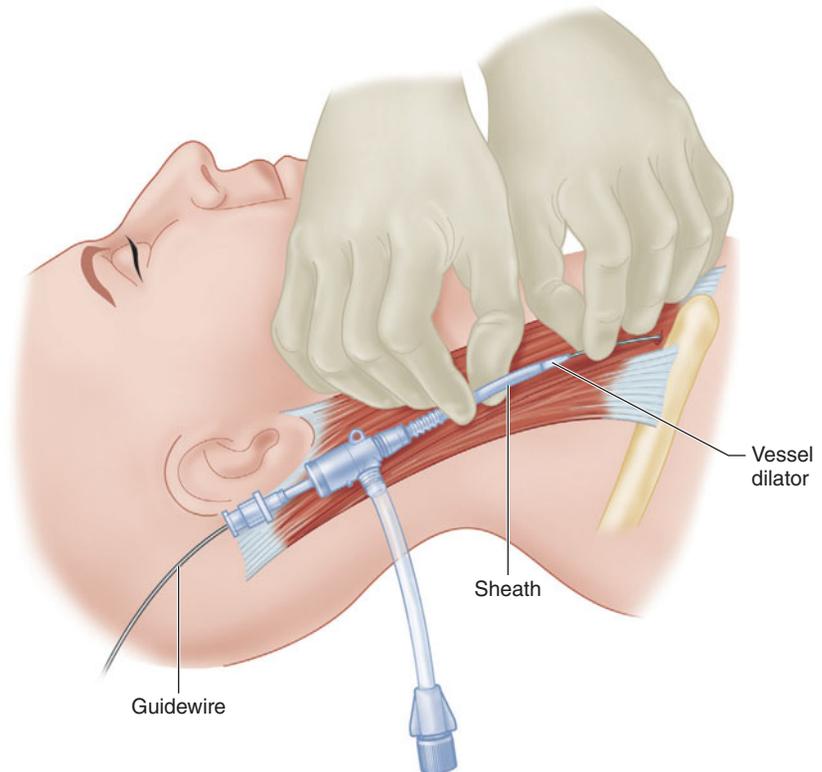

FIGURE 5-21 A percutaneous introducer consisting of a vessel dilator and sheath is passed over the guidewire.

following: wiring to connect the thermistor near the catheter tip to a thermodilution CO computer; an air channel for inflation of the balloon; a proximal port 30 cm from the tip for infusions, CO injections, and measurements of right atrial pressures; a ventricular port at 20 cm for infusion of drugs; and a distal port for aspiration of mixed venous blood samples and measurements of PA pressure.

Insertion of a PA catheter requires central venous access, which can be accomplished using Seldinger's technique, described above. Instead of a central venous catheter, a dilator and sheath are threaded over the guidewire. The sheath's lumen accommodates the PA catheter after removal of the dilator and guidewire (**Figure 5-21**).

Prior to insertion, the PA catheter is checked by inflating and deflating its balloon and irrigating all three intravascular lumens with saline. The distal port is connected to a transducer that is zeroed to the patient's midaxillary line.

The PA catheter is advanced through the introducer and into the internal jugular vein. At approximately 15 cm, the distal tip should enter the right atrium, and a central venous tracing that varies with respiration confirms an intrathoracic position. The balloon is then inflated with air according to the manufacturer's recommendations (usually 1.5 mL) to protect the endocardium from the catheter tip and to allow the right ventricle's CO to direct the catheter forward. The balloon is always deflated during withdrawal. During the catheter's advancement, the ECG should be monitored for arrhythmias. Transient ectopy from irritation of the right ventricle by the balloon and catheter tip is common and rarely requires treatment. A sudden increase in the *systolic* pressure on the distal tracing indicates a right ventricular location of the catheter tip (**Figure 5-22**). Entry into the pulmonary artery normally occurs by 35–45 cm and is heralded by a sudden increase in *diastolic* pressure.

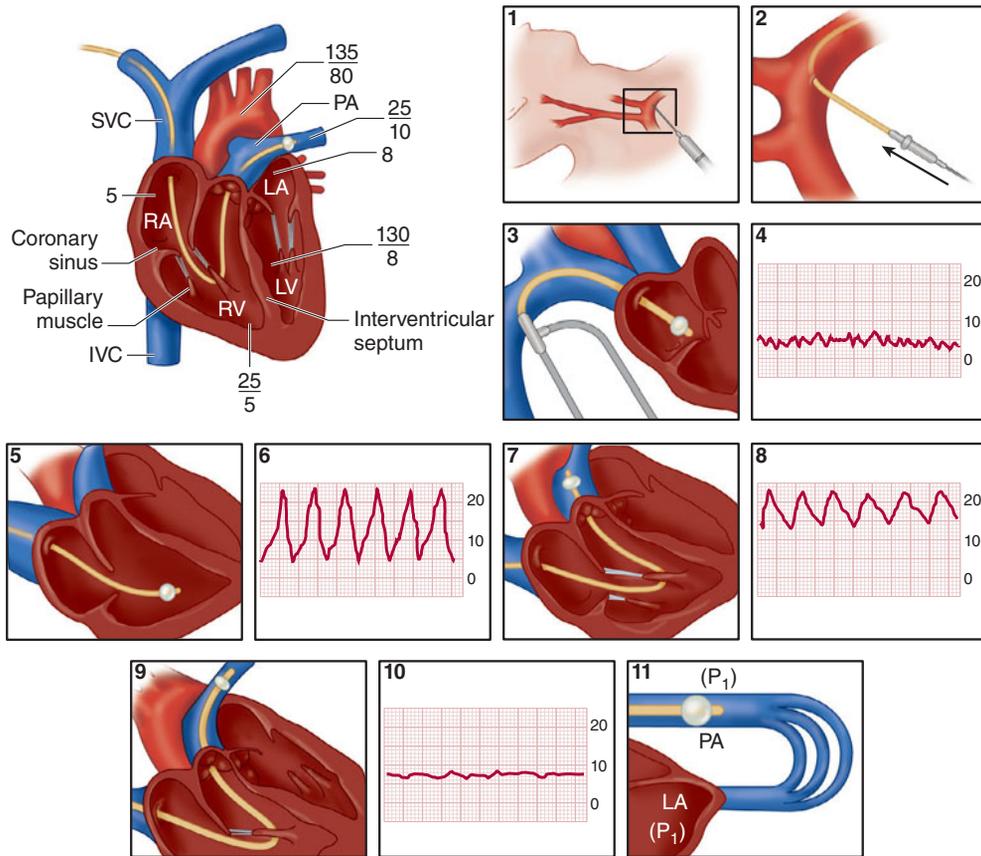

FIGURE 5-22 Although its utility is increasingly questioned, pulmonary artery catheters continue to be a part of perioperative management of the cardiac surgery patient. Following placement of a sheath introducer in the central circulation (panels 1 and 2), the pulmonary artery catheter is floated. Central line placement should always be completed using rigorous sterile technique, full body draping, and only after multiple, redundant confirmations of the correct localization of the venous circulation. Pressure guidance is used to ascertain the localization of the PA catheter in the venous circulation and the heart. Upon entry into the right atrium (panels 3 and 4), the central venous pressure tracing is noted. Passing through the tricuspid valve (panels 5 and 6)

right ventricular pressures are detected. At 35 to 50 cm depending upon patient size, the catheter will pass from the right ventricle through the pulmonic valve into the pulmonary artery (panels 7 and 8). This is noted by the measurement of diastolic pressure once the pulmonic valve is passed. Lastly, when indicated the balloon-tipped catheter will wedge or occlude a pulmonary artery branch (panels 9, 10, and 11). When this occurs, the pulmonary artery pressure equilibrates with that of the left atrium which, barring any mitral valve pathology, should be a reflection of left ventricular end-diastolic pressure. (Redrawn and reproduced, with permission, from Soni N. *Practical Procedures in Anaesthesia and Intensive Care*. Butterworth Heinemann, 1994.)

To prevent catheter knotting, the balloon should be deflated and the catheter withdrawn if pressure changes do not occur at the expected distances. In particularly difficult cases (low CO, pulmonary hypertension, or congenital heart anomalies),

flotation of the catheter may be enhanced by having the patient inhale deeply; positioning the patient in a head-up, right lateral tilt position; injecting iced saline through the proximal lumen to stiffen the catheter (which also increases the risk of perforation); or

administering a small dose of an inotropic agent to increase CO. Occasionally, the insertion may require fluoroscopy or TEE for guidance.

After attaining a PA position, minimal PA catheter advancement results in a pulmonary artery occlusion pressure (PAOP) waveform. The PA tracing should reappear when the balloon is deflated. Wedging before maximal balloon inflation signals an overwedged position, and the catheter should be slightly withdrawn (with the balloon down, of course). Because **PA rupture** may cause mortality and can occur because of balloon overinflation, the frequency of wedge readings should be minimized.

4 PA pressure should be continuously monitored to detect an overwedged position indicative of catheter migration. Furthermore, if the catheter has a right ventricular port 20 cm from the tip, distal migration can often be detected by a change in the pressure tracing that indicates a pulmonary artery location.

Correct catheter position can be confirmed by a chest radiograph.

The numerous complications of PA catheterization include all complications associated with central venous cannulation plus bacteremia, endocarditis, thrombogenesis, pulmonary infarction, PA rupture, and hemorrhage (particularly in patients taking anticoagulants, elderly or female patients, or patients with pulmonary hypertension), catheter knotting, arrhythmias, conduction abnormalities, and pulmonary valvular damage (**Table 5-2**). Even trace hemoptysis should not be ignored, as it may herald PA rupture. If the latter is suspected, prompt placement of a double-lumen tracheal tube may maintain adequate oxygenation by the unaffected lung. The risk of complications increases with the duration of catheterization, which usually should not exceed 72 hr.

Clinical Considerations

The introduction of PA catheters into the operating room revolutionized the intraoperative management of critically ill patients. PA catheters allow more precise estimation of left ventricular preload than either CVP or physical examination, as well as the sampling of mixed venous blood. Catheters with self-contained thermistors (discussed later in this

TABLE 5-2 Reported incidence of adverse effects of pulmonary artery catheterization.¹

Complication	Reported Incidence (%)
Central venous access	
Arterial puncture	0.1–13

chapter) can be used to measure CO, from which a multitude of hemodynamic values can be derived (**Table 5-3**). Some catheter designs incorporate electrodes that allow intracavitary ECG recording and pacing. Optional fiberoptic bundles allow continuous measurement of the oxygen saturation of mixed venous blood.

Starling demonstrated the relationship between left ventricular function and left ventricular end-diastolic muscle fiber length, which is usually proportionate to end-diastolic volume. If compliance is not abnormally decreased (eg, by myocardial ischemia, overload, ventricular hypertrophy,

TABLE 5-3 Hemodynamic variables derived from pulmonary artery catheterization data.¹

¹g-m, gram meter; MAP, mean arterial pressure; CVP, central venous pressure; $\overline{\text{PA}}$, mean pulmonary artery pressure; PAOP, pulmonary artery occlusion pressure.

or pericardial tamponade), LVEDP should reflect fiber length. In the presence of a normal mitral valve, left atrial pressure approaches left ventricular pressure during diastolic filling. The left atrium connects with the right side of the heart through the pulmonary vasculature. The distal lumen of a correctly wedged PA catheter is isolated from right-sided pressures by balloon inflation. Its distal opening is exposed only to capillary pressure, which—in the absence of high airway pressures or pulmonary vascular disease—equals left atrial pressure. In fact, aspiration through the distal port during balloon inflation samples arterialized blood. PAOP is an indirect measure of LVEDP which depending upon ventricular compliance approximates left ventricular end diastolic volume.

Whereas central venous pressure may reflect right ventricular function, a PA catheter may be indicated if either ventricle is markedly depressed, causing disassociation of right- and left-sided hemodynamics. CVP is poorly predictive of pulmonary capillary pressures, especially in patients with abnormal left-ventricular function. Even the PAOP does not always predict LVEDP. The relationship between left ventricular end-diastolic volume (actual preload) and PAOP (estimated preload) can

become unreliable during conditions associated with changing left atrial or ventricular compliance, mitral valve function, or pulmonary vein resistance. These conditions are common immediately following major cardiac or vascular surgery and in critically ill patients who are on inotropic agents or in septic shock.

Ultimately, the information provided by the PA catheter is like that from any perioperative monitor dependent upon its correct interpretation by the patient's care givers. In this context, the PA catheter is a tool to assist in goal-directed perioperative therapy. Given the increasing number of less invasive methods now available to obtain similar information, we suspect that PA catheterization will become mostly of historic interest.

CARDIAC OUTPUT

Indications

CO measurement to permit calculation of the SV is one of the primary reasons for PA catheterization. Currently, there are a number of alternative, less invasive methods to estimate ventricular function to assist in goal-directed therapy.

Techniques & Complications

A. Thermodilution

The injection of a quantity (2.5, 5, or 10 mL) of fluid that is below body temperature (usually room temperature or iced) into the right atrium changes the temperature of blood in contact with the thermistor at the tip of the PA catheter. The degree of change is inversely proportionate to CO: Temperature change is minimal if there is a high blood flow, whereas temperature change is greater when flow is reduced. After injection, one can plot the temperature as a function of time to produce a **thermodilution curve** (Figure 5-23). CO is determined by a computer program that integrates the area under the curve.

5 Accurate measurements of CO depend on rapid and smooth injection, precisely known injectant temperature and volume, correct entry of the calibration factors for the specific type of PA catheter into the CO computer, and avoidance of measurements during electrocautery. Tricuspid regurgitation and cardiac shunts invalidate results because only right ventricular output into the PA is actually being measured. Rapid infusion of the iced injectant has rarely resulted in cardiac arrhythmias.

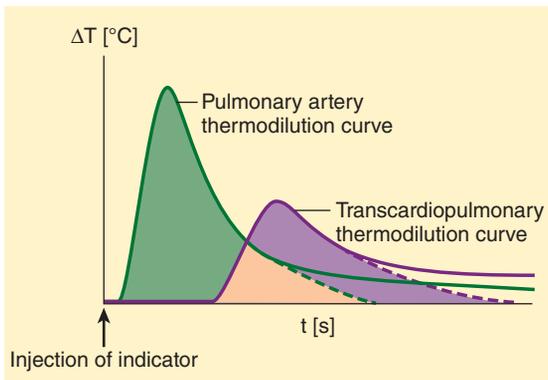

FIGURE 5-23 Comparison of thermodilution curves after injection of cold saline into the superior vena cava. The peak temperature change arrives earlier when measured in the pulmonary artery (a) than if measured in the femoral artery (b). Thereafter, both curves soon reapproximate baseline. (Redrawn and reproduced, with permission from Reuter D, Huang C, Edrich T, et al: Cardiac output monitoring using indicator dilution techniques: basics, limits and perspectives. *Anesth Analg* 2010;110:799.)

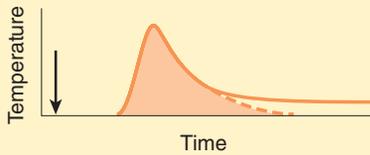

A modification of the thermodilution technique allows continuous CO measurement with a special catheter and monitor system. The catheter contains a thermal filament that introduces small pulses of heat into the blood proximal to the pulmonic valve and a thermistor that measures changes in PA blood temperature. A computer in the monitor determines CO by cross-correlating the amount of heat input with the changes in blood temperature.

Transpulmonary thermodilution (PiCCO® system) relies upon the same principles of thermodilution, but does not require PA catheterization. A central line and a thermistor-equipped arterial catheter (usually placed in the femoral artery) are necessary to perform transpulmonary thermodilution. Thermal measurements from radial artery catheters have been found to be invalid. Transpulmonary thermodilution measurements involve injection of cold indicator into the superior vena cava via a central line (Figure 5-24). A thermistor notes the change in temperature in the arterial system following the cold indicator's transit through the heart and lungs and estimates the CO.

Transpulmonary thermodilution also permits the calculation of both the global-end diastolic volume (GEDV) and the extravascular lung water (EVLW). Through mathematical analysis and extrapolation of the thermodilution curve, it is possible for the transpulmonary thermodilution computer to calculate both the mean transit time of the indicator and its exponential decay time (Figure 5-25). The intrathoracic thermal volume (ITTV) is the product of the CO and the mean transit time (MTT). The ITTV includes the pulmonary blood volume (PBV), EVLW, and the blood contained within the heart. The pulmonary thermal volume (PTV) includes both the EVLW and the PBV and is obtained by multiplying the CO by the exponential decay time (EDT). Subtracting the PTV from the ITTV gives the GEDV (Figure 5-26). The GEDV is a hypothetical volume that assumes that all of the heart's chambers are simultaneously full in diastole. With a normal index between 640 and 800 mL/m², the GEDV can assist in determining volume status. An extra vascular lung water index of less than 10 mL/kg is normative. The EVLW is the ITTV

PiCCO® - Two methods combined for precise monitoring

- Lung water (EVLW - Extravascular Lung Water)

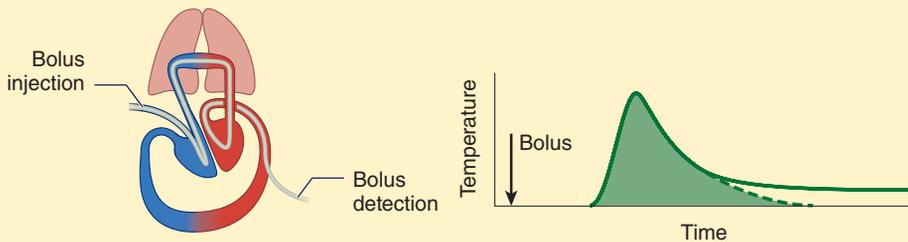

Calibration

Pulse contour analysis

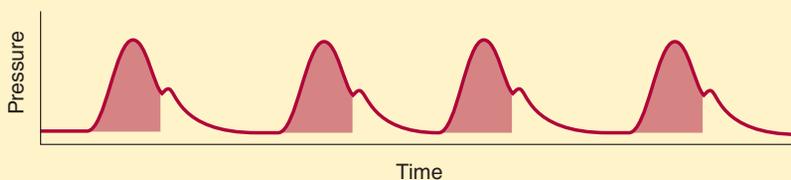

- Continuous cardiac output
- Afterload (SVR - Systemic Vascular Resistance)
- Stroke Volume (SV - Stroke Volume)
- Volume responsiveness (SVV - Stroke Volume Variation, PPV - Pulse Pressure Variation)

Transpulmonary thermodilution

- The cold indicator passes through the right heart, lungs and left heart.
- The indicator is detected in a central artery.
- Precise cardiac output measurement based on Stewart-Hamilton algorithm.
- Breathing cycle independent.
- Passage through the heart and lungs allow determination of preload volumes and lung water.

Pulse contour analysis

- Stroke volume is reflected by the area under the systolic part of the pressure curve (red area) of one heart beat.
- Cardiac output is calculated beat-by-beat: stroke volume μ heart rate

FIGURE 5-24 Two methods combined for precise monitoring. (Reproduced, with permission, from Royal Philips Electronics.)

minus the intrathoracic blood volume (ITBV). The $ITBV = GEDV \times 1.25$.

Thus $EVLW = ITTV - ITBV$. An increased EVLW can be indicative of fluid overload. Thus, through mathematical analysis of the transpulmonary

thermodilution curve, it is possible to obtain volumetric indices to guide fluid replacement therapy. Moreover, the PiCCO® system calculates SV variation and pulse pressure variation through pulse contour analysis, both of which can be used to

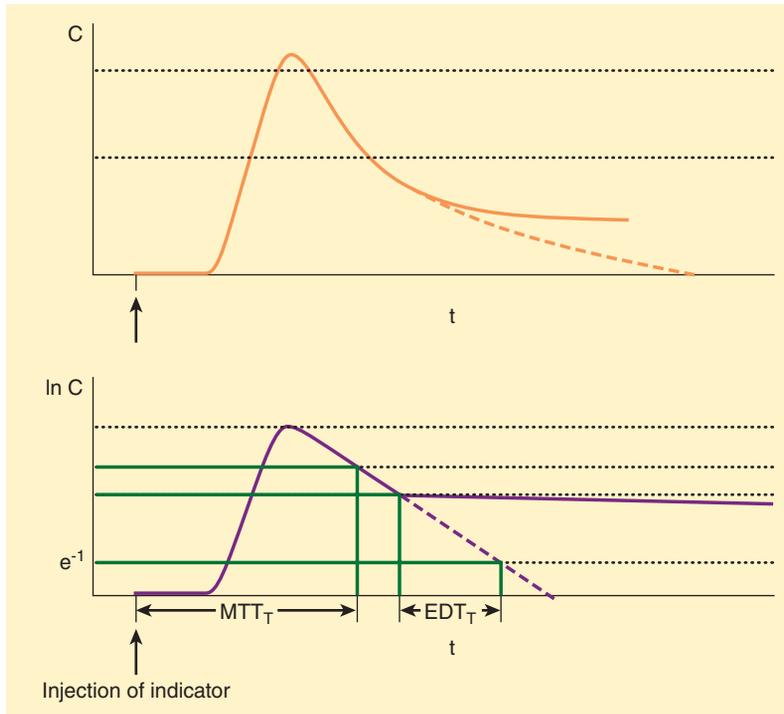

FIGURE 5-25 The upper curve represents the classic thermodilution curve, showing the concentration of an indicator over time at the site of detection. By extrapolation of the curve (dashed line), potential recirculation phenomena are excluded. Logarithmic illustration (lower

curve) allows defining the mean transit time (MTT_T) and the exponential decay time (EDT_T) of the indicator. (Redrawn and reproduced, with permission from Reuter D, Huang C, Edrich T, et al: Cardiac output monitoring using indicator dilution techniques: basics, limits and perspectives. *Anesth Analg* 2010;110:799.)

determine fluid responsiveness. Both SV and pulse pressure are decreased during positive pressure ventilation. The greater the variations over the course of positive pressure inspiration and expiration, the more likely the patient is to improve hemodynamic measures following volume administration.

B. Dye Dilution

If indocyanine green dye (or another indicator such as lithium) is injected through a central venous catheter, its appearance in the systemic arterial circulation can be measured by analyzing arterial samples with an appropriate detector (eg, a densitometer for indocyanine green). The area under the resulting **dye indicator curve** is related to CO. By analyzing arterial blood pressure and integrating it with CO, systems that use lithium (LiDCO™) also calculate

beat-to-beat SV. In the LiDCO™ system, a small bolus of lithium chloride is injected into the circulation. A lithium-sensitive electrode in an arterial catheter measures the decay in lithium concentration over time. Integrating the concentration over time graph permits the machine to calculate the CO. The LiDCO™ device, like the PiCCO® thermodilution device, employs pulse contour analysis of the arterial wave form to provide ongoing beat-to-beat determinations of CO and other calculated parameters. Lithium dilution determinations can be made in patients who have only peripheral venous access. Lithium should not be administered to patients in the first trimester of pregnancy. The dye dilution technique, however, introduces the problems of indicator recirculation, arterial blood sampling, and background tracer buildup, potentially

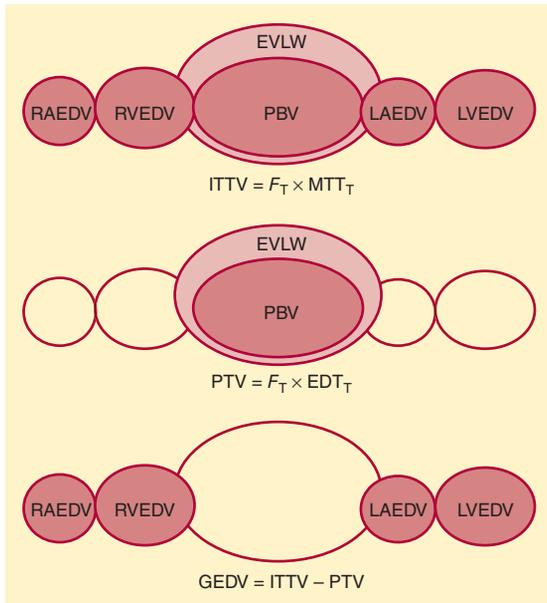

FIGURE 5-26 Assessment of global end-diastolic volume (GEDV) by transcardiopulmonary thermodilution. Upper row: The intrathroacic thermal volume (ITTV) is the complete volume of distribution of the thermal indicator, including the right atrium end-diastolic volume (RAEDV), the right ventricle (RVEDV), the left atrium (LAEDV), the left ventricle (LVEDV), the pulmonary blood volume (PBV), and the extravascular lung water (EVLW). It is calculated by multiplying cardiac output (F_T) with the mean transit time (MTT_T) of the indicator. Middle row: The pulmonary thermal volume (PTV) represents the largest mixing chamber in this system and includes the PBV and the EVLW and is assessed by multiplying F_T with the exponential decay time (EDT_T) of the thermal indicator. Bottom row: The GEDV, including the volumes of the right and the left heart, now is calculated by subtracting PTV from ITTV. (Redrawn and reproduced, with permission from Reuter D, Huang C, Edrich T, et al: Cardiac output monitoring using indicator dilution techniques: basics, limits and perspectives. *Anesth Analg* 2010;110:799.)

limiting the use of such approaches perioperatively. Nondepolarizing neuromuscular blockers may affect the lithium sensor.

C. Pulse Contour Devices

Pulse contour devices use the arterial pressure tracing to estimate the CO and other dynamic

parameters, such as pulse pressure and SV variation with mechanical ventilation. These indices are used to help determine if hypotension is likely to respond to fluid therapy.

Pulse contour devices rely upon algorithms that measure the area of the systolic portion of the arterial pressure trace from end diastole to the end of ventricular ejection. The devices then incorporate a calibration factor for the patient's vascular compliance, which is dynamic and not static. Some pulse contour devices rely first on transpulmonary thermodilution or lithium thermodilution to calibrate the machine for subsequent pulse contour measurements. The FloTrac (Edwards Life Sciences) does not require calibration with another measure and relies upon a statistical analysis of its algorithm to account for changes in vascular compliance occurring as a consequence of changed vascular tone.

D. Esophageal Doppler

Esophageal Doppler relies upon the Doppler principle to measure the velocity of blood flow in the descending thoracic aorta. The Doppler principle is integral in perioperative echocardiography, as discussed below. The Doppler effect has been described previously in this chapter and is the result of the apparent change in sound frequency when the source of the sound wave and the observer of the sound wave are in relative motion. Blood in the aorta is in relative motion compared with the Doppler probe in the esophagus. As red blood cells travel, they reflect a frequency shift, depending upon both the direction and velocity of their movement. When blood flows toward the transducer, its reflected frequency is higher than that which was transmitted by the probe. When blood cells move away from the transducer, the frequency is lower than that which was initially sent by the probe. By using the Doppler equation, it is possible to determine the velocity of blood flow in the aorta. The equation is:

$$\text{Velocity of blood flow} = \left\{ \frac{\text{frequency change}}{\cosine \text{ of the angle of incidence between the Doppler beam and the blood flow}} \right\} \times \left\{ \frac{\text{speed of sound in tissue}}{2} \right\} (\text{source frequency})$$

For Doppler to provide a reliable estimate of velocity, the angle of incidence should be as close to zero as possible, since the cosine of 0 is 1. As the

angle approaches 90°, the Doppler measure is unreliable, as the cosine of 90° is 0.

The esophageal Doppler device calculates the velocity of flow in the aorta. As the velocities of the cells in the aorta travel at different speeds over the cardiac cycle, the machine obtains a measure of all of the velocities of the cells moving over time. Mathematically integrating the velocities represents the distance that the blood travels. Next, using nomograms, the monitor approximates the area of the descending aorta. The monitor thus calculates both the distance the blood travels, as well as the area: $\text{area} \times \text{length} = \text{volume}$.

Consequently, the SV of blood in the descending aorta is calculated. Knowing the HR allows calculation of that portion of the CO flowing through the descending thoracic aorta, which is approximately 70% of total CO. Correcting for this 30% allows the monitor to estimate the patient's total CO. Esophageal Doppler is dependent upon many assumptions and nomograms, which may hinder its ability to accurately reflect CO in a variety of clinical situations.

E. Thoracic Bioimpedance

Changes in thoracic volume cause changes in thoracic resistance (bioimpedance) to low amplitude, high frequency currents. If thoracic changes in bioimpedance are measured following ventricular depolarization, SV can be continuously determined. This noninvasive technique requires six electrodes to inject microcurrents and to sense bioimpedance on both sides of the chest. Increasing fluid in the chest results in less electrical bioimpedance. Mathematical assumptions and correlations are then made to calculate CO from changes in bioimpedance. Disadvantages of thoracic bioimpedance include susceptibility to electrical interference and reliance upon correct electrode positioning. The accuracy of this technique is questionable in several groups of patients, including those with aortic valve disease, previous heart surgery, or acute changes in thoracic sympathetic nervous function (eg, those undergoing spinal anesthesia).

F. Fick Principle

The amount of oxygen consumed by an individual ($\dot{V}O_2$) equals the difference between arterial and

venous (a-v) oxygen content (C) (CaO_2 and CvO_2) multiplied by CO. Therefore

$$CO = \frac{\text{Oxygen consumption}}{\text{a-v } O_2 \text{ content difference}} = \frac{\dot{V}O_2}{CaO_2 - CvO_2}$$

Mixed venous and arterial oxygen content are easily determined if a PA catheter and an arterial line are in place. Oxygen consumption can also be calculated from the difference between the oxygen content in inspired and expired gas. Variations of the Fick principle are the basis of all indicator-dilution methods of determining CO.

G. Echocardiography

There are no more powerful tools to diagnose and assess cardiac function perioperatively than transthoracic echocardiography (TTE) and transesophageal echocardiography (TEE). Both approaches are increasingly used in the operative setting. In the operating rooms, limited access to the chest makes TEE an ideal option to visualize the heart. Both TTE and TEE can be employed preoperatively and postoperatively. TTE has the advantage of being completely noninvasive; however, acquiring the "windows" to view the heart can be difficult. Disposable TEE probes are now available that can remain in position in critically ill patients for days, during which intermittent TEE examinations can be performed.

Echocardiography can be employed by anesthesia staff in two ways, depending upon degrees of training and certification. Basic (or hemodynamic) TEE permits the anesthesiologist to discern the primary source of a patient's hemodynamic instability. Whereas in past decades the PA flotation catheter would be used to determine why the patient might be hypotensive, the anesthesiologist performing hemodynamic TEE is attempting to determine if the heart is adequately filled, contracting appropriately, not externally compressed, and devoid of any grossly obvious structural defects. At all times, information obtained from hemodynamic TEE may be correlated with other information as to the patient's general condition.

Anesthesiologists performing advanced TEE make therapeutic and surgical recommendations based upon their TEE interpretations. Various

organizations and boards have been established worldwide to certify individuals in all levels of perioperative echocardiography. More importantly, individuals who perform echocardiography should be aware of the credentialing requirements of their respective institutions.

Echocardiography has many uses, including:

- Diagnosis of the source of hemodynamic instability, including myocardial ischemia, systolic and diastolic heart failure, valvular abnormalities, hypovolemia, and pericardial tamponade
- Estimation of hemodynamic parameters, such as SV, CO, and intracavitary pressures
- Diagnosis of structural diseases of the heart, such as valvular heart disease, shunts, aortic diseases
- Guiding surgical interventions, such as mitral valve repair.

Various echocardiographic modalities are employed perioperatively by anesthesiologists, including TTE, TEE, epiaortic and epicardiac ultrasound, and three-dimensional echocardiography. Some advantages and disadvantages of the modalities are as follows:

- TTE has the advantage of being noninvasive and essentially risk free. Limited scope TTE exams are now increasingly common in the intensive care unit (**Figure 5-27**).
- Unlike TTE, TEE is an invasive procedure with the potential for life-threatening complications (esophageal rupture and mediastinitis) (**Figure 5-28**). The close proximity of the esophagus to the left atrium eliminates the problem of obtaining “windows” to view the heart and permits great detail. TEE has been used frequently in the cardiac surgical operating room over the past decades. Its use to guide therapy in general cases has been limited by both the cost of the equipment and the learning necessary to correctly interpret the images. Both TTE and TEE generate two-dimensional images of the three-dimensional heart. Consequently, it is necessary to view the heart through many

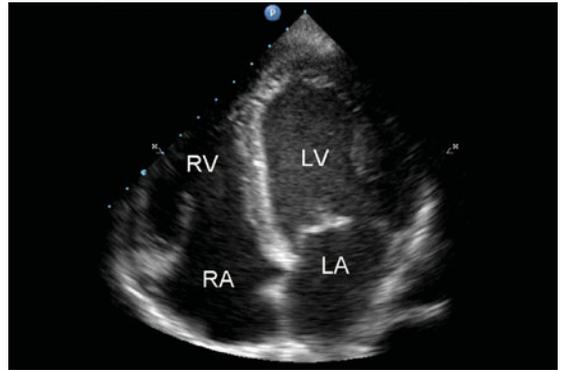

FIGURE 5-27 Normal apical four-chamber view. RV, right ventricle; LV, left ventricle; RA, right atrium; LA, left atrium. (Reproduced, with permission, from Carmody KA, et al: *Handbook of Critical Care and Emergency Ultrasound*. McGraw-Hill, 2011.)

two-dimensional image planes and windows to mentally recreate the three-dimensional anatomy. The ability to interpret these images at the advanced certification level requires much training.

- Epiaortic and epicardiac ultrasound imaging techniques employ an echo probe wrapped in a sterile sheath and manipulated by thoracic surgeons intraoperatively to obtain views of

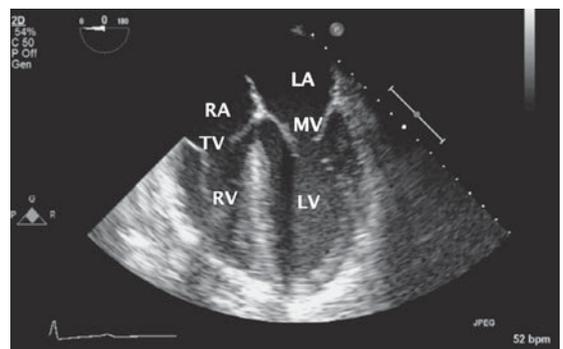

FIGURE 5-28 The structures of the heart as seen on a midesophageal four-chamber view, including the right atrium (RA), tricuspid valve (TV), right ventricle (RV), left atrium (LA), mitral valve (MV), and left ventricle (LV). (Redrawn and reproduced, with permission, from Wasnick J, Hillel Z, Kramer D, et al: *Cardiac Anesthesia & Transesophageal Echocardiography*, McGraw-Hill, 2011.)

the aorta and the heart. The air-filled trachea prevents TEE imaging of the ascending aorta. Because the aorta is manipulated during cardiac surgery, detection of atherosclerotic plaques permits the surgeon to potentially minimize the incidence of embolic stroke. Imaging of the heart with epicardial ultrasound permits intraoperative echocardiography when TEE is contraindicated because of esophageal or gastric pathology.

- Three-dimensional echocardiography (TTE and TEE) has become available in recent years (Figure 5–29). These techniques provide a three-dimensional view of the heart's structure. In particular, three-dimensional images can better quantify the heart's volumes and can generate a surgeon's view of the mitral valve to aid in guiding valve repair.

Echocardiography employs ultrasound (sound at frequencies greater than normal hearing) from 2 to 10 MHz. A piezoelectrode in the probe transducer converts electrical energy delivered to the probe into ultrasound waves. These waves then travel

through the tissues, encountering the blood, the heart, and other structures. Sound waves pass readily through tissues of similar acoustic impedance; however, when they encounter different tissues, they are scattered, refracted, or reflected back toward the ultrasound probe. The echo wave then interacts with the ultrasound probe, generating an electrical signal that can be reconstructed as an image. The machine knows the time delay between the transmitted and the reflected sound wave. By knowing the time delay, the location of the source of the reflected wave can be determined and the image generated. The TEE probe contains myriad crystals generating and processing waves, which then create the echo image. The TEE probe can generate images through multiple planes and can be physically manipulated in the stomach and esophagus, permitting visualization of heart structures (Figure 5–30). These views can be used to determine if the heart's walls are being delivered adequate blood supply (Figure 5–31). In the healthy heart, the heart's walls thicken and move inwardly with each beat. Wall motion abnormalities, in which the heart's walls fail to thicken during systole or move in a dyskinetic fashion, can be associated with myocardial ischemia.

The Doppler effect is routinely used in echocardiographic examinations to determine the heart's function. In the heart, both the blood flowing through the heart and the heart tissue move relative to the echo probe in the esophagus or on the chest wall. By using the Doppler effect, it is possible for echocardiographers to determine both the direction and the velocity of blood flow and tissue movement.

Blood flow in the heart follows the law of the conservation of mass. Therefore, the volume of blood that flows through one point (eg, the left ventricular outflow tract) must be the same volume that passes through the aortic valve. When the pathway through which the blood flows becomes narrowed (eg, aortic stenosis), the blood velocity must increase to permit the volume to pass. The increase in velocity as blood moves toward an esophageal echo probe is detected. The Bernoulli equation (pressure change = $4V^2$) allows echocardiographers to determine the pressure gradient between areas of different velocity, where v represents the area of

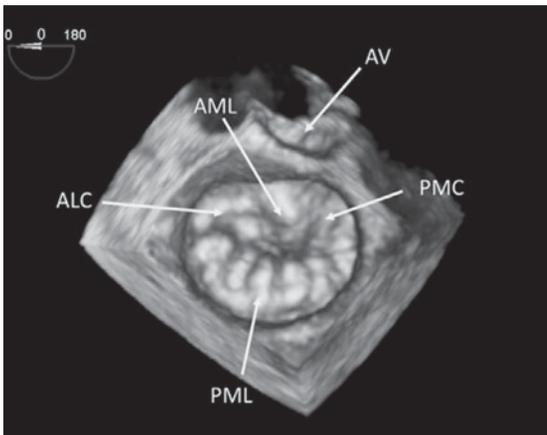

FIGURE 5–29 Three dimensional echocardiography of the mitral valve demonstrates the anterior leaflet (AML), the posterior leaflet (PML), the antero lateral commissure (ALC) and the postero medial commissure (PMC). The aortic valve (AV) is also seen. (Redrawn and reproduced, with permission, from Wasnick J, Hillel Z, Kramer D, et al: *Cardiac Anesthesia & Transesophageal Echocardiography*, McGraw-Hill, 2011.)

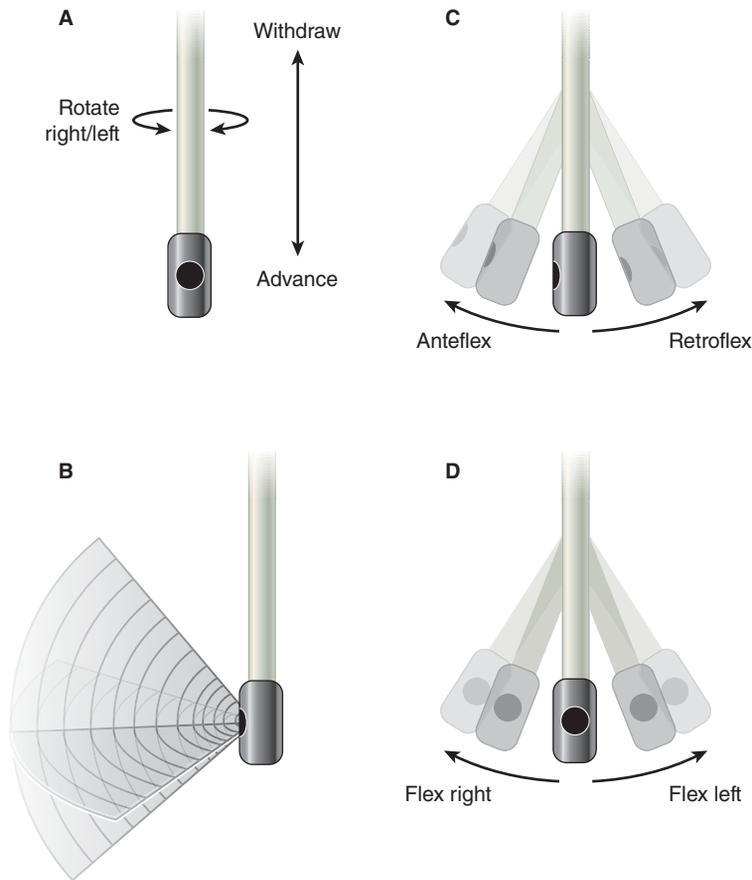

FIGURE 5-30 The echo probe is manipulated by the examiner in multiple ways to create the standard images that constitute the comprehensive perioperative tee examination. At all times never force the probe. If resistance is encountered abandon the examination. Echocardiographic information can be provided by intraoperative epicardial and epi-aortic examination. Advancing the probe in the esophagus permits the upper, mid and transgastric examinations (A). The probe can be turned in the esophagus from left to right to examine both left and right sided structures (A). Using the button located on the probe permits the echocardiographer to rotate the scan

beam through 180 degrees thereby creating various two dimensional imaging slices of the three dimensional heart (B). Lastly, panels (C) and (D) demonstrate manipulation of the tip of the probe to permit the beam to be directed to best visualize the image. (Modified and reproduced, with permission, from Shanewise JS, et.al. ASE/SCA guidelines for performing a comprehensive intraoperative multiplane transesophageal echocardiography examination; recommendations of the American Society of Echocardiography Council for Intraoperative Echocardiography and the Society for Cardiovascular Anesthesiologists Task Force for Certification in Perioperative Transesophageal Echocardiography. *Anesth Analg* 1999;89:870-884.)

maximal velocity (Figure 5-32). Using continuous wave Doppler, it is possible to determine the maximal velocity as blood accelerates through a pathologic heart structure. For example, a blood flow of

4 m/sec reflects a pressure gradient of 84 mm Hg between an area of slow flow (the left ventricular outflow tract) and a region of high flow (a stenotic aortic valve).

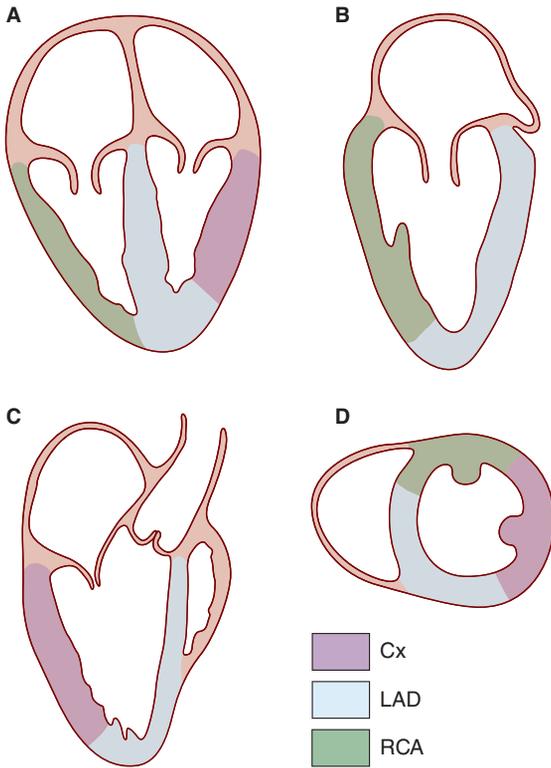

FIGURE 5-31 The midesophageal four-chamber view (A), the midesophageal two-chamber view (B), the midesophageal long-axis view (C), and the transgastric mid short-axis view (D) are depicted. The different views provide the opportunity to observe the myocardium supplied by each of the three main coronary vessels, the left circumflex (Cx), the left anterior descending (LAD) and the right coronary artery (RCA). Areas of impaired myocardial perfusion are suggested by the inability of the myocardium to both thicken and move inwardly during systole. Image D is very useful for monitoring in the operating room because left ventricular myocardium supplied by each of the three vessels can be seen in one image. (Modified and reproduced, with permission, from Shanewise JS, et.al. ASE/SCA guidelines for performing a comprehensive intraoperative multiplane transesophageal echocardiography examination; recommendations of the American Society of Echocardiography Council for Intraoperative Echocardiography and the Society for Cardiovascular Anesthesiologists Task Force for Certification in Perioperative Transesophageal Echocardiography. *Anesth Analg* 1999;89:870-884.)

Likewise, the Bernoulli equation permits echocardiographers to estimate PA and other intracavitary pressures, if assumptions are made.

$$\text{Assume } P_1 \gg P_2$$

Blood flow proceeds from an area of high pressure P_1 to an area of low pressure P_2 .

The pressure gradient = $4V^2$, where V is the maximal velocity measured in meters per second.

Thus,

$$4V^2 = P_1 - P_2$$

Thus, assuming that there is a jet of regurgitant blood flow from the left ventricle into the left atrium and that left ventricular systolic pressure (P_1) is the same as systemic blood pressure (eg, no aortic stenosis), it is possible to calculate left atrial pressure (P_2). In this manner, echocardiographers can estimate intracavitary pressures when there are pressure gradients, measurable flow velocities between areas

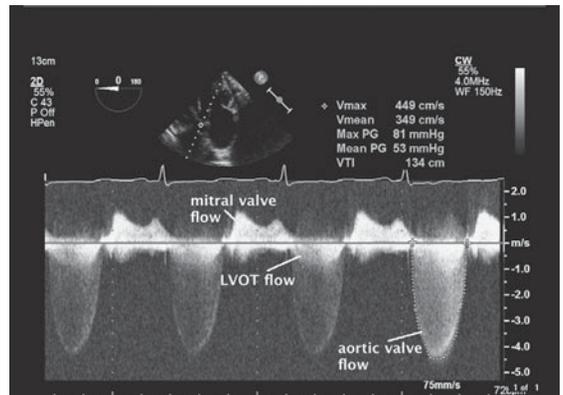

FIGURE 5-32 The time-velocity interval (TVI) of the aortic valve is calculated using continuous wave Doppler, while pulse wave Doppler is useful for measurements at lower blood velocities. This continuous wave Doppler has been aligned parallel to that aortic valve flow as imaged using the deep transgastric view. Of note, the bold velocity across the aortic valve is greater than 4 m/sec. (Redrawn and reproduced, with permission, from Wasnick J, Hillel Z, Kramer D, et al: *Cardiac Anesthesia & Transesophageal Echocardiography*, McGraw-Hill, 2011.)

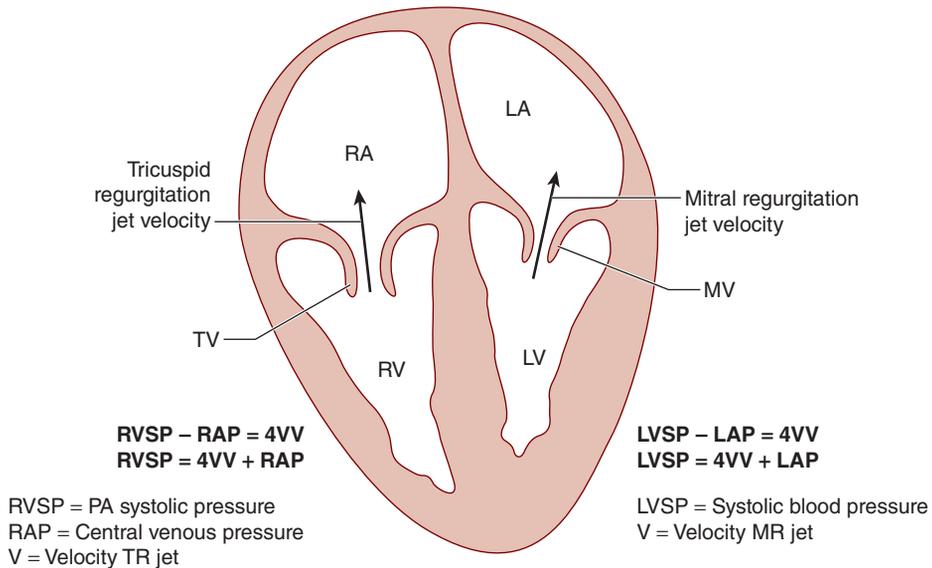

FIGURE 5-33 Intracavity pressures can be calculated using known pressures and the Bernoulli equation when regurgitant jets are present. The PA systolic pressure is obtained when tricuspid regurgitation is present and the right atrial pressure known. Assuming no pulmonic valve disease, the right ventricular systolic pressure and the pulmonary systolic pressure are the same. The left atrial

pressure can be similarly calculated if mitral regurgitation is present. Again, assuming no valvular disease LV systolic pressure should equal systemic systolic blood pressure. Subtracting $4V^2$ from the LVSP estimates the left atrial pressure. (Redrawn and reproduced, with permission, from Wasnick J, Hillel Z, Kramer D, et al: *Cardiac Anesthesia & Transesophageal Echocardiography*, McGraw-Hill, 2011.)

of high and low pressure, and knowledge of either P_1 or P_2 (Figure 5-33).

The Doppler principle is also used by echocardiographers to identify areas of abnormal flow using color flow Doppler. Color flow Doppler creates a visual picture of the heart's blood flow by assigning a color code to the velocities in the heart. Blood flow directed away from the echocardiographic transducer is color-coded blue, whereas that which is moving toward the probe is red. The higher the velocity of flow, the lighter the color hue (Figure 5-34). When the velocity of blood flow becomes greater than that which the machine can measure, flow toward the probe is misinterpreted as flow away from the probe, creating images of turbulent flow and "aliasing" of the image. Such changes in flow pattern are used by echocardiographers to identify areas of pathology.

Doppler can also be used to provide an estimate of SV and CO. Similar to esophageal Doppler probes

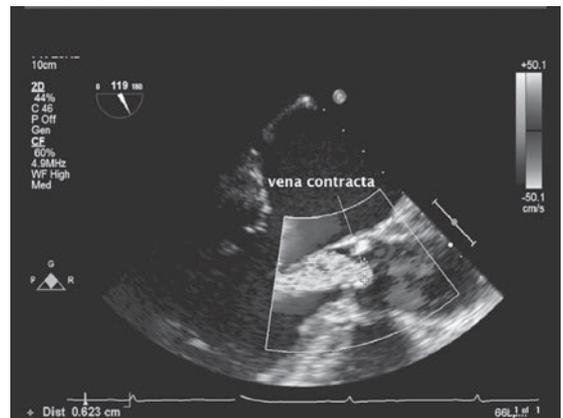

FIGURE 5-34 The color flow Doppler image of the mid-esophageal aortic valve long-axis view demonstrates measurement of the vena contracta of aortic regurgitation. The vena contracta represents the smallest diameter of the regurgitant jet at the level of the aortic valve. A vena contracta of 6.2 mm grades the aortic regurgitation in this case as severe. (Redrawn and reproduced, with permission, from Wasnick J, Hillel Z, Kramer D, et al: *Cardiac Anesthesia & Transesophageal Echocardiography*, McGraw-Hill, 2011.)

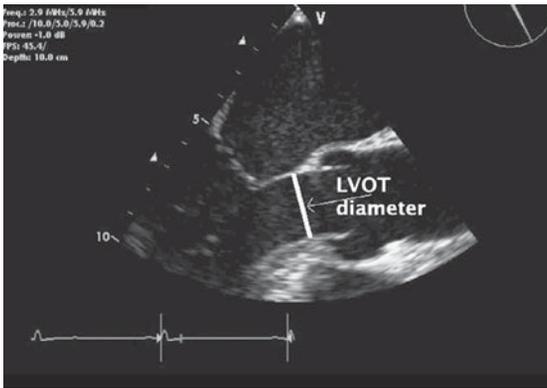

FIGURE 5-35 The midesophageal long-axis view is employed in this image to measure the diameter of the left ventricular outflow tract (LVOT). Knowing the diameter of the LVOT permits calculation of the LVOT area ($D^2 \times 0.785 = \text{LVOT area}$). (Redrawn and reproduced, with permission, from Wasnick J, Hillel Z, Kramer D, et al: *Cardiac Anesthesia & Transesophageal Echocardiography*, McGraw-Hill, 2011.)

previously described, TTE and TEE can be used to estimate CO. Assuming that the left ventricular outflow tract is a cylinder, it is possible to measure its diameter (Figure 5-35). Knowing this, it is possible to calculate the area through which blood flows using the following equation:

$$\text{Area} = \pi r^2 = 0.785 \times \text{diameter}^2$$

Next, the time velocity integral is determined. A Doppler beam is aligned in parallel with the left ventricular outflow tract (Figure 5-36). The velocities passing through the left ventricular outflow tract are recorded, and the machine integrates the velocity/time curve to determine the distance the blood traveled.

$$\text{Area} \times \text{length} = \text{volume}$$

In this instance, the SV is calculated:

$$\text{SV} \times \text{HR} = \text{CO}$$

Lastly, Doppler can be used to examine the movement of the myocardial tissue. Tissue velocity is normally 8–15 cm/sec (much less than that of

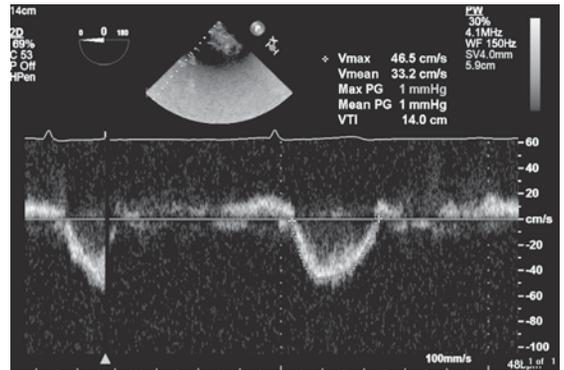

FIGURE 5-36 PW Doppler is employed in this deep transgastric view interrogation of the left ventricular outflow tract (LVOT). Blood is flowing in the LVOT away from the esophagus. Therefore, the flow velocities appear below the baseline. Flow velocity through the LVOT is 46.5 cm/s. This is as expected when there is no pathology noted as blood is ejected along the LVOT. Tracing the flow envelope (dotted lines) identifies the time-velocity interval (TVI). In this example the TVI is 14 cm. (Redrawn and reproduced, with permission, from Wasnick J, Hillel Z, Kramer D, et al: *Cardiac Anesthesia & Transesophageal Echocardiography*, McGraw-Hill, 2011.)

blood, which is 100 cm/s). Using the tissue Doppler function of the echo machine, it is possible to discern both the directionality and velocity of the heart's movement. During diastolic filling, the lateral annulus myocardium will move toward a TEE probe. Reduced myocardial velocities (<8 cm/s) are associated with impaired diastolic function and higher left ventricular end-diastolic pressures.

Ultimately, echocardiography can provide comprehensive cardiovascular monitoring. Its routine use outside of the cardiac operating room has been hindered by both the costs of the equipment and the training required to correctly interpret the images. As equipment becomes more readily available, it is likely that anesthesia staff will perform an increasing number of echocardiographic examinations for hemodynamic monitoring perioperatively. When questions arise beyond those related to hemodynamic guidance, interpretation by an individual credentialed in advanced perioperative echocardiography is warranted.

CASE DISCUSSION

Hemodynamic Monitoring and Management of a Complicated Patient

A 68-year-old male presents with a perforated colon secondary to diverticulitis. Vital signs are: heart rate, 120 beats/min; blood pressure, 80 mm Hg/55 mm Hg; respiratory rate, 28 breaths/min; and body temperature, 38 C°. He is scheduled for emergency exploratory laparotomy. His past history includes placement of a drug-eluting stent in the left anterior descending artery two weeks earlier. His medications include metoprolol and clopidogrel.

What hemodynamic monitors should be employed?

This patient presents with multiple medical issues that could lead to perioperative hemodynamic instability. He has a history of coronary artery disease for which he has been given stents. His previous and current ECGs should be reviewed for signs of new ST- and T-wave changes, heralding ischemia. He is both tachycardic and febrile, and, consequently, may be concurrently ischemic, vasodilated, and hypovolemic. All of these conditions could complicate perioperative management.

Arterial cannulation and monitoring will provide beat-to-beat blood pressure determinations intraoperatively and will also provide for blood gas measurements in a patient likely to be acidotic and hemodynamically unstable. Central venous access is obtained to permit volume resuscitation and to provide a port for delivery of fluid for transpulmonary measurements of CO and SV variation. Alternatively, pulse contour analysis can be employed from an arterial trace to determine volume responsiveness, should the patient become hemodynamically unstable. Echocardiography can be used to determine ventricular function, filling pressures, and CO and to provide surveillance for the development of ischemia-induced wall motion abnormalities.

PA catheters can also be placed to measure CO and pulmonary capillary occlusion pressure.

The choice of hemodynamic monitors remains with the individual physician and the availability of various monitoring techniques. It is important to also consider monitors that will be available in the postoperative setting to insure continuation of goal-directed therapy.

Noncardiovascular Monitoring

KEY CONCEPTS

- 1 Capnography rapidly and reliably indicates esophageal intubation—a common cause of anesthetic catastrophe—but does not detect bronchial intubation.
- 2 Close monitoring of neuromuscular blockade using both clinical and quantitative means can reduce the incidence of postoperative curarization.

The previous chapter reviewed routine hemodynamic monitoring used by anesthesiologists. This chapter examines the vast array of techniques and devices used perioperatively to monitor neuromuscular transmission, neurological condition, respiratory gas exchange, and body temperature.

Respiratory Gas Exchange Monitors

PRECORDIAL & ESOPHAGEAL STETHOSCOPES

Indications

Prior to the routine availability of gas exchange monitors, anesthesiologists used a precordial or esophageal stethoscope to ensure that the lungs were being ventilated in the event that the circuit became disconnected. Likewise, the heart tones could be auscultated to confirm a beating heart. Although less essential today because other modalities are available, the finger on the pulse and auscultation remain front-line monitors, especially when technology fails. Chest auscultation remains the primary method to confirm bilateral lung ventilation in the operating room, even if end tidal CO₂ detection

is the primary mechanism to exclude esophageal intubation.

Contraindications

Instrumentation of the esophagus should be avoided in patients with esophageal varices or strictures.

Techniques & Complications

A precordial stethoscope (Wenger chestpiece) is a heavy, bell-shaped piece of metal placed over the chest or suprasternal notch. Although its weight tends to maintain its position, double-sided adhesive disks provide an acoustic seal to the patient's skin. Various chestpieces are available, but the child size works well for most patients. The bell is connected to the anesthesiologist by extension tubing.

The esophageal stethoscope is a soft plastic catheter (8–24F) with balloon-covered distal openings (**Figure 6–1**). Although the quality of breath and heart sounds is much better than with a precordial stethoscope, its use is limited to intubated patients. Temperature probes, electrocardiogram (ECG) leads, ultrasound probes, and even atrial pacemaker electrodes have been incorporated into esophageal stethoscopes. Placement through the mouth or nose can occasionally cause mucosal irritation and bleeding. Rarely, the stethoscope slides into the trachea

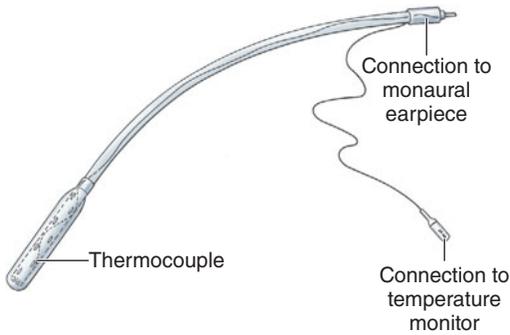

FIGURE 6-1 Esophageal stethoscope.

instead of the esophagus, resulting in a gas leak around the tracheal tube cuff.

Clinical Considerations

The information provided by a precordial or esophageal stethoscope includes confirmation of ventilation, quality of breath sounds (eg, stridor, wheezing), regularity of heart rate, and quality of heart tones (muffled tones are associated with decreased cardiac output).

The confirmation of bilateral breath sounds after tracheal intubation, however, is made with a binaural stethoscope.

PULSE OXIMETRY

Indications & Contraindications

Pulse oximeters are mandatory monitors for any anesthetic, including cases of moderate sedation. There are no contraindications.

Techniques & Complications

Pulse oximeters combine the principles of oximetry and plethysmography to noninvasively measure oxygen saturation in arterial blood. A sensor containing light sources (two or three light-emitting diodes) and a light detector (a photodiode) is placed across a finger, toe, earlobe, or any other perfused tissue that can be transilluminated. When the light source and detector are opposite one another across the perfused tissue, transmittance oximetry is used. When the light source and detector are placed on

the same side of the patient (eg, the forehead), the backscatter (reflectance) of light is recorded by the detector.

Oximetry depends on the observation that oxygenated and reduced hemoglobin differ in their absorption of red and infrared light (Lambert–Beer law). Specifically, oxyhemoglobin (HbO_2) absorbs more infrared light (940 nm), whereas deoxyhemoglobin absorbs more red light (660 nm) and thus appears blue, or cyanotic, to the naked eye. The change in light absorption during arterial pulsations is the basis of oximetric determinations (**Figure 6-2**). The ratio of the absorptions at the red and infrared wavelengths is analyzed by a microprocessor to provide the oxygen saturation (SpO_2) of arterial blood based on established norms. The greater the ratio of red/ infrared absorption, the lower the arterial saturation. Arterial pulsations are identified by plethysmography, allowing corrections for light absorption by nonpulsating venous blood and tissue. Heat from the light source or sensor pressure may, rarely, result in tissue damage if the monitor is not periodically moved. No user calibration is required.

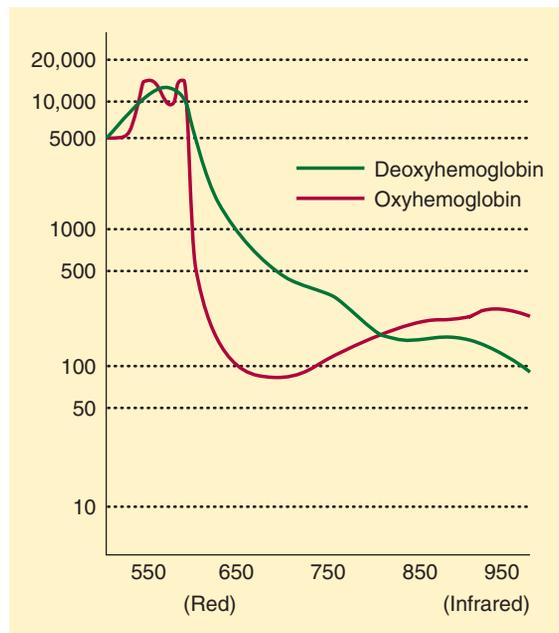

FIGURE 6-2 Oxyhemoglobin and deoxyhemoglobin differ in their absorption of red and infrared light.

Clinical Considerations

In addition to SpO_2 , pulse oximeters provide an indication of tissue perfusion (pulse amplitude) and measure heart rate. Because SpO_2 is normally close to 100%, only gross abnormalities are detectable in most anesthetized patients. Depending on a particular patient's oxygen-hemoglobin dissociation curve, a 90% saturation may indicate a PaO_2 of less than 65 mm Hg. This compares with clinically detectable cyanosis, which requires 5 g of desaturated hemoglobin and usually corresponds to an SpO_2 of less than 80%. Bronchial intubation will usually go undetected by pulse oximetry in the absence of lung disease or low fraction of inspired oxygen concentrations (FIO_2).

Because carboxyhemoglobin (COHb) and HbO_2 absorb light at 660 nm identically, pulse oximeters that compare only two wavelengths of light will register a falsely high reading in patients with carbon monoxide poisoning. Methemoglobin has the same absorption coefficient at both red and infrared wavelengths. The resulting 1:1 absorption ratio corresponds to a saturation reading of 85%. **Thus, methemoglobinemia causes a falsely low saturation reading when SaO_2 is actually greater than 85% and a falsely high reading if SaO_2 is actually less than 85%.**

Most pulse oximeters are inaccurate at low SpO_2 , and all demonstrate a delay between changes in SaO_2 and SpO_2 . **Other causes of pulse oximetry artifact include excessive ambient light, motion, methylene blue dye, venous pulsations in a dependent limb, low perfusion (eg, low cardiac output, profound anemia, hypothermia, increased systemic vascular resistance), malpositioned sensor, and leakage of light from the light-emitting diode to the photodiode, bypassing the arterial bed (optical shunting).** Nevertheless, pulse oximetry can be an invaluable aid to the rapid diagnosis of hypoxia, which may occur in unrecognized esophageal intubation, and it furthers the goal of monitoring oxygen delivery to vital organs. In the recovery room, pulse oximetry helps identify postoperative pulmonary problems, such as severe hypoventilation, bronchospasm, and atelectasis.

Two extensions of pulse oximetry technology are mixed venous blood oxygen saturation

(SvO_2) and noninvasive brain oximetry. The former requires the placement of a pulmonary artery catheter containing fiberoptic sensors that continuously determine SvO_2 in a manner analogous to pulse oximetry. Because SvO_2 varies with changes in hemoglobin concentration, cardiac output, arterial oxygen saturation, and whole-body oxygen consumption, its interpretation is somewhat complex. A variation of this technique involves placing the fiberoptic sensor in the internal jugular vein, which provides measurements of jugular bulb oxygen saturation in an attempt to assess the adequacy of cerebral oxygen delivery.

Noninvasive brain oximetry monitors regional oxygen saturation (rSO_2) of hemoglobin in the brain. A sensor placed on the forehead emits light of specific wavelengths and measures the light reflected back to the sensor (near-infrared optical spectroscopy). Unlike pulse oximetry, brain oximetry measures venous and capillary blood oxygen saturation in addition to arterial blood saturation. Thus, its oxygen saturation readings represent the average oxygen saturation of all regional microvascular hemoglobin (approximately 70%). Cardiac arrest, cerebral embolization, deep hypothermia, or severe hypoxia cause a dramatic decrease in rSO_2 . (See the section "Neurological System Monitors.")

CAPNOGRAPHY

Indications & Contraindications

Determination of end-tidal CO_2 ($EtCO_2$) concentration to confirm adequate ventilation is mandatory during all anesthetic procedures, but particularly so for general anesthesia. A rapid fall of $EtCO_2$ is a sensitive indicator of air embolism, a major complication of sitting craniotomies. There are no contraindications.

Techniques & Complications

Capnography is a valuable monitor of the pulmonary, cardiovascular, and anesthetic breathing systems. Capnographs in common use rely on the absorption of infrared light by CO_2 (Figure 6-3). As with oximetry, absorption of infrared light by CO_2 is governed by the Beer-Lambert law.

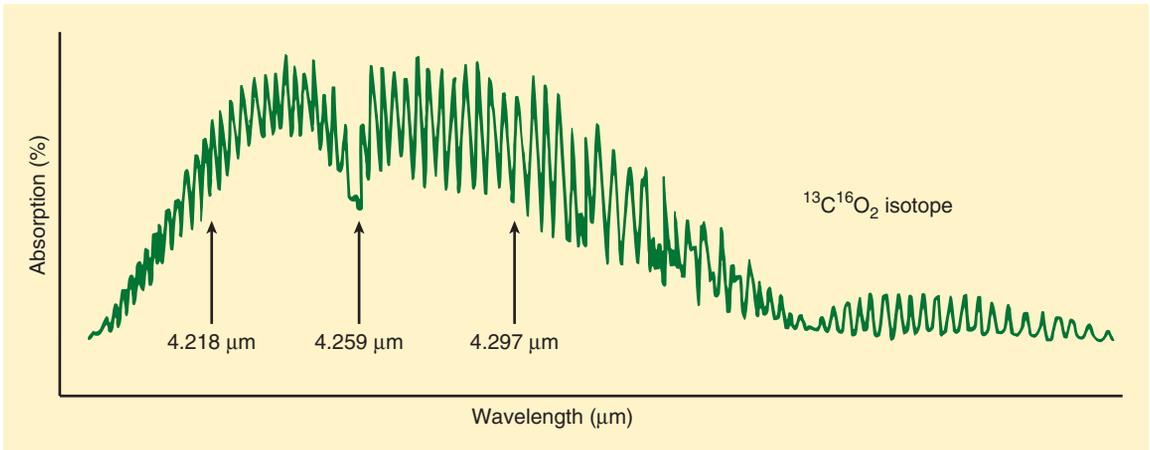

FIGURE 6-3 Absorption spectrum for CO_2 . (Reproduced, with permission, from Hill DW: *Methods of analysis in the gaseous and vapour phase*. In: *Scientific Foundations of Anesthesia*. Scurr C, Feldman S [editors]. Year Book, 1982, p 85.)

A. Nondiverting (Flowthrough)

Nondiverting (mainstream) capnographs measure CO_2 passing through an adaptor placed in the breathing circuit (Figure 6-4). Infrared light transmission through the gas is measured and CO_2 concentration is determined by the monitor. Because of problems with drift, older flowthrough models self-zeroed during inspiration. Thus, they were incapable

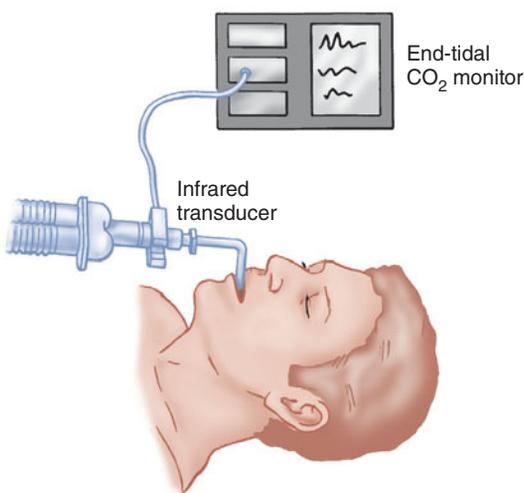

FIGURE 6-4 A nondiverting sensor placed in-line analyzes CO_2 concentration at the sampling site.

of detecting inspired CO_2 , such as would occur with a breathing circuit malfunction (eg, absorbent exhaustion, sticking unidirectional valves). The weight of the sensor causes traction on the tracheal tube, and its generation of radiant heat can cause skin burns. Newer designs address these problems.

B. Diverting (Aspiration)

Diverting (sidestream) capnographs continuously suction gas from the breathing circuit into a sample cell within the monitor. CO_2 concentration is determined by comparing infrared light absorption in the sample cell with a chamber free of CO_2 . Continuous aspiration of anesthetic gas essentially represents a leak in the breathing circuit that will contaminate the operating room unless it is scavenged or returned to the breathing system. High aspiration rates (up to 250 mL/min) and low-dead-space sampling tubing usually increase sensitivity and decrease lag time. If tidal volumes (V_T) are small (eg, pediatric patients), however, a high rate of aspiration may entrain fresh gas from the circuit and dilute EtCO_2 measurement. Low aspiration rates (less than 50 mL/min) can retard EtCO_2 measurement and underestimate it during rapid ventilation. New units autocalibrate, but older units must be zeroed to room air and against a known CO_2 concentration (usually 5%). Diverting units are prone to water precipitation in the aspiration tube and sampling cell that can cause

obstruction of the sampling line and erroneous readings. Expiratory valve malfunction is detected by the presence of CO_2 in inspired gas. Although inspiratory valve failure also results in rebreathing CO_2 , this is not as readily apparent because part of the inspiratory volume will still be free of CO_2 , causing the monitor to read zero during part of the inspiratory phase.

Clinical Considerations

Other gases (eg, nitrous oxide) also absorb infrared light, leading to a pressure-broadening effect. To minimize the error introduced by nitrous oxide, various modifications and filters have been incorporated into monitor design. Capnographs rapidly and reliably indicate esophageal intubation—a common cause of anesthetic catastrophe—but do not reliably detect bronchial intubation. Although there may be some CO_2 in the stomach from swallowing expired air, this should be washed out within a few breaths. Sudden cessation of CO_2 during the expiratory phase may indicate a circuit disconnection. The increased metabolic rate caused by malignant hyperthermia causes a marked rise in EtCO_2 .

The gradient between PaCO_2 and EtCO_2 (normally 2–5 mm Hg) reflects alveolar dead space (alveoli that are ventilated but not perfused). Any significant reduction in lung perfusion (eg, air embolism, decreased cardiac output, or decreased blood pressure) increases alveolar dead space, dilutes expired CO_2 , and lessens EtCO_2 . True capnographs (as opposed to capnometers) display a waveform of CO_2 concentration that allows recognition of a variety of conditions (Figure 6-5).

ANESTHETIC GAS ANALYSIS

Indications

Analysis of anesthetic gases is essential during any procedure requiring inhalation anesthesia. There are no contraindications to analyzing these gases.

Techniques

Techniques for analyzing multiple anesthetic gases involve mass spectrometry, Raman spectroscopy,

infrared spectrophotometry, or piezoelectric crystal (quartz) oscillation. Mass spectrometry and Raman spectroscopy are primarily of historical interest, as most anesthetic gases are now measured by infrared absorption analysis.

Infrared units use a variety of techniques similar to that described for capnography. These devices are all based on the Beer–Lambert law, which provides a formula for measuring an unknown gas within inspired gas because the absorption of infrared light passing through a solvent (inspired or expired gas) is proportional to the amount of the unknown gas. Oxygen and nitrogen do not absorb infrared light. There are a number of commercially available devices that use a single- or dual-beam infrared light source and positive or negative filtering. Because oxygen molecules do not absorb infrared light, their concentration cannot be measured with monitors that rely on infrared technology and, hence, it must be measured by other means (see below).

Clinical Considerations

A. Piezoelectric Analysis

The piezoelectric method uses oscillating quartz crystals, one of which is covered with lipid. Volatile anesthetics dissolve in the lipid layer and change the frequency of oscillation, which, when compared with the frequency of oscillation of an uncovered crystal, allows the concentration of the volatile anesthetic to be calculated. Neither these devices nor infrared photoacoustic analysis allow different anesthetic agents to be distinguished. New dual-beam infrared optical analyzers do allow gases to be separated and an improperly filled vaporizer to be detected.

B. Oxygen Analysis

To measure the FiO_2 of inhaled gas, manufacturers of anesthesia machines have relied on various technologies.

C. Galvanic Cell

Galvanic cell (fuel cell) contains a lead anode and gold cathode bathed in potassium chloride. At the gold terminal, hydroxyl ions are formed that react with the lead electrode (thereby gradually consuming it) to produce lead oxide, causing current, which is proportional to the amount of oxygen being

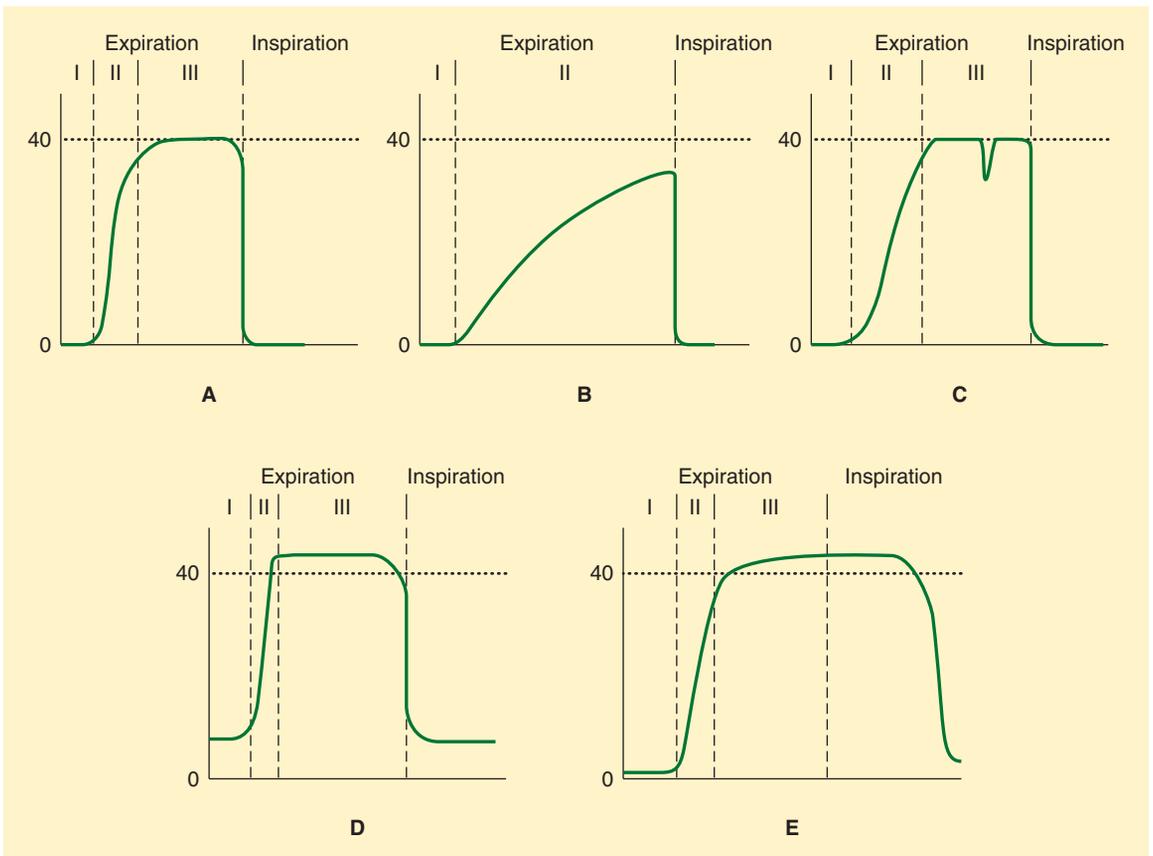

FIGURE 6-5 A: A normal capnograph demonstrating the three phases of expiration: phase I—dead space; phase II—mixture of dead space and alveolar gas; phase III—alveolar gas plateau. **B:** Capnograph of a patient with severe chronic obstructive pulmonary disease. No plateau is reached before the next inspiration. The gradient between end-tidal CO_2 and arterial CO_2 is increased.

C: Depression during phase III indicates spontaneous respiratory effort. **D:** Failure of the inspired CO_2 to return to zero may represent an incompetent expiratory valve or exhausted CO_2 absorbent. **E:** The persistence of exhaled gas during part of the inspiratory cycle signals the presence of an incompetent inspiratory valve.

measured, to flow. Because the lead electrode is consumed, monitor life can be prolonged by exposing it to room air when not in use. These are the oxygen monitors used on many anesthesia machines in the inspiratory limb.

D. Paramagnetic Analysis

Oxygen is a nonpolar gas, but it is paramagnetic, and when placed in a magnetic field, the gas will expand, contracting when the magnet is turned off. By switching the field on and off and comparing the

resulting change in volume (or pressure or flow) to a known standard, the amount of oxygen can be measured.

E. Polarographic Electrode

A polarographic electrode has a gold (or platinum) cathode and a silver anode, both bathed in an electrolyte, separated from the gas to be measured by a semipermeable membrane. Unlike the galvanic cell, a polarographic electrode works only if a small voltage is applied to two electrodes. When voltage

is applied to the cathode, electrons combine with oxygen to form hydroxide ions. The amount of current that flows between the anode and the cathode is proportional to the amount of oxygen present.

F. Spirometry

Newer anesthesia machines can measure (and therefore manage) airway pressures, volume, and flow to calculate resistance and compliance and to display the relationship of these variables as flow (ie, volume or pressure–volume loops). Measurements of flow and volume are made by mechanical devices that are usually fairly lightweight and are often placed in the inspiratory limb of the anesthesia circuit.

The most fundamental measurements include low peak inspiratory pressure and high peak inspiratory pressure, which indicate either a ventilator or circuit disconnect, or an airway obstruction, respectively. By measuring V_T and breathing frequency (f), exhaled minute ventilation (V_E) can be calculated, providing some sense of security that ventilation requirements are being met.

Spirometric loops and waveforms are characteristically altered by certain disease processes and events. If a normal loop is observed shortly after induction of anesthesia and a subsequent loop is different, the observant anesthesiologist is alerted to the fact that pulmonary and/or airway compliance may have changed. Spirometric loops are usually displayed as flow versus volume and volume versus pressure (Figure 6–6). There are characteristic changes with obstruction, bronchial intubation, reactive airways disease, and so forth.

Neurological System Monitors

ELECTROENCEPHALOGRAPHY

Indications & Contraindications

The electroencephalogram (EEG) is occasionally used during cerebrovascular surgery to confirm the adequacy of cerebral oxygenation. Monitoring the depth of anesthesia with a full 16-lead, 8-channel EEG is not warranted, considering the availability of simpler techniques. There are no contraindications.

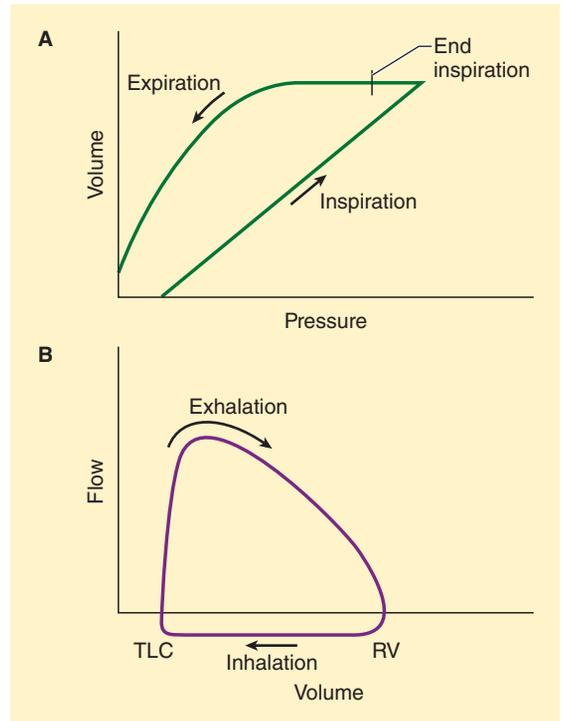

FIGURE 6–6 A: Normal volume–pressure loop. B: Normal flow–volume loop.

Techniques & Complications

The EEG is a recording of electrical potentials generated by cells in the cerebral cortex. Although standard ECG electrodes can be used, silver disks containing a conductive gel are preferred. Platinum or stainless steel needle electrodes traumatize the scalp and have high impedance (resistance); however, they can be sterilized and placed in a surgical field. Electrode position (montage) is governed by the international 10–20 system (Figure 6–7). Electric potential differences between combinations of electrodes are filtered, amplified, and displayed by an oscilloscope or pen recorder. EEG activity occurs mostly at frequencies between 1–30 cycles/sec (Hz). Alpha waves have a frequency of 8–13 Hz and are found often in a resting adult with eyes closed. Beta waves at 8–13 Hz are found in concentrating individuals, and at times, in individuals under anesthesia. Delta waves have a frequency of

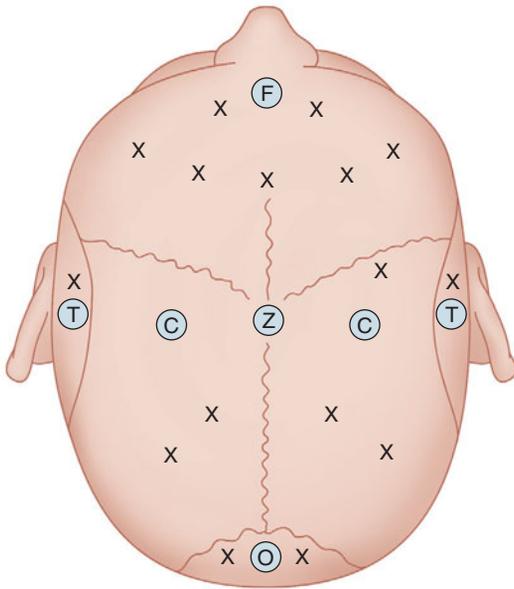

FIGURE 6-7 International 10–20 system. Montage letters refer to cranial location. F, frontal; C, coronal; T, temporal; O, occipital; Z, middle.

0.5–4 Hz and are found in brain injury, deep sleep, and anesthesia. Theta waves (4–7 Hz) are also found in sleeping individuals and during anesthesia. EEG waves are also characterized by their amplitude, which is related to their potential (high amplitude, >50 microV; medium amplitude, 20–50 microV; and low amplitude, <20 microV). Lastly, the EEG is examined as to symmetry between the left and right hemispheres.

Examination of a multichannel EEG is at times performed during surgery to detect areas of cerebral ischemia, such as during carotid endarterectomy as well as during epilepsy surgery. Likewise, it can be used to detect EEG isoelectricity and maximal cerebral protection during hypothermic arrest. The strip chart EEG is cumbersome in the operating room, and often the EEG is processed using power spectral analysis. Frequency analysis divides the EEG into a series of sine waves at different frequencies and then plots the power of the signal at each frequency, allowing for a presentation of EEG activity in a more manageable way than reviewing the raw EEG (**Figure 6-8**).

During inhalational anesthesia, initial beta activation is followed by slowing, burst suppression, and isoelectricity. Intravenous agents, depending on dose and drug used, can produce a variety of EEG patterns.

To reduce the incidence of anesthesia awareness, devices have been developed in recent years that process two-channel EEG signals and create a dimensionless variable to indicate wakefulness. Bispectral index (BIS) is most commonly used in this regard. BIS monitors examine four components within the EEG that are associated with the anesthetic state: (1) low frequency, as found during deep anesthesia; (2) high-frequency beta activation found during “light” anesthesia; (3) suppressed EEG waves; and (4) burst suppression.

Other devices attempt to include measures of spontaneous muscle activity, as influenced by the activity of subcortical structures not contributing to the EEG to further provide an assessment of anesthetic depth. Various devices, each with its own algorithm to process the EEG and/or incorporate other variables to ascertain patient wakefulness, may become available in the future (**Table 6-1**).

Controversy still exists as to the exact role of processed EEG devices in assessing anesthetic depth. Some studies have demonstrated a reduced awareness when these devices were used, whereas other studies have failed to reveal any advantage over the use of inhalational gas measurements to ensure a minimal alveolar concentration of anesthetic agent. Because individual EEG responsiveness to anesthetic agents may be variable, EEG monitors to assess anesthesia depth or to titrate anesthetic delivery might not always ensure an absence of wakefulness. Moreover, many monitors have a delay, which might only indicate a risk for the patient being aware after he or she had already become conscious (**Table 6-2**).

Clinical Considerations

To perform a bispectral analysis, data measured by EEG are taken through a number of steps (**Figure 6-9**) to calculate a single number that correlates with depth of anesthesia/hypnosis.

BIS values of 65–85 have been advocated as a measure of sedation, whereas values of 40–65

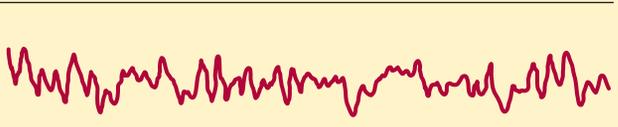

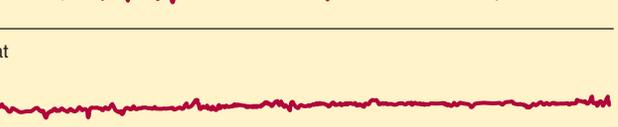

Patient State	Device	Features	Reading	Frontal Electroencephalography (EEG) Trace
Wakeful	EEG	$\uparrow f$, \downarrow Amp, blinks	$\uparrow \gamma, \beta, \alpha, \downarrow \theta, \delta$

have been recommended for general anesthesia (Figure 6-10). Bispectral analysis may reduce patient awareness during anesthesia, an issue that is important to the public.

Many of the initial studies of its use were not prospective, randomized, controlled trials, but were primarily observational in nature. Artifacts can be a

problem. The monitor, in and of itself, costs several thousand dollars and the electrodes are approximately \$10 to \$15 per anesthetic and cannot be reused.

Some cases with awareness have been identified as having a BIS of less than 65. However, in other cases of awareness, either there were problems with

TABLE 6-1 Characteristics of the commercially available monitors of anesthetic depth.

Parameters	Machine/ Manufacturer	Consumable	Physiologic Signals	Recommended Range of Values for Anesthesia	Principles of Measurement
Bispectral index (BIS)	A-2000/Aspect Medical Systems, Newton, MA	BIS sensor	Single channel EEG	40–60	BIS is derived from the weighted sum of three EEG parameters: relative α/β ratio; bio-coherence of the EEG waves; and burst suppression. The relative contribution of these parameters has been tuned to correlate with the degree of sedation produced by various sedative agents. BIS ranges from 0 (asleep)–100 (awake).
Patient state index (PSI)	Patient state analyzer (PSA 400)/ Physiometrix, Inc., N. Billerica, MA	PSArray ²	4-channel EEG	25–50	PSI is derived from progressive discriminant analysis of several quantitative EEG variables that are sensitive to changes in the level of anesthesia, but insensitive to the specific agents producing such changes. It includes changes in power spectrum in various EEG frequency bands; hemispheric symmetry; and synchronization between brain regions and the inhibition of regions of the frontal cortex. PSI ranges from 0 (asleep)-100 (awake).
Narcotrend stage Narcotrend index	Narcotrend monitor/ Monitor-Technik, Bad Bramstedt, Germany	Ordinary ECG electrode	1–2 channel EEG	Narcotrend stage D ₀₋₂ to C ₁ , which corresponds to an index of 40–60	The Narcotrend monitor classifies EEG signals into different stages of anesthesia (A = awake; B ₀₋₂ = sedated; C ₀₋₂ = light anesthesia; D ₀₋₂ = general anesthesia; E _{0,1} = general anesthesia with deep hypnosis; F _{0,1} = burst suppression). The classification algorithm is based on a discriminant analysis of entropy measures and EEG spectral variables. More recently the monitor converts the Narcotrend stages into a dimensionless number from 0 (asleep) to 100 (awake) by nonlinear regression.
Entropy	S/5 Entropy Module, M-ENTROPY/ Datex-Ohmeda, Instrumentarium Corp., Helsinki, Finland	Special entropy sensor	Single-channel EEG	40–60	Entropy described the 'irregularity' of the EEG signal. As the dose of anesthetic is increased, EEG becomes more regular and the entropy value approaches zero. M-ENTROPY calculates the entropy of the EEG spectrum (spectral entropy). In order to shorten the response time, it uses different time windows according to the corresponding EEG frequencies. Two spectral parameters are calculated: state entropy (frequency band 0–32 Hz) and response entropy (0–47 Hz), which also includes muscle activity. Both entropy variables have been re-scaled, so that 0 is asleep and 100 is awake.
Aline autoregressive index (AAI)	AEP/2 monitor/ Danmeter A/S, Odense, Demark	Ordinary ECG electrode	AEP	10–25	AAI is derived from the middle latency AEP (20–80 ms). AAI is extracted from an autoregressive model with exogenous input (ARX model) so that only 18 sweeps are required to reproduce the AEP waveform in 2–6 s. The resultant waveform is then transformed into a numeric index (0–100) that describes the shape of the AEP. AAI > 60 is awake, AAI of 0 indicates deep anesthesia.
Cerebral state index (CSI)	Cerebral state monitor (CSM), Danmeter A/S, Odense, Demark	Ordinary ECG electrode	Single-channel EEG	40–60	CSI is a weighted sum of (1) α ratio, (2) β ratio, (3) difference between the two and (4) burst suppression. It correlates with the degree of sedation by an 'adaptive neuro-fuzzy inference system'. CSI ranges from 0 (asleep) to 100 (awake).

TABLE 6-2 Checklist for preventing awareness.

- ✓ Check all equipment, drugs, and dosages; ensure that drugs are clearly labeled and that infusions are running into veins.
- ✓ Consider administering an amnesic premedication.
- ✓ Avoid or minimize the administration of muscle relaxants. Use a peripheral nerve stimulator to guide minimal required dose.
- ✓ Consider using the isolated forearm technique if intense paralysis is indicated.
- ✓ Choose potent inhalation agents rather than total intravenous anesthesia, if possible.
- ✓ Administer at least 0.5 to 0.7 minimum alveolar concentration (MAC) of the inhalation agent.
- ✓ Set an alarm for a low anesthetic gas concentration.
- ✓ Monitor anesthetic gas concentration during cardiopulmonary bypass from the bypass machine.
- ✓ Consider alternative treatments for hypotension other than decreasing anesthetic concentration.
- ✓ If it is thought that sufficient anesthesia cannot be administered because of concern about hemodynamic compromise, consider the administration of benzodiazepines or scopolamine for amnesia.
- ✓ Supplement hypnotic agents with analgesic agents such as opioids or local anesthetics, which may help decrease the experience of pain in the event of awareness.
- ✓ Consider using a brain monitor, such as a raw or processed electroencephalogram but do not try to minimize the anesthetic dose based on the brain monitor because there currently is insufficient evidence to support this practice.
- ✓ Monitor the brain routinely if using total intravenous anesthesia.
- ✓ Evaluate known risk factors for awareness, and if specific risk factors are identified consider increasing administered anesthetic concentration.
- ✓ Redose intravenous anesthesia when delivery of inhalation anesthesia is difficult, such as during a long intubation attempt or during rigid bronchoscopy.

Reproduced, with permission, from Mashour GA, Orser BA, Avidan MS: Intraoperative awareness: from neurobiology to clinical practice. *Anesthesiology* 2011;114:1218.

the recordings, or awareness could not be related to any specific time or BIS value. Whether this monitoring technique becomes a standard of care in the future remains to be seen, and studies are ongoing.

Detection of awareness often can minimize its consequences. Use of the Brice questions during postoperative visits can alert anesthesia providers

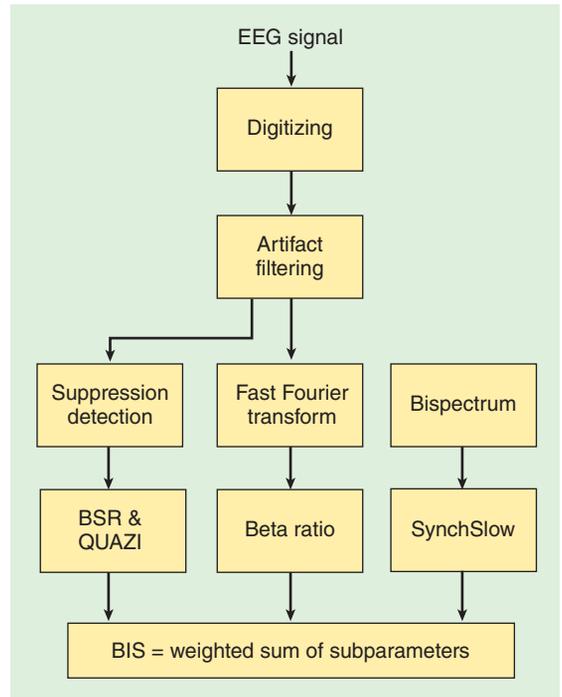

FIGURE 6-9 Calculation of the Bispectral Index. EEG, electroencephalogram; BSR, burst suppression ratio; BIS, Bispectral Index Scale. (Reproduced, with permission, from Rampil JJ: A primer for EEG signal processing in anesthesia. *Anesthesiology* 1998;89:980.)

of a potential awareness event. Ask patients to recall the following:

- What do you remember before going to sleep?
- What do you remember right when awakening?
- Do you remember anything in between going to sleep and awakening?
- Did you have any dreams while asleep?

Close follow-up and involvement of mental health experts may avoid the traumatic stress that can be associated with awareness events. Increasingly, patients are managed with regional anesthesia and propofol sedation. Patients undergoing such anesthetics should be made aware that they are not having general anesthesia and might recall perioperative events. Clarification of the techniques used may prevent patients so managed from the belief that they “were awake” during anesthesia.

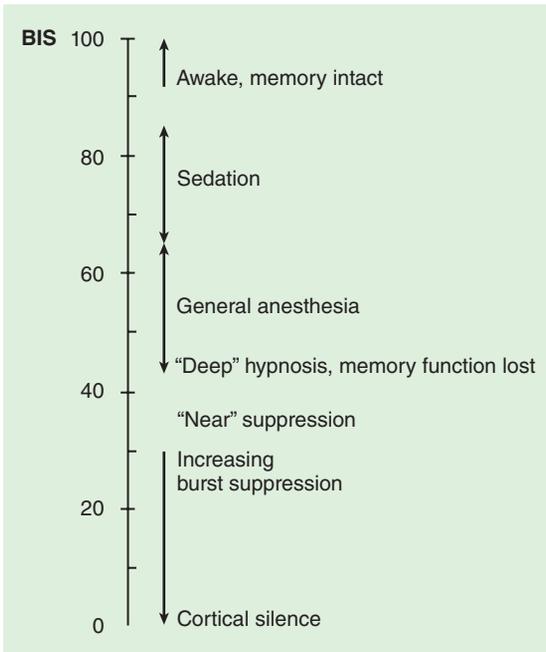

FIGURE 6-10 The Bispectral Index Scale (BIS versions 3.0 and higher) is a dimensionless scale from 0 (complete cortical electroencephalographic suppression) to 100 (awake). BIS values of 65–85 have been recommended for sedation, whereas values of 40–65 have been recommended for general anesthesia. At BIS values lower than 40, cortical suppression becomes discernible in a raw electroencephalogram as a burst suppression pattern. (Reproduced, with permission, from Johansen JW et al: Development and clinical application of electroencephalographic bispectrum monitoring. *Anesthesiology* 2000;93:1337.)

EVOKED POTENTIALS

Indications

Indications for intraoperative monitoring of **evoked potentials** (EPs) include surgical procedures associated with possible neurological injury: spinal fusion with instrumentation, spine and spinal cord tumor resection, brachial plexus repair, thoracoabdominal aortic aneurysm repair, epilepsy surgery, and cerebral tumor resection. Ischemia in the spinal cord or cerebral cortex can be detected by EPs. EP monitoring facilitates probe localization during stereotactic neurosurgery. Auditory EPs have also been used to assess the effects of general anesthesia

on the brain. The middle latency auditory EP may be a more sensitive indicator than BIS in regard to anesthetic depth. The amplitude and latency of this signal following an auditory stimulus is influenced by anesthetics.

Contraindications

Although there are no specific contraindications for somatosensory-evoked potentials (SEPs), this modality is severely limited by the availability of monitoring sites, equipment, and trained personnel. Sensitivity to anesthetic agents can also be a limiting factor, particularly in children. Motor-evoked potentials (MEPs) are contraindicated in patients with retained intracranial metal, a skull defect, and implantable devices, as well as after seizures and any major cerebral insult. Brain injury secondary to repetitive stimulation of the cortex and inducement of seizures is a concern with MEPs.

Techniques & Complications

EP monitoring noninvasively assesses neural function by measuring electrophysiological responses to sensory or motor pathway stimulation. Commonly monitored EPs are brainstem auditory evoked responses (BAERs), SEPs, and increasingly, MEPs (Figure 6-11).

For SEPs, a brief electrical current is delivered to a sensory or mixed peripheral nerve by a pair of electrodes. If the intervening pathway is intact, a nerve action potential will be transmitted to the contralateral sensory cortex to produce an EP. This potential can be measured by cortical surface electrodes, but is usually measured by scalp electrodes. To distinguish the cortical response to a specific stimulus, multiple responses are averaged and background noise is eliminated. EPs are represented by a plot of voltage versus time. The resulting waveforms are analyzed for their poststimulus latency (the time between stimulation and potential detection) and peak amplitude. These are compared with baseline tracings. Technical and physiological causes of a change in an EP must be distinguished from changes due to neural damage. Complications of EP monitoring are rare, but include skin irritation and pressure ischemia at the sites of electrode application.

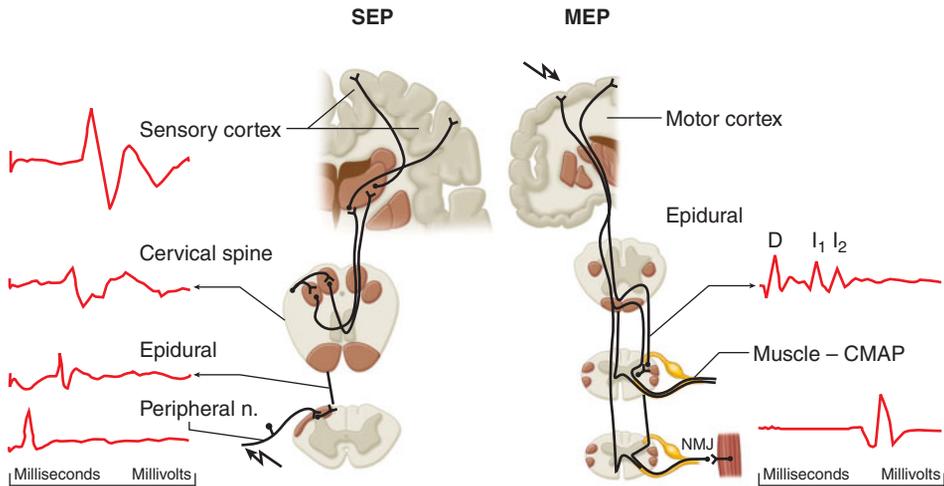

FIGURE 6-11 Neuroanatomic pathways of somatosensory-evoked potential and motor-evoked potential. The somatosensory-evoked potential (SEP) is produced by stimulation of a peripheral nerve wherein a response can be measured. The electrical volley ascends the spinal cord by the posterior columns and can be recorded in the epidural space and over the posterior cervical spine. It crosses the mid-line after synapsing at the cervicomedullary junction and ascends the lemniscal pathways having a second synapse in the thalamus. From there, it travels to the primary sensory cortex where the cortical response is measured. The motor-evoked potential (MEP) is produced

by stimulation of the motor cortex leading to an electrical volley that descends to the anterior horn cells of the spinal cord via the corticospinal tract. After synapsing there it travels via a peripheral nerve and crosses the neuromuscular junction (NMJ) to produce a muscle response. The MEP can be measured in the epidural space as D and I waves produced by direct and indirect (via internuncial neurons) stimulation of the motor cortex, respectively. It can also be measured as a compound muscle action potential (CMAP) in the muscle. (Reproduced, with permission, from Sloan TB, Janik D, Jameson L: Multimodality monitoring of the central nervous system using motor-evoked potentials. *Curr Opin Anaesthesiol.* 2008;21:560.)

Clinical Considerations

EPs are altered by many variables other than neural damage. The effect of anesthetics is complex and not easily summarized. **In general, balanced anesthetic techniques (nitrous oxide, neuromuscular blocking agents, and opioids) cause minimal changes, whereas volatile agents (halothane, sevoflurane, desflurane, and isoflurane) are best avoided or used at a constant low dose.** Early-occurring (specific) EPs are less affected by anesthetics than are late-occurring (nonspecific) responses. Changes in BAERs may provide a measure of the depth of anesthesia. Physiological (eg, blood pressure, temperature, and oxygen saturation) and pharmacological factors should be kept as constant as possible.

Persistent obliteration of EPs is predictive of postoperative neurological deficit. Although SEPs usually identify spinal cord damage, because of their different anatomic pathways, *sensory* (dorsal

spinal cord) EP preservation does not guarantee normal *motor* (ventral spinal cord) function (false negative). Furthermore, SEPs elicited from posterior tibial nerve stimulation cannot distinguish between peripheral and central ischemia (false positive). Techniques that elicit MEPs by using transcranial magnetic or electrical stimulation of the cortex allow the detection of action potentials in the muscles if the neural pathway is intact. The advantage of using MEPs as opposed to SEPs for spinal cord monitoring is that MEPs monitor the ventral spinal cord, and if sensitive and specific enough, can be used to indicate which patients might develop a postoperative motor deficit. MEPs are more sensitive to spinal cord ischemia than are SEPs. The same considerations for SEPs are applicable to MEPs in that they are affected by volatile inhalational agents, high-dose benzodiazepines, and moderate hypothermia (temperatures less than 32°C). MEPs

require monitoring of the level of neuromuscular blockade. Close communication with a neurophysiologist is essential prior to the start of any case where these monitors are used to review the optimal anesthetic technique to ensure monitoring integrity. MEPs are sensitive to volatile anesthetics. Consequently, intravenous techniques are often preferred.

CEREBRAL OXIMETRY AND OTHER MONITORS OF THE BRAIN

Cerebral oximetry uses near infrared spectroscopy (NIRS). Using reflectance spectroscopy near infrared light is emitted by a probe on the scalp (Figure 6–12). Receptors are likewise positioned to detect the reflected light from both deep and superficial structures. As with pulse oximetry, oxygenated and deoxygenated hemoglobin absorb light at different frequencies. Likewise, cytochrome absorbs infrared light in the mitochondria. The NIRS saturation largely reflects the absorption of venous hemoglobin, as it does not have the ability to identify the pulsatile arterial component. Regional saturations of less than 40% on NIRS measures, or changes of greater than 25% of baseline measures, may herald neurological events secondary to decreased cerebral oxygenation.

Measurements of jugular venous bulb saturation can also provide estimates of cerebral tissue oxygen extraction/decreased cerebral oxygen delivery. Reduced saturations may indicate poor outcomes. Direct tissue oxygen monitoring of the brain is accomplished by placement of a probe to determine the oxygen tension in the brain tissue. In addition to maintaining a cerebral perfusion pressure that is greater than 60 mm Hg and an intracranial pressure that is less than 20 mm Hg, neuroanesthesiologists/intensivists attempt to preserve brain tissue oxygenation by intervening when oxygen tissue tension is less than 20 mm Hg. Such interventions center upon improving oxygen delivery by increasing FIO_2 , augmenting hemoglobin, adjusting cardiac output, or decreasing oxygen demand.

Other Monitors

TEMPERATURE Indications

The temperature of patients undergoing anesthesia must be monitored. Postoperative temperature is increasingly used as a quality anesthesia indicator. Hypothermia is associated with delayed drug metabolism, increased blood glucose, vasoconstriction, impaired coagulation, and impaired resistance to surgical infections. Hyperthermia can likewise

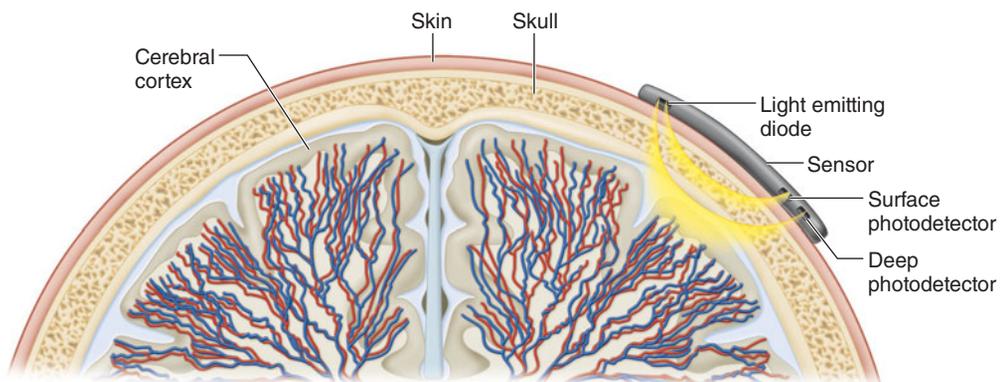

FIGURE 6–12 Principle of the INVOS® near-infrared spectroscopy technique. (Reproduced, with permission, from Rubio A, Hakami L, Münch F, Tandler R, Harig F, Weyand M: Noninvasive

control of adequate cerebral oxygenation during low-flow antegrade selective cerebral perfusion on adults and infants in the aortic arch surgery. *J Card Surg* 2008;23:474.)

have deleterious effects perioperatively, leading to tachycardia, vasodilation, and neurological injury. Consequently, temperature must be measured and recorded perioperatively.

Contraindications

There are no contraindications, although a particular monitoring site may be unsuitable in certain patients.

Techniques & Complications

Intraoperatively, temperature is usually measured using a thermistor or thermocouple. Thermistors are semiconductors whose resistance decreases predictably with warming. A thermocouple is a circuit of two dissimilar metals joined so that a potential difference is generated when the metals are at different temperatures. Disposable thermocouple and thermistor probes are available for monitoring the temperature of the tympanic membrane, nasopharynx, esophagus, bladder, rectum, and skin. Infrared sensors estimate temperature from the infrared energy that is produced. Tympanic membrane temperatures reflect core body temperature; however, the devices used may not reliably measure the temperature at the tympanic membrane. Complications of temperature monitoring are usually related to trauma caused by the probe (eg, rectal or tympanic membrane perforation).

Each monitoring site has advantages and disadvantages. The tympanic membrane theoretically reflects brain temperature because the auditory canal's blood supply is the external carotid artery. Trauma during insertion and cerumen insulation detract from the routine use of tympanic probes. Rectal temperatures have a slow response to changes in core temperature. Nasopharyngeal probes are prone to cause epistaxis, but accurately measure core temperature if placed adjacent to the nasopharyngeal mucosa. The thermistor on a pulmonary artery catheter also measures core temperature. There is a variable correlation between axillary temperature and core temperature, depending on skin perfusion. Liquid crystal adhesive strips placed on the skin are inadequate indicators of core body temperature during surgery. Esophageal temperature sensors, often incorporated into esophageal stethoscopes, provide

the best combination of economy, performance, and safety. To avoid measuring the temperature of tracheal gases, the temperature sensor should be positioned behind the heart in the lower third of the esophagus. Conveniently, heart sounds are most prominent at this location. For more on the clinical considerations of temperature control, see Chapter 52.

URINARY OUTPUT

Indications

Urinary bladder catheterization is the only reliable method of monitoring urinary output. Insertion of a urinary catheter is indicated in patients with congestive heart failure, renal failure, advanced hepatic disease, or shock. Catheterization is routine in some surgical procedures such as cardiac surgery, aortic or renal vascular surgery, craniotomy, major abdominal surgery, or procedures in which large fluid shifts are expected. Lengthy surgeries and intraoperative diuretic administration are other possible indications. Occasionally, postoperative bladder catheterization is indicated in patients having difficulty voiding in the recovery room after general or regional anesthesia.

Contraindications

Bladder catheterization should be done with utmost care in patients at high risk for infection.

Techniques & Complications

Bladder catheterization is usually performed by surgical or nursing personnel. To avoid unnecessary trauma, a urologist should catheterize patients suspected of having abnormal urethral anatomy. A soft rubber Foley catheter is inserted into the bladder transurethrally and connected to a disposable calibrated collection chamber. To avoid urine reflux and minimize the risk of infection, the chamber should remain at a level below the bladder. Complications of catheterization include urethral trauma and urinary tract infections. Rapid decompression of a distended bladder can cause hypotension. Suprapubic catheterization of the bladder with tubing inserted through a large-bore needle is an uncommon alternative.

Clinical Considerations

An additional advantage of placing a Foley catheter is the ability to include a thermistor in the catheter tip so that bladder temperature can be monitored. As long as urinary output is high, bladder temperature accurately reflects core temperature. An added value with more widespread use of urometers is the ability to electronically monitor and record urinary output and temperature.

Urinary output is a reflection of kidney perfusion and function and an indicator of renal, cardiovascular, and fluid volume status. Inadequate urinary output (oliguria) is often arbitrarily defined as urinary output of less than 0.5 mL/kg/hr, but actually is a function of the patient's concentrating ability and osmotic load. Urine electrolyte composition, osmolality, and specific gravity aid in the differential diagnosis of oliguria.

PERIPHERAL NERVE STIMULATION

Indications

Because of the variation in patient sensitivity to neuromuscular blocking agents, the neuromuscular function of all patients receiving intermediate- or long-acting neuromuscular blocking agents should be monitored. In addition, peripheral nerve stimulation is helpful in assessing paralysis during rapid-sequence inductions or during continuous infusions of short-acting agents. Furthermore, peripheral nerve stimulators can help locate nerves to be blocked by regional anesthesia.

Contraindications

There are no contraindications to neuromuscular monitoring, although certain sites may be precluded by the surgical procedure. Additionally, atrophied muscles in areas of hemiplegia or nerve damage may appear refractory to neuromuscular blockade secondary to the proliferation of receptors. Determining the degree of neuromuscular blockade using such an extremity could lead to potential overdosing of competitive neuromuscular blocking agents.

Techniques & Complications

A peripheral nerve stimulator delivers current (60–80 mA) to a pair of either ECG silver chloride pads or subcutaneous needles placed over a peripheral motor nerve. The evoked mechanical or electrical response of the innervated muscle is observed. Although electromyography provides a fast, accurate, and quantitative measure of neuromuscular transmission, visual or tactile observation of muscle contraction is usually relied upon in clinical practice. Ulnar nerve stimulation of the adductor pollicis muscle and facial nerve stimulation of the orbicularis oculi are most commonly monitored (Figure 6–13). Because it is the inhibition of the

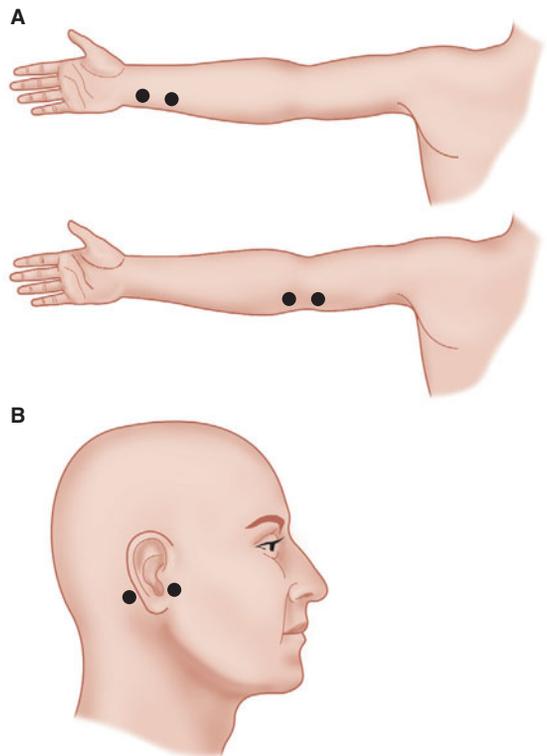

FIGURE 6–13 **A:** Stimulation of the ulnar nerve causes contraction of the adductor pollicis muscle. **B:** Stimulation of the facial nerve leads to orbicularis oculi contraction. The orbicularis oculi recovers from neuromuscular blockade before the adductor pollicis. (Reproduced, with permission, from Dorsch JA, Dorsch SE: *Understanding Anesthesia Equipment*, 4th ed. Williams & Wilkins, 1999.)

neuromuscular receptor that needs to be monitored, direct stimulation of muscle should be avoided by placing electrodes over the course of the nerve and not over the muscle itself. To deliver a supramaximal stimulation to the underlying nerve, peripheral nerve stimulators must be capable of generating at least a 50-mA current across a 1000- Ω load. This current is uncomfortable for a conscious patient. Complications of nerve stimulation are limited to skin irritation and abrasion at the site of electrode attachment.

Because of concerns of residual neuromuscular blockade, increased attention has been focused on providing quantitative measures of the degree of neuromuscular blockade perioperatively. Acceleromyography uses a piezoelectric transducer on the muscle to be stimulated. Movement of the muscle generates an electrical current that can be quantified and displayed. Indeed, acceleromyography can better predict residual paralysis, compared with routine tactile train-of-four monitoring used in most operating rooms, if calibrated from the beginning of the operative period to establish baselines prior to administration of neuromuscular blocking agents.

Clinical Considerations

The degree of neuromuscular blockade is monitored by applying various patterns of electrical stimulation (Figure 6-14). All stimuli are 200 μ s in duration and of square-wave pattern and equal current intensity. A twitch is a single pulse that is delivered from every 1 to every 10 sec (1–0.1 Hz). Increasing block results in decreased evoked response to stimulation.

Train-of-four stimulation denotes four successive 200- μ s stimuli in 2 sec (2 Hz). The twitches in a train-of-four pattern progressively fade as nondepolarizing muscle relaxant block increases. The ratio of the responses to the first and fourth twitches is a sensitive indicator of nondepolarizing muscle paralysis. Because it is difficult to estimate the train-of-four ratio, it is more convenient to visually observe the sequential disappearance of the twitches, as this also correlates with the extent of blockade. Disappearance of the fourth twitch represents a 75% block, the third twitch an 80% block,

and the second twitch a 90% block. Clinical relaxation usually requires 75% to 95% neuromuscular blockade.

Tetany at 50 or 100 Hz is a sensitive test of neuromuscular function. Sustained contraction for 5 sec indicates adequate—but not necessarily complete—reversal from neuromuscular blockade. Double-burst stimulation (DBS) represents two variations of tetany that are less painful to the patient. The DBS_{3,3} pattern of nerve stimulation consists of three short (200- μ s) high-frequency bursts separated by 20 ms intervals (50 Hz) followed 750 ms later by another three bursts. DBS_{3,2} consists of three 200- μ s impulses at 50 Hz followed 750 ms later by two such impulses. DBS is more sensitive than train-of-four stimulation for the clinical (ie, visual) evaluation of fade.

Because muscle groups differ in their sensitivity to neuromuscular blocking agents, use of the peripheral nerve stimulator cannot replace direct observation of the muscles (eg, the diaphragm) that need to be relaxed for a specific surgical procedure. Furthermore, recovery of adductor pollicis function does not exactly parallel recovery of muscles required to maintain an airway. **The diaphragm, rectus abdominis, laryngeal adductors, and orbicularis oculi muscles recover from neuromuscular blockade sooner than do the adductor pollicis.** Other indicators of adequate recovery include sustained (≥ 5 s) head lift, the ability to generate an inspiratory pressure of at least -25 cm H₂O, and a forceful hand grip. Twitch tension is reduced by hypothermia of the monitored muscle group (6%/°C). Decisions regarding adequacy of reversal of neuromuscular blockade, as well as timing of extubation, should be made only by considering both the patient's clinical presentation and assessments determined by peripheral nerve stimulation. Postoperative residual curarization (PORC) remains a problem in post-anesthesia care, producing potentially injurious airway and respiratory function compromise. Reversal of neuromuscular blocking agents is warranted, as is the use of intermediate acting neuromuscular blocking agents instead of longer acting drugs.

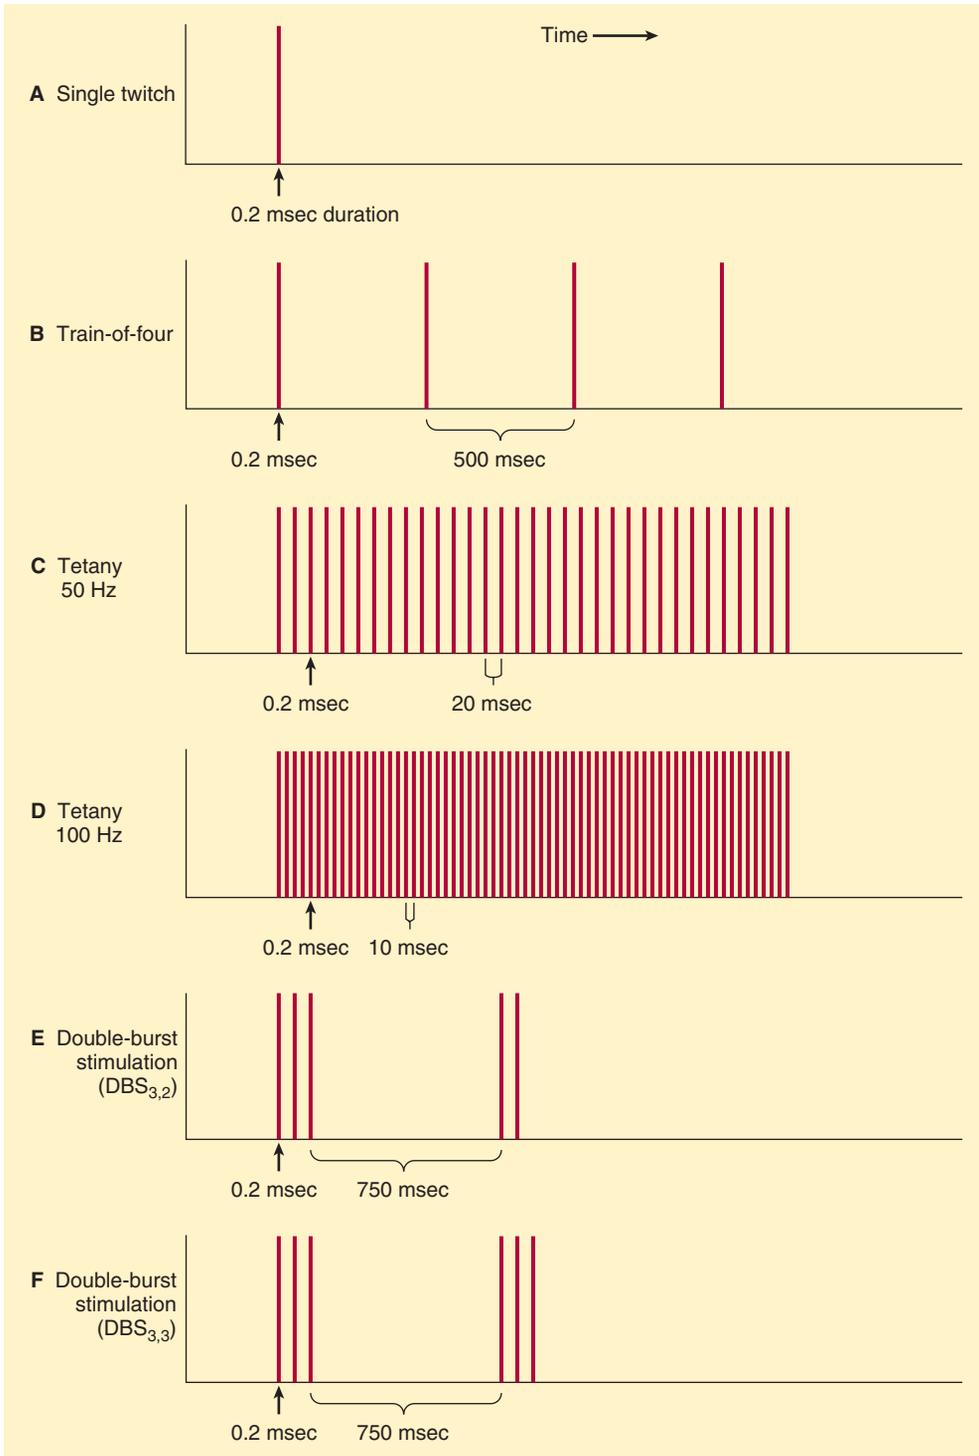

FIGURE 6-14 Peripheral nerve stimulators can generate various patterns of electrical impulses.

CASE DISCUSSION

Monitoring During Magnetic Resonance Imaging

A 50-year-old man with recent onset of seizures is scheduled for magnetic resonance imaging (MRI). A prior MRI attempt was unsuccessful because of the patient's severe claustrophobic reaction. The radiologist requests your help in providing either sedation or general anesthesia.

Why does the MRI suite pose special problems for the patient and the anesthesiologist?

MRI studies tend to be long (often more than 1 h) and many scanners totally surround the body, causing a high incidence of claustrophobia in patients already anxious about their health. Good imaging requires immobility, something that is difficult to achieve in many patients without sedation or general anesthesia.

Because the MRI uses a powerful magnet, no ferromagnetic objects can be placed near the scanner. This includes implanted prosthetic joints, artificial pacemakers, surgical clips, batteries, ordinary anesthesia machines, watches, pens, or credit cards. Ordinary metal lead wires for pulse oximeters or electrocardiography act as antennas and may attract enough radiofrequency energy to distort the MRI image or even cause patient burns. In addition, the scanner's magnetic field causes severe monitor artifact. The more powerful the scanner's magnet, as measured in Tesla units (1 T = 10,000 gauss), the greater the potential problem. Other obstacles include poor access to the patient during the imaging (particularly the patient's airway), hypothermia in pediatric patients, dim lighting within the patient tunnel, and very loud noise (up to 100 dB).

How have these monitoring and anesthesia machine problems been addressed?

Equipment manufacturers have modified monitors so that they are compatible with the MRI environment. These modifications include non-ferromagnetic electrocardiographic electrodes, graphite and copper cables, extensive filtering and gating of signals, extra-long blood pressure cuff

tubing, and use of fiberoptic technologies. Anesthesia machines with no ferromagnetic components (eg, aluminum gas cylinders) have been fitted with MRI-compatible ventilators and long circle systems or Mapleson D breathing circuits.

What factors influence the choice between general anesthesia and intravenous sedation?

Although most patients will tolerate an MRI study with sedation, head injured and pediatric patients present special challenges and will often require general anesthesia. Because of machine and monitoring limitations, an argument could be made that sedation, when possible, would be a safer choice. On the other hand, loss of airway control from deep sedation could prove catastrophic because of poor patient access and delayed detection. Other important considerations include the monitoring modalities available at a particular facility and the general medical condition of the patient.

Which monitors should be considered mandatory in this case?

The patient should receive at least the same level of monitoring and care in the MRI suite as in the operating room for a similarly noninvasive procedure. Thus, the American Society of Anesthesiologists Standards for Basic Anesthetic Monitoring (see Guidelines on next page) apply as they would to a patient undergoing general anesthesia.

Continuous auscultation of breath sounds with a plastic (not metal) precordial stethoscope can help to identify airway obstruction caused by excessive sedation. Palpation of a peripheral pulse or listening for Korotkoff sounds is impractical in this setting. Ensuring adequacy of circulation depends on electrocardiographic and oscillometric blood pressure monitoring. End-tidal CO₂ analyzers can be adapted to sedation cases by connecting the sampling line to a site near the patient's mouth or nose if nasal cannula with a CO₂ sampling channel are not available. Because room air entrainment precludes exact measurements, this technique provides a qualitative indicator of ventilation. Whenever sedation is planned, equipment for emergency conversion to general anesthesia (eg, tracheal tubes, resuscitation bag) must be immediately available.

Is the continuous presence of anesthesia personnel required during these cases?

Absolutely, yes. Sedated patients need to have continuous monitored anesthesia care to prevent a multitude of unforeseen complications, such as apnea or emesis.

7

Pharmacological Principles

KEY CONCEPTS

- 1 Drug molecules obey the law of mass action. When the plasma concentration exceeds the tissue concentration, the drug moves from the plasma into tissue. When the plasma concentration is less than the tissue concentration, the drug moves from the tissue back to plasma.
- 2 Most drugs that readily cross the blood–brain barrier (eg, lipophilic drugs like hypnotics and opioids) are avidly taken up in body fat.
- 3 Biotransformation is the chemical process by which the drug molecule is altered in the body. The liver is the primary organ of metabolism for drugs.
- 4 Small unbound molecules freely pass from plasma into the glomerular filtrate. The nonionized (uncharged) fraction of drug is reabsorbed in the renal tubules, whereas the ionized (charged) portion is excreted in urine.
- 5 Elimination half-life is the time required for the drug concentration to fall by 50%. For drugs described by multicompartment pharmacokinetics (eg, all drugs used in anesthesia), there are multiple elimination half-lives.
- 6 The offset of a drug's effect cannot be predicted from half-lives. The context-sensitive half-time is a clinically useful concept to describe the rate of decrease in drug concentration and should be used instead of half-lives to compare the pharmacokinetic properties of intravenous drugs used in anesthesia.

The clinical practice of anesthesiology is connected more directly than any other specialty to the science of clinical pharmacology. One would think, therefore, that the study of pharmacokinetics and pharmacodynamics would receive attention comparable to that given to airway assessment, choice of inhalation anesthetic for ambulatory surgery, or neuromuscular blockade in anesthesiology curricula and examinations. The frequent

misidentification or misuse of pharmacokinetic principles and measurements suggests that this is not the case.

PHARMACOKINETICS

Pharmacokinetics defines the relationships among drug dosing, drug concentration in body fluids and tissues, and time. It consists of four linked

processes: absorption, distribution, biotransformation, and excretion.

Absorption

Absorption defines the processes by which a drug moves from the site of administration to the bloodstream. There are many possible routes of drug administration: oral, sublingual, rectal, inhalational, transdermal, transmucosal, subcutaneous, intramuscular, and intravenous. Absorption is influenced by the physical characteristics of the drug (solubility, pK_a , diluents, binders, and formulation), dose, and the site of absorption (eg, gut, lung, skin, muscle). Bioavailability is the fraction of the administered dose reaching the systemic circulation. For example, nitroglycerin is well absorbed by the gastrointestinal tract but has low bioavailability when administered orally. The reason is that nitroglycerin undergoes extensive first-pass hepatic metabolism as it transits the liver before reaching the systemic circulation.

Oral drug administration is convenient, inexpensive, and relatively tolerant of dosing errors. However, it requires cooperation of the patient, exposes the drug to first-pass hepatic metabolism, and permits gastric pH, enzymes, motility, food, and other drugs to potentially reduce the predictability of systemic drug delivery.

Nonionized (uncharged) drugs are more readily absorbed than ionized (charged) forms. Therefore, an acidic environment (stomach) favors the absorption of acidic drugs ($A^- + H^+ \rightarrow AH$), whereas a more alkaline environment (intestine) favors basic drugs ($BH^+ \rightarrow H^+ + B$). Most drugs are largely absorbed from the intestine rather than the stomach because of the greater surface area of the small intestine and longer transit duration.

All venous drainage from the stomach and small intestine flows to the liver. As a result, the bioavailability of highly metabolized drugs may be significantly reduced by first-pass hepatic metabolism. Because the venous drainage from the mouth and esophagus flows into the superior vena cava rather than into the portal system, sublingual or buccal drug absorption bypasses the liver and first-pass metabolism. Rectal administration partly bypasses the portal system, and represents an alternative route in small children or patients who are unable to tolerate oral ingestion.

However, rectal absorption can be erratic, and many drugs irritate the rectal mucosa.

Transdermal drug administration can provide prolonged continuous administration for some drugs. However, the stratum corneum is an effective barrier to all but small, lipid-soluble drugs (eg, clonidine, nitroglycerin, scopolamine, fentanyl, and free-base local anesthetics [EMLA]).

Parenteral routes of drug administration include subcutaneous, intramuscular, and intravenous injection. Subcutaneous and intramuscular absorption depend on drug diffusion from the site of injection to the bloodstream. The rate at which a drug enters the bloodstream depends on both blood flow to the injected tissue and the injectate formulation. Drugs dissolved in solution are absorbed faster than those present in suspensions. Irritating preparations can cause pain and tissue necrosis (eg, intramuscular diazepam). Intravenous injections completely bypass the process of absorption.

Distribution

Once absorbed, a drug is distributed by the bloodstream throughout the body. Highly perfused organs (the so-called vessel-rich group) receive a disproportionate fraction of the cardiac output (Table 7-1). Therefore, these tissues receive a disproportionate amount of drug in the first minutes following drug administration. These tissues approach equilibration with the plasma concentration more quickly than less well perfused tissues due to the differences in

TABLE 7-1 Tissue group composition, relative body mass, and percentage of cardiac output.

Tissue Group	Composition	Body Mass (%)	Cardiac Output (%)
Vessel-rich	Brain, heart, liver, kidney, endocrine glands	10	75
Muscle	Muscle, skin	50	19
Fat	Fat	20	6
Vessel-poor	Bone, ligament, cartilage	20	0

blood flow. However, less well perfused tissues such as fat and skin may have enormous capacity to absorb lipophilic drugs, resulting in a large reservoir of drug following long infusions.

1 Drug molecules obey the law of mass action. When the plasma concentration exceeds the concentration in tissue, the drug moves from the plasma into tissue. When the plasma concentration is less than the concentration in tissue, the drug moves from the tissue back to plasma.

Distribution is a major determinant of end-organ drug concentration. The rate of rise in drug concentration in an organ is determined by that organ's perfusion and the relative drug solubility in the organ compared with blood. The equilibrium concentration in an organ relative to blood depends only on the relative solubility of the drug in the organ relative to blood, unless the organ is capable of metabolizing the drug.

Molecules in blood are either free or bound to plasma proteins and lipids. The free concentration equilibrates between organs and tissues. However, the equilibration between bound and unbound molecules is instantaneous. As unbound molecules of drug diffuse into tissue, they are instantly replaced by previously bound molecules. Plasma protein binding does not affect the rate of transfer directly, but it does affect relative solubility of the drug in blood and tissue. If the drug is highly bound in tissues, and unbound in plasma, then the relative solubility favors drug transfer into tissue. Put another way, a drug that is highly bound in tissue, but not in blood, will have a very large free drug concentration gradient driving drug into the tissue. Conversely, if the drug is highly bound in plasma and has few binding sites in the tissue, then transfer of a small amount of drug may be enough to bring the free drug concentration into equilibrium between blood and tissue. Thus, high levels of binding in blood relative to tissues increase the rate of onset of drug effect, because fewer molecules need to transfer into the tissue to produce an effective free drug concentration.

Albumin binds many acidic drugs (eg, barbiturates), whereas α_1 -acid glycoprotein (AAG) binds basic drugs (local anesthetics). If the concentrations of these proteins are diminished or (typically less important) if the protein-binding sites are occupied

by other drugs, then the relative solubility of the drugs in blood is decreased, increasing tissue uptake. Kidney disease, liver disease, chronic congestive heart failure, and malignancies decrease albumin production. Trauma (including surgery), infection, myocardial infarction, and chronic pain increase AAG levels. Pregnancy is associated with reduced AAG concentrations. Note that these changes will have very little effect on propofol, which is administered with its own binding molecules (the lipid in the emulsion).

Lipophilic molecules can readily transfer between the blood and organs. Charged molecules are able to pass in small quantities into most organs. However, the blood–brain barrier is a special case. Permeation of the central nervous system by ionized drugs is limited by pericapillary glial cells and endothelial cell tight junctions. Most drugs that **2** readily cross the blood–brain barrier (eg, lipophilic drugs like hypnotics and opioids) are avidly taken up in body fat.

The time course of distribution of drugs into peripheral tissues is complex and can only be assessed with computer models. Following intravenous bolus administration, rapid distribution of drug from the plasma into peripheral tissues accounts for the profound decrease in plasma concentration observed in the first few minutes. For each tissue, there is a point in time at which the apparent concentration in the tissue is the same as the concentration in the plasma. The redistribution phase (for each tissue) follows this moment of equilibration. During redistribution, drug returns from peripheral tissues back into the plasma. This return of drug back to the plasma slows the rate of decline in plasma drug concentration.

Distribution generally contributes to rapid emergence by removing drug from the plasma for many minutes following administration of a bolus infusion. Following prolonged infusions, redistribution generally delays emergence as drug returns from tissue reservoirs to the plasma for many hours.

The complex process of drug distribution into and out of tissues is one reason that half-lives are clinically useless. The offset of a drug's clinical actions are best predicted by computer models using the context-sensitive half-time or decrement times. The *context-sensitive half-time* is the time required

for a 50% decrease in plasma drug concentration to occur following a pseudo steady-state infusion (in other words, an infusion that has continued long enough to yield nearly steady-state concentrations). Here the “context” is the duration of the infusion. The *context-sensitive decrement time* is a more generalized concept referring to any clinically relevant decreased concentration in any tissue, particularly the brain or effect site.

The volume of distribution, V_d , is the *apparent* volume into which a drug has “distributed” (ie, mixed). This volume is calculated by dividing a bolus dose of drug by the plasma concentration at time 0. In practice, the concentration used to define the V_d is often obtained by extrapolating subsequent concentrations back to “0 time” when the drug was injected, as follows:

$$V_d = \frac{\text{Bolus dose}}{\text{Concentration}_{\text{time}0}}$$

The concept of a single V_d does not apply to any intravenous drugs used in anesthesia. All intravenous anesthetic drugs are better modeled with at least two compartments: a central compartment and a peripheral compartment. The behavior of many of these drugs is best described using three compartments: a central compartment, a rapidly equilibrating peripheral compartment, and a slowly equilibrating peripheral compartment. The central compartment may be thought of as including the blood and any ultra-rapidly equilibrating tissues such as the lungs. The peripheral compartment is composed of the other body tissues. For drugs with two peripheral compartments, the rapidly equilibrating compartment comprises the organs and muscles, while the slowly equilibrating compartment roughly represents distribution of the drug into fat and skin. These compartments are designated V_1 (central), V_2 (rapid distribution), and V_3 (slow distribution). The volume of distribution at steady state, V_{dss} is the algebraic sum of these compartment volumes. V_1 is calculated by the above equation showing the relationship between volume, dose, and concentration. The other volumes are calculated through pharmacokinetic modeling.

A small V_{dss} implies that the drug has high aqueous solubility and will remain largely within the intravascular space. For example, the V_{dss} of

pancuronium is about 15 L in a 70-kg person, indicating that pancuronium is mostly present in body water, with little distribution into fat. However, the typical anesthetic drug is lipophilic, resulting in a V_{dss} that exceeds total body water (approximately 40 L). For example, the V_{dss} for fentanyl is about 350 L in adults, and the V_{dss} for propofol may exceed 5000 L. V_{dss} does not represent a real volume but rather reflects the volume into which the drug would need to distribute to account for the observed plasma concentration given the dose that was administered.

Biotransformation

3 Biotransformation is the chemical process by which the drug molecule is altered in the body. The liver is the primary organ of metabolism for drugs. The exception is esters, which undergo hydrolysis in the plasma or tissues. The end products of biotransformation are often (but not necessarily) inactive and water soluble. Water solubility allows excretion by the kidneys.

Metabolic biotransformation is frequently divided into phase I and phase II reactions. Phase I reactions convert a parent compound into more polar metabolites through oxidation, reduction, or hydrolysis. Phase II reactions couple (conjugate) a parent drug or a phase I metabolite with an endogenous substrate (eg, glucuronic acid) to form water-soluble metabolites that can be eliminated in the urine or stool. Although this is usually a sequential process, phase I metabolites may be excreted without undergoing phase II biotransformation, and a phase II reaction can precede or occur without a phase I reaction.

Hepatic clearance is the volume of blood or plasma (whichever was measured in the assay) cleared of drug per unit of time. The units of clearance are units of flow: volume per unit time. Clearance may be expressed in milliliters per minute, liters per hour, or any other convenient unit of flow.

If every molecule of drug that enters the liver is metabolized, then hepatic clearance will equal liver blood flow. This is true for very few drugs, although it is very nearly the case for propofol. For most drugs, only a fraction of the drug that enters the liver is removed. The fraction removed is called the *extraction ratio*. The hepatic clearance can therefore be expressed as the liver blood flow times the

extraction ratio. If the extraction ratio is 50%, then hepatic clearance is 50% of liver blood flow. The clearance of drugs efficiently removed by the liver (ie, having a high hepatic extraction ratio) is proportional to hepatic blood flow. For example, because the liver removes almost all of the propofol that goes through it, if the hepatic blood flow doubles, then the clearance of propofol doubles. Induction of liver enzymes has no effect on propofol clearance, because the liver so efficiently removes all of the propofol that goes through it. Even severe loss of liver tissue, as occurs in cirrhosis, has little effect on propofol clearance. Drugs such as propofol have flow-dependent clearance.

Many drugs have low hepatic extraction ratios and are slowly cleared by the liver. For these drugs, the rate-limiting step is not the flow of blood to the liver, but rather the metabolic capacity of the liver itself. Changes in liver blood flow have little effect on the clearance of such drugs. However, if liver enzymes are induced, then clearance will increase because the liver has more capacity to metabolize the drug. Conversely, if the liver is damaged, then less capacity is available for metabolism and clearance is reduced. Drugs with low hepatic extraction ratios thus have capacity-dependent clearance. The extraction ratios of methadone and alfentanil are 10% and 15% respectively, making these capacity-dependent drugs.

Excretion

Some drugs and many drug metabolites are excreted by the kidneys. Renal clearance is the rate of elimination of a drug from the body by kidney excretion. This concept is analogous to hepatic clearance, and similarly, renal clearance can be expressed as the renal blood flow times the renal extraction ratio.

4 Small unbound drugs freely pass from plasma into the glomerular filtrate. The nonionized (uncharged) fraction of drug is reabsorbed in the renal tubules, whereas the ionized (charged) portion is excreted in urine. The fraction of drug ionized depends on the pH; thus renal elimination of drugs that exist in ionized and nonionized forms depends in part on urinary pH. The kidney actively secretes some drugs into the renal tubules.

Many drugs and drug metabolites pass from the liver into the intestine via the biliary system. Some

drugs excreted into the bile are then reabsorbed in the intestine, a process called *enterohepatic recirculation*. Occasionally metabolites excreted in bile are subsequently converted back to the parent drug. For example, lorazepam is converted by the liver to lorazepam glucuronide. In the intestine, β -glucuronidase breaks the ester linkage, converting lorazepam glucuronide back to lorazepam.

Compartment Models

Multicompartment models provide a mathematical framework that can be used to relate drug dose to changes in drug concentrations over time. Conceptually, the compartments in these models are tissues with a similar distribution time course. For example, the plasma and lungs are components of the central compartment. The organs and muscles, sometimes called the vessel-rich group, could be the second, or rapidly equilibrating, compartment. Fat and skin have the capacity to bind large quantities of lipophilic drug but are poorly perfused. These could represent the third, or slowly equilibrating, compartment. This is an intuitive definition of compartments, and it is important to recognize that the compartments of a pharmacokinetic model are mathematical abstractions that relate dose to observed concentration. A one-to-one relationship does not exist between any compartment and any organ or tissue in the body.

Many drugs used in anesthesia are well described by a two-compartment model. This is generally the case if the studies used to characterize the pharmacokinetics do not include rapid arterial sampling over the first few minutes (**Figure 7-1**). Without rapid arterial sampling the ultra-rapid initial drop in plasma concentration immediately after a bolus injection is missed, and the central compartment volume is blended into the rapidly equilibrating compartment. When rapid arterial sampling is used in pharmacokinetic experiments, the results are generally a three-compartment model. In these cases the number of identifiable compartments is a function of the experimental design and not a characteristic of the drug.

In compartmental models the instantaneous concentration at the time of a bolus injection is assumed to be the amount of the bolus divided by the central compartment volume. This is not

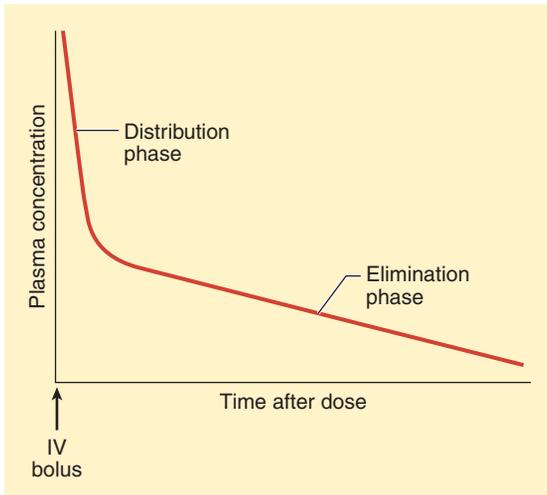

FIGURE 7-1 Two-compartment model demonstrates the distribution phase (α phase) and the elimination phase (β phase). During the distribution phase, the drug moves from the central compartment to the peripheral compartment. The elimination phase consists of metabolism and excretion.

correct. If the bolus is given over a few seconds, the instantaneous concentration is 0, because the drug is all in the vein, still flowing to the heart. It takes only a minute or two for the drug to mix in the central compartment volume. This misspecification is common to conventional pharmacokinetic models. More physiologically based models, sometimes called *front-end kinetic models*, can characterize the initial delay in concentration. These models are useful only if the concentrations over the first few minutes are clinically important. After the first few minutes, front-end models resemble conventional compartmental models.

In the first few minutes following initial bolus administration of a drug, the concentration drops very rapidly as the drug quickly diffuses into peripheral compartments. The decline is typically an order of magnitude over 10 minutes. For drugs with very rapid hepatic clearance (eg, propofol) or those that are metabolized in the blood (eg, remifentanyl), metabolism contributes significantly to the rapid initial drop in concentration. Following this very rapid drop there is a period of slower decrease in plasma concentration. During this period, the rapidly

equilibrating compartment is no longer removing drug from the plasma. Instead, drug returns to the plasma from the rapidly equilibrating compartment. The reversed role of the rapidly equilibrating tissues from extracting drug to returning drug accounts for the slower rate of decline in plasma concentration in this intermediate phase. Eventually there is an even slower rate of decrease in plasma concentration, which is log-linear until the drug is completely eliminated from the body. This terminal log-linear phase occurs after the slowly equilibrating compartment shifts from net removal of drug from the plasma to net return of drug to the plasma. During this terminal phase the organ of elimination (typically the liver) is exposed to the body's entire body drug load, which accounts for the very slow rate of decrease in plasma drug concentration during this final phase.

The mathematical models used to describe a drug with two or three compartments are, respectively:

$$Cp(t) = Ae^{-\alpha t} + Be^{-\beta t}$$

and

$$Cp(t) = Ae^{-\alpha t} + Be^{-\beta t} + Ce^{-\gamma t}$$

where $Cp(t)$ equals plasma concentration at time t , and α , β , and γ are the exponents that characterize the very rapid (ie, very steep), intermediate, and slow (ie, log-linear) portions of the plasma concentration over time, respectively. Drugs described by two-compartment and three-compartment models will have two or three half-lives. Each half-life is calculated as the natural log of 2 (0.693), divided by the exponent. The coefficients A , B , and C represent the contribution of each of the exponents to the overall decrease in concentration over time.

The two-compartment model is described by a curve with two exponents and two coefficients, whereas the three-compartment model is described by a curve with three exponents and three coefficients. The mathematical relationships among compartments, clearances, coefficients, and exponents are complex. Every coefficient and every exponent is a function of every volume and every clearance.

5 Elimination half-life is the time required for the drug concentration to fall by 50%. For drugs described by multicompartment pharmacokinetics

(eg, all drugs used in anesthesia), there are multiple elimination half-lives, in other words the elimination half-time is context dependent. The offset of a drug's effect cannot be predicted from half-lives. Moreover, one cannot easily determine how rapidly a drug effect will disappear simply by looking at coefficients, exponents, and half-lives. For example, the terminal half-life of sufentanil is about 10 h, whereas that of alfentanil is 2 h. This does not mean that recovery from alfentanil will be faster, because clinical recovery from clinical dosing will be influenced by all half-lives, not just the terminal one. Computer models readily demonstrate that recovery from an infusion lasting several hours will be faster when the drug administered is sufentanil than it will be when the infused drug is alfentanil. The time required for a 50% decrease in concentration depends on the duration or “context” of the infusion. The context-sensitive half-time, discussed earlier, captures this concept and should be used instead of half-lives to compare the pharmacokinetic properties of intravenous drugs used in anesthesia.

PHARMACODYNAMICS

Pharmacodynamics, the study of how drugs affect the body, involves the concepts of potency, efficacy, and therapeutic window. Pharmacokinetic models can range from entirely empirical dose versus response relationships to mechanistic models of ligand–receptor binding. The fundamental pharmacodynamic concepts are captured in the relationship between exposure to a drug and physiological response to the drug, often called the *dose–response* or *concentration–response relationship*.

Exposure–Response Relationships

As the body is exposed to an increasing amount of a drug, the response to the drug similarly increases, typically up to a maximal value. This fundamental concept in the exposure versus response relationship is captured graphically by plotting exposure (usually dose or concentration) on the x axis as the independent variable, and the body's response on the y axis as the dependent variable. Depending on the circumstances, the dose or concentration may be plotted on a linear scale (Figure 7–2A) or a logarithmic

scale (Figure 7–2B), while the response is typically plotted either as the actual measured response (Figure 7–2A) or as a fraction of the baseline or maximum physiological measurement (Figure 7–2B). For our purposes here, basic pharmacodynamic properties are described in terms of concentration, but any metric of drug exposure (dose, area under the curve, etc) could be used.

The shape of the relationship is typically sigmoidal, as shown in Figure 7–2. The sigmoidal

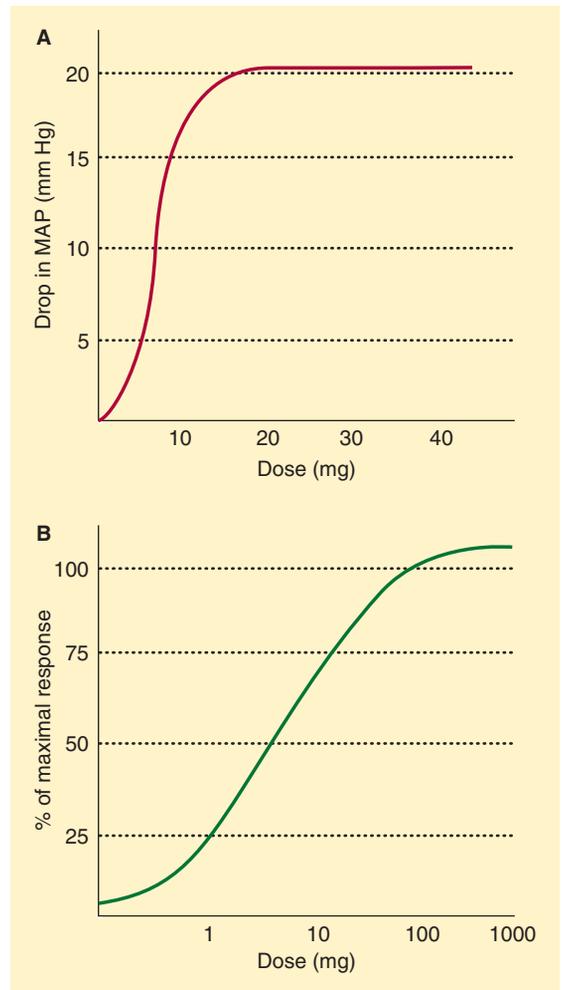

FIGURE 7-2 The shape of the dose–response curve depends on whether the dose or steady-state plasma concentration (C_{pss}) is plotted on a linear **A**: or logarithmic **B**: scale. MAP, mean arterial pressure.

shape reflects the observation that often a certain amount of drug must be present before there is any measurable physiological response. Thus, the left side of the curve is flat until the drug concentration reaches a minimum threshold. The right side is also flat, reflecting the maximum physiological response of the body, beyond which the body simply cannot respond to additional drug (with the possible exception of eating and weight). Thus, the curve is flat on both the left and right sides. A sigmoidal curve is required to connect the baseline to the asymptote, which is why sigmoidal curves are ubiquitous when modeling pharmacodynamics

The sigmoidal relationship between exposure and response is defined by one of two interchangeable relationships:

$$\text{Effect} = E_0 + E_{\max} \frac{C^\gamma}{C_{50}^\gamma + C^\gamma}$$

or

$$\text{Effect} = E_0 + (E_{\max} - E_0) \frac{C^\gamma}{C_{50}^\gamma + C^\gamma}$$

In both cases, E_0 is the baseline effect in the absence of drug, C is drug concentration, C_{50} is the concentration associated with half-maximal effect, and γ describes the steepness of the concentration versus response relationship. For the first equation, E_{\max} is the maximum change from baseline. In the second equation, E_{\max} is the maximum physiological measurement, not the maximum change from baseline.

Once defined in this fashion, each parameter of the pharmacodynamic model speaks to the specific concepts mentioned earlier. E_{\max} is related to the intrinsic efficacy of a drug. Highly efficacious drugs have a large maximum physiological effect, characterized by a large E_{\max} . For drugs that lack efficacy, E_{\max} will equal E_0 . C_{50} is a measure of drug potency. Highly potent drugs have a low C_{50} ; thus small amounts produce the drug effect. Drugs lacking potency have a high C_{50} , indicating that a large amount of drug is required to achieve the drug effect. The parameter γ indicates steepness of the relationship between concentration and effect. A γ value less than 1 indicates a very gradual increase in drug effect with increasing concentration. A

γ value greater than 4 suggests that once drug effect is observed, small increases in drug concentration produce large increases in drug effect until the maximum effect is reached.

The curve described above represents the relationship of drug concentration to a continuous physiological response. The same relationship can be used to characterize the probability of a binary (yes/no) response to a drug dose:

$$\text{Probability} = P_0 + (P_{\max} - P_0) \frac{C^\gamma}{C_{50}^\gamma + C^\gamma}$$

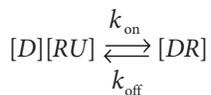

In this case, the probability (P) ranges from 0 (no chance) to 1 (certainty). P_0 is the probability of a “yes” response in the absence of drug. P_{\max} is the maximum probability, necessarily less than or equal to 1. As before, C is the concentration, C_{50} is the concentration associated with half-maximal effect, and γ describes the steepness of the concentration versus response relationship. Half-maximal effect is the same as 50% probability of a response when P_0 is 0 and P_{\max} is 1.

The *therapeutic window* for a drug is the range between the concentration associated with a desired therapeutic effect and the concentration associated with a toxic drug response. This range can be measured either between two different points on the same concentration versus response curve, or the distance between two distinct curves. For a drug such as sodium nitroprusside, a single concentration versus response curve defines the relationship between concentration and decrease in blood pressure. The therapeutic window might be the difference in the concentration producing a desired 20% decrease in blood pressure and a toxic concentration that produces a 60% decrease in blood pressure. However, for a drug such as lidocaine, the therapeutic window might be the difference between the C_{50} for local anesthesia and the C_{50} for lidocaine-induced seizures, the latter being a separate concentration versus response relationship. The therapeutic index is the C_{50} for toxicity divided by the C_{50} for the desired therapeutic effect. Because of the risk of ventilatory and cardiovascular depression (even at concentrations only slightly greater than those producing anesthesia), most inhaled and intravenous hypnotics are considered to have very low therapeutic indices relative to other drugs.

Drug Receptors

Drug receptors are macromolecules, typically proteins, that bind a drug (agonist) and mediate the drug response. Pharmacological antagonists reverse the effects of the agonist but do not otherwise exert an effect of their own. Competitive antagonism occurs when the antagonist competes with the agonist for the binding site, each potentially displacing the other. Noncompetitive antagonism occurs when the antagonist, through covalent binding or another process, permanently impairs the drug's access to the receptor.

The drug effect is governed by the fraction of receptors that are occupied by an agonist. That fraction is based on the concentration of the drug, the concentration of the receptor, and the strength of binding between the drug and the receptor. This binding is described by the law of mass action, which states that the reaction rate is proportional to the concentrations of the reactants:

where $[D]$ is the concentration of the drug, $[RU]$ is the concentration of unbound receptor, and $[DR]$ is the concentration of bound receptor. The rate constant k_{on} defines the rate of ligand binding to the receptor. The rate constant k_{off} defines the rate of ligand unbinding from the receptor. According to the law of mass action, the rate of receptor binding, $d[DR]/dt$ is:

$$\frac{d[DR]}{dt} = [D][RU]k_{\text{on}} - [DR]k_{\text{off}}$$

Steady state occurs almost instantly. Because the rate of formation at steady state is 0, it follows that:

$$[D][RU]k_{\text{on}} = [DR]k_{\text{off}}$$

In this equation, k_{d} is the dissociation rate constant, defined as $k_{\text{off}}/k_{\text{on}}$. If we define f , fractional receptor occupancy, as:

$$\frac{[DR]}{[DR] + [RU]}$$

then we can solve for receptor occupancy as:

$$f = \frac{[D]}{k_{\text{d}} + [D]}$$

The receptors are half occupied when $[D] = k_{\text{d}}$. Thus, k_{d} is the concentration of drug associated with 50% receptor occupancy.

Receptor occupancy is only the first step in mediating drug effect. Binding of the drug to the receptor can trigger a myriad of subsequent steps, including opening or closing of an ion channel, activation of a G protein, activation of an intracellular kinase, direct interaction with a cellular structure, or direct binding to DNA.

Like the concentration versus response curve, the shape of the curve relating fractional receptor occupancy to drug concentration is intrinsically sigmoidal. However, the concentration associated with 50% receptor occupancy and the concentration associated with 50% of maximal drug effect are not necessarily the same. Maximal drug effect could occur at very low receptor occupancy, or (for partial agonists) at greater than 100% receptor occupancy.

Prolonged binding and activation of a receptor by an agonist may lead to hyporeactivity ("desensitization") and tolerance. If the binding of an endogenous ligand is chronically blocked, then receptors may proliferate resulting in hyperreactivity and increased sensitivity.

Inhalation Anesthetics

KEY CONCEPTS

- 1 The greater the uptake of anesthetic agent, the greater the difference between inspired and alveolar concentrations, and the slower the rate of induction.
- 2 Three factors affect anesthetic uptake: solubility in the blood, alveolar blood flow, and the difference in partial pressure between alveolar gas and venous blood.
- 3 Low-output states predispose patients to overdosage with soluble agents, as the rate of rise in alveolar concentrations will be markedly increased.
- 4 Many of the factors that speed induction also speed recovery: elimination of rebreathing, high fresh gas flows, low anesthetic-circuit volume, low absorption by the anesthetic circuit, decreased solubility, high cerebral blood flow, and increased ventilation.
- 5 The unitary hypothesis proposes that all inhalation agents share a common mechanism of action at the molecular level. This is supported by the observation that the anesthetic potency of inhalation agents correlates directly with their lipid solubility (Meyer–Overton rule). There is an ongoing debate as to the mechanism of anesthetic action. Anesthetic interactions at specific protein ion channels, as well as more nonspecific membrane effects, may combine to produce the anesthetized state.
- 6 The minimum alveolar concentration (MAC) is the alveolar concentration of an inhaled anesthetic that prevents movement in 50% of patients in response to a standardized stimulus (eg, surgical incision).
- 7 Prolonged exposure to anesthetic concentrations of nitrous oxide can result in bone marrow depression (megaloblastic anemia) and even neurological deficiencies (peripheral neuropathies).
- 8 Halothane hepatitis is extremely rare (1 per 35,000 cases). Patients exposed to multiple halothane anesthetics at short intervals, middle-aged obese women, and persons with a familial predisposition to halothane toxicity or a personal history of toxicity are considered to be at increased risk. Desflurane and isoflurane undergo much less metabolism than halothane, resulting in fewer of the metabolite protein adducts that lead to immunologically mediated hepatic injury.
- 9 Isoflurane dilates coronary arteries, but is not nearly as potent a dilator as nitroglycerin or adenosine. Dilation of normal coronary arteries could theoretically divert blood away from fixed stenotic lesions.
- 10 The low solubility of desflurane in blood and body tissues causes a very rapid induction of and emergence from anesthesia.

—Continued next page

Continued—

- 11 Rapid increases in desflurane concentration lead to transient but sometimes worrisome elevations in heart rate, blood pressure, and catecholamine levels that are more pronounced than occur with isoflurane, particularly in patients with cardiovascular disease.
- 12 Nonpungency and rapid increases in alveolar anesthetic concentration make sevoflurane an excellent choice for smooth and rapid inhalation inductions in pediatric and adult patients.

Nitrous oxide, chloroform, and ether were the first universally accepted general anesthetics. Methoxyflurane and enflurane, two potent halogenated agents, were used for many years in North American anesthesia practice. Methoxyflurane was the most potent inhalation agent, but its high solubility and low vapor pressure yielded longer inductions and emergences. Up to 50% of it was metabolized by cytochrome P-450 (CYP) enzymes to free fluoride (F^-), oxalic acid, and other nephrotoxic compounds. Prolonged anesthesia with methoxyflurane was associated with a vasopressin-resistant, high-output, renal failure that was most commonly seen when F^- levels increased to greater than 50 $\mu\text{mol/L}$. Enflurane has a nonpungent odor and is nonflammable at clinical concentrations. It depresses myocardial contractility. It also increases the secretion of cerebrospinal fluid (CSF) and the resistance to CSF outflow. During deep anesthesia with hypocarbia electroencephalographic changes can progress to a spike-and-wave pattern producing tonic-clonic seizures. Because of these concerns, methoxyflurane and enflurane are no longer used.

Five inhalation agents continue to be used in clinical anesthesiology: nitrous oxide, halothane, isoflurane, desflurane, and sevoflurane.

The course of a general anesthetic can be divided into three phases: (1) induction, (2) maintenance, and (3) emergence. Inhalation anesthetics, such as halothane and sevoflurane, are particularly useful in the induction of pediatric patients in whom it may be difficult to start an intravenous line. Although adults are usually induced with intravenous agents, the nonpungency and rapid onset of sevoflurane

make inhalation induction practical for them as well. Regardless of the patient's age, anesthesia is often maintained with inhalation agents. Emergence depends primarily upon redistribution from the brain and pulmonary elimination of these agents.

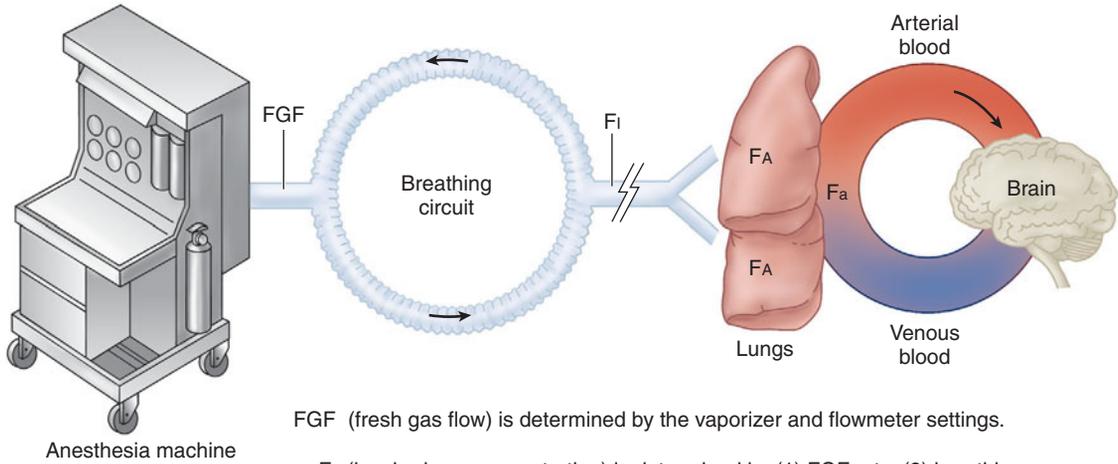

Because of their unique route of administration, inhalation anesthetics have useful pharmacological properties not shared by other anesthetic agents. For instance, administration via the pulmonary circulation allows a more rapid appearance of the drug in arterial blood than intravenous administration.

Pharmacokinetics of Inhalation Anesthetics

Although the mechanism of action of inhalation anesthetics is complex, likely involving numerous membrane proteins and ion channels, it is clear that producing their ultimate effect depends on attainment of a therapeutic tissue concentration in the central nervous system (CNS). There are many steps in between the anesthetic vaporizer and the anesthetic's deposition in the brain ([Figure 8-1](#)).

FACTORS AFFECTING INSPIRATORY CONCENTRATION (F_i)

The fresh gas leaving the anesthesia machine mixes with gases in the breathing circuit before being inspired by the patient. Therefore, the patient is not necessarily receiving the concentration set on the

FGF (fresh gas flow) is determined by the vaporizer and flowmeter settings.

F_i (inspired gas concentration) is determined by (1) FGF rate; (2) breathing-circuit volume; and (3) circuit absorption.

F_A (alveolar gas concentration) is determined by (1) uptake (uptake = $\lambda \cdot b/g \times C(A-V) \times Q$); (2) ventilation; and (3) the concentration effect and second gas effect:

- a) concentrating effect
- b) augmented inflow effect

F_a (arterial gas concentration) is affected by ventilation/perfusion mismatching.

FIGURE 8-1 Inhalation anesthetic agents must pass through many barriers between the anesthesia machine and the brain.

vaporizer. The actual composition of the inspired gas mixture depends mainly on the fresh gas flow rate, the volume of the breathing system, and any absorption by the machine or breathing circuit. The higher the fresh gas flow rate, the smaller the breathing system volume, and the lower the circuit absorption, the closer the inspired gas concentration will be to the fresh gas concentration. Clinically, these attributes translate into faster induction and recovery times.

FACTORS AFFECTING ALVEOLAR CONCENTRATION (F_A)

Uptake

If there were no uptake of anesthetic agent by the body, the alveolar gas concentration (F_A) would

rapidly approach the inspired gas concentration (F_i). Because anesthetic agents are taken up by the pulmonary circulation during induction, alveolar concentrations lag behind inspired concentrations ($F_A/F_i < 1.0$). The greater the uptake, the slower the rate of rise of the alveolar concentration and the lower the $F_A:F_i$ ratio.

Because the concentration of a gas is directly proportional to its partial pressure, the alveolar partial pressure will also be slow to rise. The alveolar partial pressure is important because it determines the partial pressure of anesthetic in the blood and, ultimately, in the brain. Similarly, the partial pressure of the anesthetic in the brain is directly proportional to its brain tissue concentration, which determines clinical effect.

1 Therefore, the greater the uptake of anesthetic agent, the greater the difference between inspired and alveolar concentrations, and the slower the rate of induction.

TABLE 8-1 Partition coefficients of volatile anesthetics at 37°C.¹

Agent	Blood/ Gas	Brain/ Blood	Muscle/ Blood	Fat/ Blood
Nitrous oxide	0.47	1.1	1.2	2.3
Halothane	2.4	2.9	3.5	60
Isoflurane	1.4	2.6	4.0	45
Desflurane	0.42	1.3	2.0	27
Sevoflurane	0.65	1.7	3.1	48

¹These values are averages derived from multiple studies and should be used for comparison purposes, not as exact numbers.

2 Three factors affect anesthetic uptake: solubility in the blood, alveolar blood flow, and the difference in partial pressure between alveolar gas and venous blood.

Relatively soluble agents, such as nitrous oxide, are taken up by the blood less avidly than more soluble agents, such as halothane. As a consequence, the alveolar concentration of nitrous oxide rises faster than that of halothane, and induction is faster. The relative solubilities of an anesthetic in air, blood, and tissues are expressed as partition coefficients (Table 8-1). Each coefficient is the ratio of the concentrations of the anesthetic gas in each of two phases at steady state. Steady state is defined as equal partial pressures in the two phases. For instance, the blood/gas partition coefficient ($\lambda_{b/g}$) of nitrous oxide at 37°C is 0.47. In other words, at steady state, 1 mL of blood contains 0.47 as much nitrous oxide as does 1 mL of alveolar gas, even though the partial pressures are the same. Stated another way, blood has 47% of the capacity for nitrous oxide as alveolar gas. Nitrous oxide is much less soluble in blood than is halothane, which has a blood/gas partition coefficient at 37°C of 2.4. Thus, almost five times more halothane than nitrous oxide must be dissolved to raise the partial pressure of blood. The higher the blood/gas coefficient, the greater the anesthetic's solubility and the greater its uptake by the pulmonary circulation. As a consequence of this increased solubility, alveolar partial pressure rises more slowly, and induction is prolonged. Because fat/blood partition coefficients are greater than 1, blood/gas solubility is

increased by postprandial lipidemia and is decreased by anemia.

The second factor that affects uptake is alveolar blood flow, which—in the absence of pulmonary shunting—is essentially equal to cardiac output. If the cardiac output drops to zero, so will anesthetic uptake. As cardiac output increases, anesthetic uptake increases, the rise in alveolar partial pressure slows, and induction is delayed. The effect of changing cardiac output is less pronounced for insoluble anesthetics, as so little is taken up regardless of alveolar blood flow. Low-output states predispose **3** patients to overdosage with soluble agents, as the rate of rise in alveolar concentrations will be markedly increased.

The final factor affecting uptake of anesthetic by the pulmonary circulation is the partial pressure difference between alveolar gas and venous blood. This gradient depends on tissue uptake. If anesthetics did not pass into organs such as the brain, venous and alveolar partial pressures would become identical, and there would be no pulmonary uptake. The transfer of anesthetic from blood to tissues is determined by three factors analogous to systemic uptake: tissue solubility of the agent (tissue/blood partition coefficient), tissue blood flow, and the difference in partial pressure between arterial blood and the tissue.

To better understand inhaled anesthetic uptake and distribution, tissues have been classified into four groups based on their solubility and blood flow (Table 8-2). The highly perfused vessel-rich group (brain, heart, liver, kidney, and endocrine organs) is

TABLE 8-2 Tissue groups based on perfusion and solubilities.

Characteristic	Vessel Rich	Muscle	Fat	Vessel Poor
Percentage of body weight	10	50	20	20
Percentage of cardiac output	75	19	6	0
Perfusion (mL/min/100 g)	75	3	3	0
Relative solubility	1	1	20	0

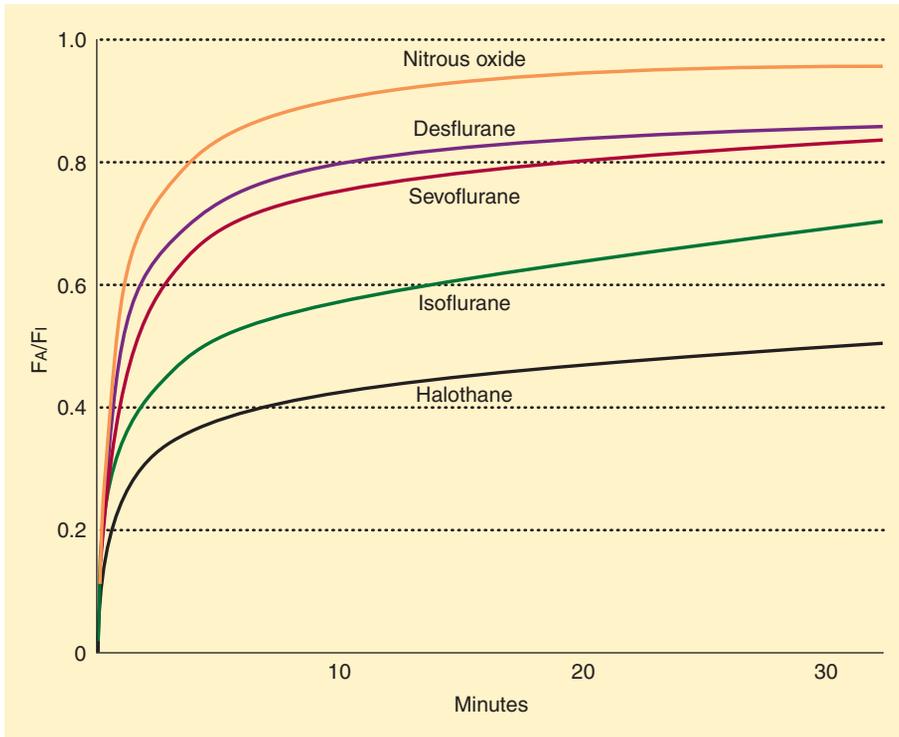

FIGURE 8-2 F_A rises toward F_I faster with nitrous oxide (an insoluble agent) than with halothane (a soluble agent). See Figure 8-1 for an explanation of F_A and F_I .

the first to encounter appreciable amounts of anesthetic. Moderate solubility and small volume limit the capacity of this group, so it is also the first to reach steady state (ie, arterial and tissue partial pressures are equal). The muscle group (skin and muscle) is not as well perfused, so uptake is slower. In addition, it has a greater capacity due to a larger volume, and uptake will be sustained for hours. Perfusion of the fat group nearly equals that of the muscle group, but the tremendous solubility of anesthetic in fat leads to a total capacity (tissue/blood solubility \times tissue volume) that would take days to approach steady state. The minimal perfusion of the vessel-poor group (bones, ligaments, teeth, hair, and cartilage) results in insignificant uptake.

Anesthetic uptake produces a characteristic curve that relates the rise in alveolar concentration to time (Figure 8-2). The shape of this graph is determined by the uptakes of individual tissue

groups (Figure 8-3). The initial steep rate of uptake is due to unopposed filling of the alveoli by ventilation. The rate of rise slows as the vessel-rich group—and eventually the muscle group—approach steady state levels of saturation.

Ventilation

The lowering of alveolar partial pressure by uptake can be countered by increasing alveolar ventilation. In other words, constantly replacing anesthetic taken up by the pulmonary bloodstream results in better maintenance of alveolar concentration. The effect of increasing ventilation will be most obvious in raising the F_A/F_I for soluble anesthetics, as they are more subject to uptake. Because the F_A/F_I very rapidly approaches 1.0 for insoluble agents, increasing ventilation has minimal effect. In contrast to the effect of anesthetics on cardiac output, anesthetics that depress spontaneous ventilation (eg, ether or

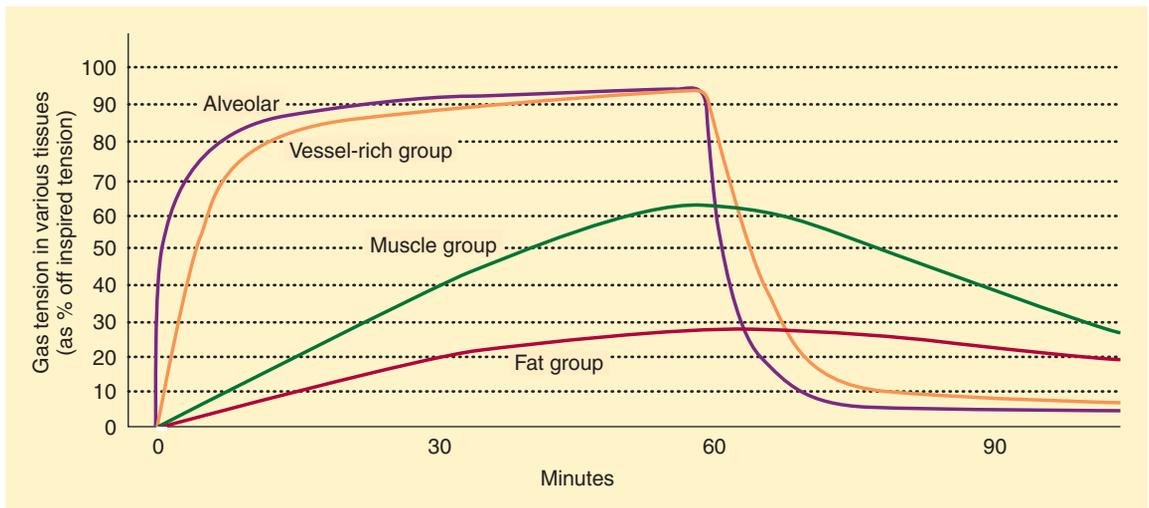

FIGURE 8-3 The rise and fall in alveolar partial pressure precedes that of other tissues. (Modified and reproduced, with permission, from Cowles AL et al: Uptake and distribution of inhalation anesthetic agents in clinical practice. *Anesth Analg* 1968;4:404.)

halothane) will decrease the rate of rise in alveolar concentration and create a negative feedback loop.

Concentration

The slowing of induction due to uptake from alveolar gas can be reduced by increasing the inspired concentration. Interestingly, increasing the inspired concentration not only increases the alveolar concentration, but also increases its rate of rise (ie, increases F_A/F_I), because of two phenomena (see Figure 8-1) that produce a so-called “concentrating effect.” First, if 50% of an anesthetic is taken up by the pulmonary circulation, an inspired concentration of 20% (20 parts of anesthetic per 100 parts of gas) will result in an alveolar concentration of 11% (10 parts of anesthetic remaining in a total volume of 90 parts of gas). On the other hand, if the inspired concentration is raised to 80% (80 parts of anesthetic per 100 parts of gas), the alveolar concentration will be 67% (40 parts of anesthetic remaining in a total volume of 60 parts of gas). Thus, even though 50% of the anesthetic is taken up in both examples, a higher inspired concentration results in a disproportionately higher alveolar concentration. In this example, increasing the inspired concentration 4-fold results in a 6-fold increase in alveolar concentration. The extreme case is an inspired concentration of 100%

(100 parts of 100), which, despite a 50% uptake, will result in an alveolar concentration of 100% (50 parts of anesthetic remaining in a total volume of 50 parts of gas).

The second phenomenon responsible for the concentration effect is the augmented inflow effect. Using the example above, the 10 parts of absorbed gas must be replaced by an equal volume of the 20% mixture to prevent alveolar collapse. Thus, the alveolar concentration becomes 12% (10 plus 2 parts of anesthetic in a total of 100 parts of gas). In contrast, after absorption of 50% of the anesthetic in the 80% gas mixture, 40 parts of 80% gas must be inspired. This further increases the alveolar concentration from 67% to 72% (40 plus 32 parts of anesthetic in a volume of 100 parts of gas).

The concentration effect is more significant with nitrous oxide, than with the volatile anesthetics, as the former can be used in much higher concentrations. Nonetheless, a high concentration of nitrous oxide will augment (by the same mechanism) not only its own uptake, but theoretically that of a concurrently administered volatile anesthetic. The concentration effect of one gas upon another is called the second gas effect, which is probably insignificant in the clinical practice of anesthesiology.

FACTORS AFFECTING ARTERIAL CONCENTRATION (F_a)

Ventilation/Perfusion Mismatch

Normally, alveolar and arterial anesthetic partial pressures are assumed to be equal, but in fact, the arterial partial pressure is consistently less than end-expiratory gas would predict. Reasons for this may include venous admixture, alveolar dead space, and nonuniform alveolar gas distribution. Furthermore, the existence of ventilation/perfusion mismatching will increase the alveolar–arterial difference. Mismatch acts as a restriction to flow: It raises the pressure in front of the restriction, lowers the pressure beyond the restriction, and reduces the flow through the restriction. The overall effect is an increase in the alveolar partial pressure (particularly for highly soluble agents) and a decrease in the arterial partial pressure (particularly for poorly soluble agents). Thus, a bronchial intubation or a right-to-left intracardiac shunt will slow the rate of induction with nitrous oxide more than with halothane.

FACTORS AFFECTING ELIMINATION

Recovery from anesthesia depends on lowering the concentration of anesthetic in brain tissue. Anesthetics can be eliminated by biotransformation, transcutaneous loss, or exhalation. Biotransformation usually accounts for a minimal increase in the rate of decline of alveolar partial pressure. Its greatest impact is on the elimination of soluble anesthetics that undergo extensive metabolism (eg, methoxyflurane). The greater biotransformation of halothane compared with isoflurane accounts for halothane's faster elimination, even though it is more soluble. The CYP group of isozymes (specifically CYP 2E1) seems to be important in the metabolism of some volatile anesthetics. Diffusion of anesthetic through the skin is insignificant.

4 The most important route for elimination of inhalation anesthetics is the alveolus. Many of the factors that speed induction also speed recovery: elimination of rebreathing, high fresh gas

flows, low anesthetic-circuit volume, low absorption by the anesthetic circuit, decreased solubility, high cerebral blood flow (CBF), and increased ventilation. Elimination of nitrous oxide is so rapid that alveolar oxygen and CO_2 are diluted. The resulting **diffusion hypoxia** is prevented by administering 100% oxygen for 5–10 min after discontinuing nitrous oxide. The rate of recovery is usually faster than induction because tissues that have not reached equilibrium will continue to take up anesthetic until the alveolar partial pressure falls below the tissue partial pressure. For instance, fat will continue to take up anesthetic and hasten recovery until the partial pressure exceeds the alveolar partial pressure. This redistribution is not as useful after prolonged anesthesia (fat partial pressures of anesthetic will have come “closer” to arterial partial pressures at the time the anesthetic was removed from fresh gas)—thus, the speed of recovery also depends on the length of time the anesthetic has been administered.

Pharmacodynamics of Inhalation Anesthetics

THEORIES OF ANESTHETIC ACTION

General anesthesia is an altered physiological state characterized by reversible loss of consciousness, analgesia, amnesia, and some degree of muscle relaxation. The multitude of substances capable of producing general anesthesia is remarkable: inert elements (xenon), simple inorganic compounds (nitrous oxide), halogenated hydrocarbons (halothane), ethers (isoflurane, sevoflurane, desflurane), and complex organic structures (propofol). A unifying theory explaining anesthetic action would have to accommodate this diversity of structure. In fact, the various agents probably produce anesthesia by differing sets of molecular mechanisms. Inhalational agents interact with numerous ion channels present in the CNS and peripheral nervous system. Nitrous oxide and xenon are believed to inhibit *N*-methyl-D-aspartate (NMDA) receptors. NMDA receptors are excitatory receptors in the brain. Other inhalational agents may interact at other receptors

(eg, gamma-aminobutyric acid [GABA]-activated chloride channel conductance) leading to anesthetic effects. Additionally, some studies suggest that inhalational agents continue to act in a nonspecific manner, thereby affecting the membrane bilayer. It is possible that inhalational anesthetics act on multiple protein receptors that block excitatory channels and promote the activity of inhibitory channels affecting neuronal activity, as well as by some nonspecific membrane effects.

There does not seem to be a single macroscopic site of action that is shared by all inhalation agents. Specific brain areas affected by various anesthetics include the reticular activating system, the cerebral cortex, the cuneate nucleus, the olfactory cortex, and the hippocampus; however, to be clear, general anesthetics bind throughout the CNS. Anesthetics have also been shown to depress excitatory transmission in the spinal cord, particularly at the level of the dorsal horn interneurons that are involved in pain transmission. Differing aspects of anesthesia may be related to different sites of anesthetic action. For example, unconsciousness and amnesia are probably mediated by cortical anesthetic action, whereas the suppression of purposeful withdrawal from pain may be related to subcortical structures, such as the spinal cord or brain stem. One study in rats revealed that removal of the cerebral cortex did not alter the potency of the anesthetic! Indeed, measures of minimal alveolar concentration (MAC), the anesthetic concentration that prevents movement in 50% of subjects or animals, are dependent upon anesthetic effects at the spinal cord and not at the cortex.

5 Past understanding of anesthetic action attempted to identify a unitary hypothesis of anesthetic effects. This hypothesis proposes that all inhalation agents share a common mechanism of action at the molecular level. This was previously supported by the observation that the anesthetic potency of inhalation agents correlates directly with their lipid solubility (Meyer–Overton rule). The implication is that anesthesia results from molecules dissolving at specific lipophilic sites. Of course, not all lipid-soluble molecules are anesthetics (some are actually convulsants), and the correlation between anesthetic potency and lipid solubility is only approximate (**Figure 8–4**).

Neuronal membranes contain a multitude of hydrophobic sites in their phospholipid bilayer. Anesthetic binding to these sites could expand the bilayer beyond a critical amount, altering membrane function (critical volume hypothesis). Although this theory is almost certainly an oversimplification, it explains an interesting phenomenon: the reversal of anesthesia by increased pressure. Laboratory animals exposed to elevated hydrostatic pressure develop a resistance to anesthetic effects. Perhaps the pressure is displacing a number of molecules from the membrane or distorting the anesthetic binding sites in the membrane, increasing anesthetic requirements. However, studies in the 1980s demonstrated the ability of anesthetics to inhibit protein actions, shifting attention to the numerous ion channels that might affect neuronal transmission and away from the critical volume hypothesis.

General anesthetic action could be due to alterations in any one (or a combination) of several cellular systems, including voltage-gated ion channels, ligand-gated ion channels, second messenger functions, or neurotransmitter receptors. For example, many anesthetics enhance GABA inhibition of the CNS. Furthermore, GABA receptor agonists seem to enhance anesthesia, whereas GABA antagonists reverse some anesthetic effects. There seems to be a strong correlation between anesthetic potency and potentiation of GABA receptor activity. Thus, anesthetic action may relate to binding in relatively hydrophobic domains in channel proteins (GABA receptors). Modulation of GABA function may prove to be a principal mechanism of action for many anesthetic drugs.

The glycine receptor α_1 -subunit, whose function is enhanced by inhalation anesthetics, is another potential anesthetic site of action.

The tertiary and quaternary structure of amino acids within an anesthetic-binding pocket could be modified by inhalation agents, perturbing the receptor itself, or indirectly producing an effect at a distant site.

Other ligand-gated ion channels whose modulation may play a role in anesthetic action include nicotinic acetylcholine receptors and NMDA receptors.

Investigations into mechanisms of anesthetic action are likely to remain ongoing for many years,

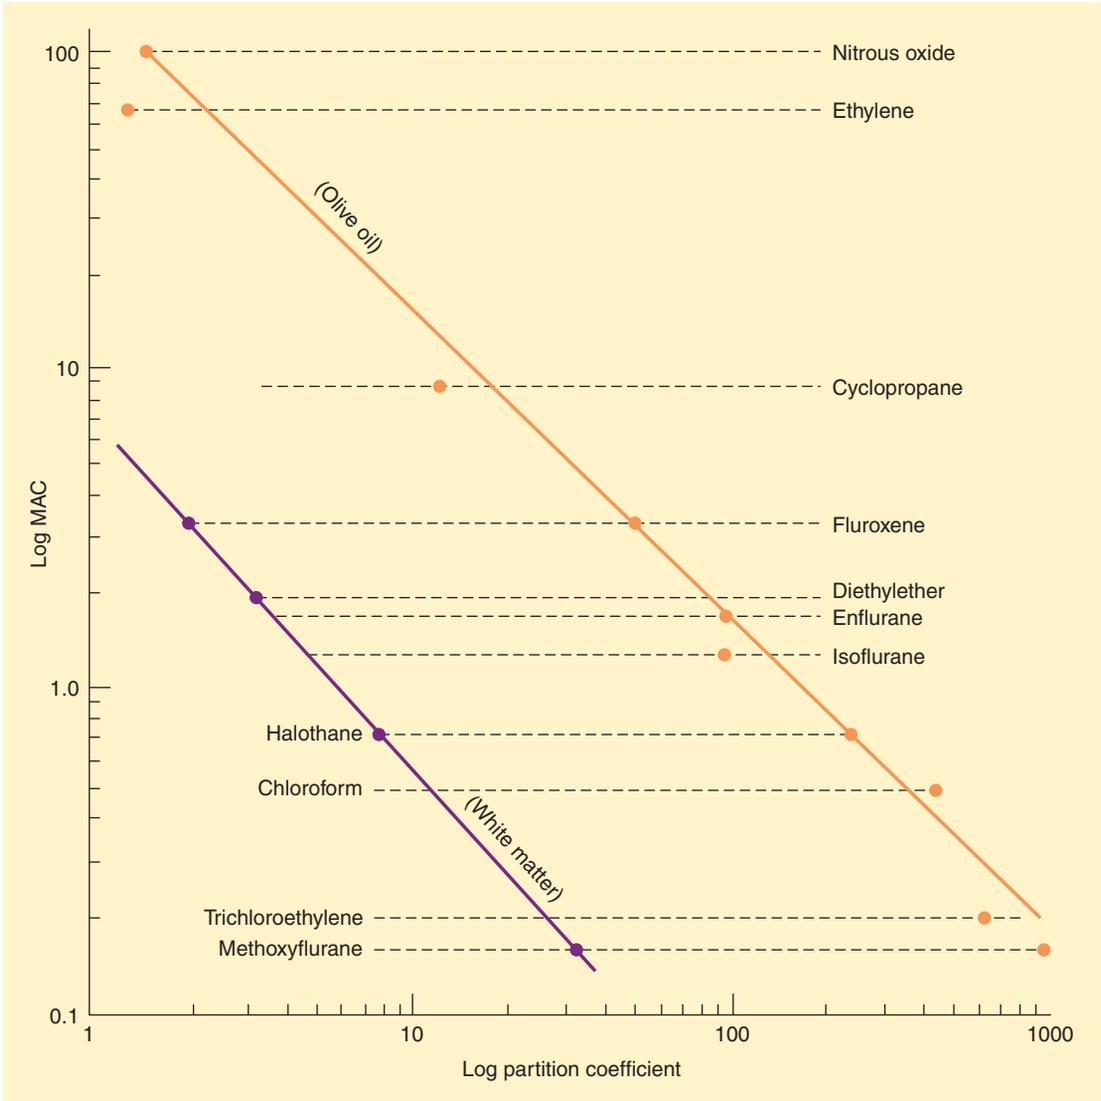

FIGURE 8-4 There is a good but not perfect correlation between anesthetic potency and lipid solubility. MAC, minimum alveolar concentration. (Modified and reproduced, with permission, from Lowe HJ, Hagler K: *Gas Chromatography in Biology and Medicine*. Churchill, 1969.)

as many protein channels may be affected by individual anesthetic agents, and no obligatory site has yet been identified. Selecting among so many molecular targets for the one(s) that provide optimum effects with minimal adverse actions will be the challenge in designing better inhalational agents.

ANESTHETIC NEUROTOXICITY

In recent years, there has been ongoing concern that general anesthetics damage the developing brain. It has been suggested that early exposure to anesthetics can promote cognitive impairment in later life. Concern has been raised that anesthetic exposure

affects the development and the elimination of synapses in the infant brain. For example, animal studies have demonstrated that isoflurane exposure promotes neuronal apoptosis and subsequent learning disability. Volatile anesthetics have been shown to promote apoptosis by altering cellular calcium homeostatic mechanisms.

Human studies exploring whether anesthesia is harmful in children are difficult, as conducting a randomized controlled trial for that purpose only would be unethical. Studies that compare populations of children who have had anesthetics with those who have not are also complicated by the reality that the former population is likewise having surgery and receiving the attention of the medical community. Consequently, children receiving anesthetics may be more likely to be diagnosed with learning difficulties in the first place. Data from one large study demonstrated that children who underwent surgery and anesthesia had a greater likelihood of carrying the diagnosis of a developmental disorder; however, the finding was not supported in twins (ie, the incidence of developmental disability was not greater in a twin who was exposed to anesthesia and surgery than in one who was not).

Human, animal, and laboratory trials demonstrating or refuting that anesthetic neurotoxicity leads to developmental disability in children are underway. As of this writing, there is insufficient and conflicting evidence to warrant changes in anesthetic practice (see: www.smarttots.org).

ANESTHETIC NEUROPROTECTION AND CARDIAC PRECONDITIONING

Although inhalational agents have been suggested as contributing to neurotoxicity, they have also been shown to provide both neurologic and cardiac protective effects against ischemia-reperfusion injury. Ischemic preconditioning implies that a brief ischemic episode protects a cell from future, more pronounced ischemic events. Various molecular mechanisms have been suggested to protect cells preconditioned either through ischemic events or secondary to pharmacologic mechanisms, such as

through the use of inhalational anesthetics. In the heart, preconditioning in part arises from actions at ATP-sensitive potassium (K_{ATP}) channels.

The exact mechanism of anesthetic preconditioning is likely to be multifocal and includes the opening of K_{ATP} channels, resulting in less mitochondrial calcium ion concentration and reduction of reactive oxygen species (ROS) production. ROS are associated with cellular injury. For example, excitatory NMDA receptors are linked to the development of neuronal injury. NMDA antagonists, such as the noble anesthetic gas Xenon, have been shown to be neuroprotective. Xenon has an anti-apoptotic effect that may be secondary to its inhibition of calcium ion influx following cell injury. Other inhalational agents, such as sevoflurane, have been shown to reduce markers of myocardial cell injury (eg, troponin T), compared with intravenous anesthetic techniques.

As with neurotoxicity, the role of inhalational anesthetics in tissue protection is the subject of ongoing investigation.

MINIMUM ALVEOLAR CONCENTRATION

6 The minimum alveolar concentration (MAC) of an inhaled anesthetic is the alveolar concentration that prevents movement in 50% of patients in response to a standardized stimulus (eg, surgical incision). MAC is a useful measure because it mirrors brain partial pressure, allows comparisons of potency between agents, and provides a standard for experimental evaluations (Table 8-3). Nonetheless, it should be remembered that this is a median value with limited usefulness in managing individual patients, particularly during times of rapidly changing alveolar concentrations (eg, induction).

The MAC values for different anesthetics are roughly additive. For example, a mixture of 0.5 MAC of nitrous oxide (53%) and 0.5 MAC of halothane (0.37%) produces the same likelihood that movement in response to surgical incision will be suppressed as 1.0 MAC of isoflurane (1.7%) or 1.0 MAC of any other single agent. In contrast to CNS depression, the degree of myocardial depression may not be equivalent at the same MAC: 0.5 MAC of halothane causes more myocardial depression than 0.5 MAC

TABLE 8-3 Properties of modern inhalation anesthetics.

Agent	Structure	MAC% ¹	Vapor Pressure (mm Hg at 20°C)

¹These minimum alveolar concentration (MAC) values are for 30- to 55-year old human subjects and are expressed as a percentage of 1 atmosphere. High altitude requires a higher inspired concentration of anesthetic to achieve the same partial pressure.

²A concentration greater than 100% means that hyperbaric conditions are required to achieve 1.0 MAC.

of nitrous oxide. MAC represents only one point on the dose–response curve—it is the equivalent of a median effective dose (ED₅₀). MAC multiples are clinically useful if the concentration–response curves of the anesthetics being compared are parallel, nearly linear, and continuous for the effect being predicted. Roughly 1.3 MAC of any of the volatile anesthetics (eg, for halothane: 1.3 × 0.74% = 0.96%) has been found to prevent movement in about 95% of patients (an approximation of the ED₉₅); 0.3–0.4 MAC is associated with awakening from anesthesia (MAC awake) when the inhaled drug is the only agent maintaining anesthetic (a rare circumstance).

MAC can be altered by several physiological and pharmacological variables (Table 8-4). **One of the most striking is the 6% decrease in MAC per decade of age, regardless of volatile anesthetic.**

MAC is relatively unaffected by species, sex, or duration of anesthesia. Surprisingly, MAC is not altered after spinal cord transection in rats, leading to the hypothesis that the site of anesthetic inhibition of motor responses lies in the spinal cord.

Clinical Pharmacology of Inhalation Anesthetics

NITROUS OXIDE

Physical Properties

Nitrous oxide (N₂O; laughing gas) is colorless and essentially odorless. Although nonexplosive and nonflammable, nitrous oxide is as capable as oxygen of supporting combustion. Unlike the potent volatile

agents, nitrous oxide is a gas at room temperature and ambient pressure. It can be kept as a liquid under pressure because its critical temperature lies above room temperature. Nitrous oxide is a relatively inexpensive anesthetic; however, concerns regarding its safety have led to continued interest in alternatives such as xenon (Table 8-5). As noted earlier, nitrous oxide, like xenon, is an NMDA receptor antagonist.

Effects on Organ Systems

A. Cardiovascular

Nitrous oxide has a tendency to stimulate the sympathetic nervous system. Thus, even though nitrous oxide directly depresses myocardial contractility in

TABLE 8-5 Advantages and disadvantages of xenon (Xe) anesthesia.

Advantages
Inert (probably nontoxic with no metabolism)
Minimal cardiovascular effects
Low blood solubility
Rapid induction and recovery
Does not trigger malignant hyperthermia
Environmentally friendly
Nonexplosive
Disadvantages
High cost
Low potency (MAC = 70%) ¹

⁴Percentage of absorbed anesthetic undergoing metabolism.

vitro, arterial blood pressure, cardiac output, and heart rate are essentially unchanged or slightly elevated in vivo because of its stimulation of catecholamines (Table 8-6). Myocardial depression may be unmasked in patients with coronary artery disease or severe hypovolemia. Constriction of pulmonary vascular smooth muscle increases pulmonary vascular resistance, which results in a generally modest elevation of right ventricular end-diastolic pressure. Despite vasoconstriction of cutaneous vessels, peripheral vascular resistance is not significantly altered.

B. Respiratory

Nitrous oxide increases respiratory rate (tachypnea) and decreases tidal volume as a result of CNS

stimulation and, perhaps, activation of pulmonary stretch receptors. The net effect is a minimal change in minute ventilation and resting arterial CO₂ levels. Hypoxic drive, the ventilatory response to arterial hypoxia that is mediated by peripheral chemoreceptors in the carotid bodies, is markedly depressed by even small amounts of nitrous oxide. This is a concern in the recovery room.

C. Cerebral

By increasing CBF and cerebral blood volume, nitrous oxide produces a mild elevation of intracranial pressure. Nitrous oxide also increases cerebral oxygen consumption (CMRO₂). These two effects make nitrous oxide theoretically less attractive than

other agents for neuroanesthesia. Concentrations of nitrous oxide below MAC may provide analgesia in dental surgery, labor, traumatic injury, and minor surgical procedures.

D. Neuromuscular

In contrast to other inhalation agents, nitrous oxide does not provide significant muscle relaxation. In fact, at high concentrations in hyperbaric chambers, nitrous oxide causes skeletal muscle rigidity. Nitrous oxide is not a triggering agent of malignant hyperthermia.

E. Renal

Nitrous oxide seems to decrease renal blood flow by increasing renal vascular resistance. This leads to a drop in glomerular filtration rate and urinary output.

F. Hepatic

Hepatic blood flow probably falls during nitrous oxide anesthesia, but to a lesser extent than with the volatile agents.

G. Gastrointestinal

Use of nitrous oxide in adults increases the risk of postoperative nausea and vomiting, presumably as a result of activation of the chemoreceptor trigger zone and the vomiting center in the medulla.

Biotransformation & Toxicity

During emergence, almost all nitrous oxide is eliminated by exhalation. A small amount diffuses out through the skin. Biotransformation is limited to the less than 0.01% that undergoes reductive metabolism in the gastrointestinal tract by anaerobic bacteria.

By irreversibly oxidizing the cobalt atom in vitamin B₁₂, nitrous oxide inhibits enzymes that are vitamin B₁₂ dependent. These enzymes include methionine synthetase, which is necessary for myelin formation, and thymidylate synthetase, which is **7** necessary for DNA synthesis. Prolonged exposure to anesthetic concentrations of nitrous oxide can result in bone marrow depression (megaloblastic anemia) and even neurological deficiencies (peripheral neuropathies). However, administration of nitrous oxide for bone marrow harvest does not

seem to affect the viability of bone marrow mononuclear cells. Because of possible teratogenic effects, nitrous oxide is often avoided in pregnant patients who are not yet in the third trimester. Nitrous oxide may also alter the immunological response to infection by affecting chemotaxis and motility of polymorphonuclear leukocytes.

Contraindications

Although nitrous oxide is insoluble in comparison with other inhalation agents, it is 35 times more soluble than nitrogen in blood. Thus, it tends to diffuse into air-containing cavities more rapidly than nitrogen is absorbed by the bloodstream. For instance, if a patient with a 100-mL pneumothorax inhales 50% nitrous oxide, the gas content of the pneumothorax will tend to approach that of the bloodstream. Because nitrous oxide will diffuse into the cavity more rapidly than the air (principally nitrogen) diffuses out, the pneumothorax expands until it contains 100 mL of air and 100 mL of nitrous oxide. If the walls surrounding the cavity are rigid, pressure rises instead of volume. **Examples of conditions in which nitrous oxide might be hazardous include venous or arterial air embolism, pneumothorax, acute intestinal obstruction with bowel distention, intracranial air (pneumocephalus following dural closure or pneumoencephalography), pulmonary air cysts, intraocular air bubbles, and tympanic membrane grafting.** Nitrous oxide will even diffuse into tracheal tube cuffs, increasing the pressure against the tracheal mucosa. Obviously, nitrous oxide is of limited value in patients requiring high inspired oxygen concentrations.

Drug Interactions

Because the high MAC of nitrous oxide prevents its use as a complete general anesthetic, it is frequently used in combination with the more potent volatile agents. The addition of nitrous oxide decreases the requirements of these other agents (65% nitrous oxide decreases the MAC of the volatile anesthetics by approximately 50%). Although nitrous oxide should not be considered a benign carrier gas, it does attenuate the circulatory and respiratory effects of volatile anesthetics in adults. Nitrous oxide

potentiates neuromuscular blockade, but less so than the volatile agents. The concentration of nitrous oxide flowing through a vaporizer can influence the concentration of volatile anesthetic delivered. For example, decreasing nitrous oxide concentration (ie, increasing oxygen concentration) increases the concentration of volatile agent despite a constant vaporizer setting. This disparity is due to the relative solubilities of nitrous oxide and oxygen in liquid volatile anesthetics. The second gas effect was discussed earlier. Nitrous oxide is an ozone-depleting gas with greenhouse effects.

HALOTHANE

Physical Properties

Halothane is a halogenated alkane (see Table 8–3). The carbon–fluoride bonds are responsible for its nonflammable and nonexplosive nature. Thymol preservative and amber-colored bottles retard spontaneous oxidative decomposition. It is rarely used in the United States.

Effects on Organ Systems

A. Cardiovascular

A dose-dependent reduction of arterial blood pressure is due to direct myocardial depression; 2.0 MAC of halothane in patients not undergoing surgery results in a 50% decrease in blood pressure and cardiac output. Cardiac depression—from interference with sodium–calcium exchange and intracellular calcium utilization—causes an increase in right atrial pressure. Although halothane is a coronary artery vasodilator, coronary blood flow decreases, due to the drop in systemic arterial pressure. Adequate myocardial perfusion is usually maintained, as oxygen demand also drops. Normally, hypotension inhibits baroreceptors in the aortic arch and carotid bifurcation, causing a decrease in vagal stimulation and a compensatory rise in heart rate. Halothane blunts this reflex. Slowing of sinoatrial node conduction may result in a junctional rhythm or bradycardia. In infants, halothane decreases cardiac output by a combination of decreased heart rate and depressed myocardial contractility. Halothane sensitizes the heart to the arrhythmogenic effects of

epinephrine, so that doses of epinephrine above 1.5 mcg/kg should be avoided. Although organ blood flow is redistributed, systemic vascular resistance is unchanged.

B. Respiratory

Halothane typically causes rapid, shallow breathing. The increased respiratory rate is not enough to counter the decreased tidal volume, so alveolar ventilation drops, and resting PaCO_2 is elevated. **Apneic threshold**, the highest PaCO_2 at which a patient remains apneic, also rises because the difference between it and resting PaCO_2 is not altered by general anesthesia. Similarly, halothane limits the increase in minute ventilation that normally accompanies a rise in PaCO_2 . Halothane's ventilatory effects are probably due to central (medullary depression) and peripheral (intercostal muscle dysfunction) mechanisms. These changes are exaggerated by preexisting lung disease and attenuated by surgical stimulation. The increase in PaCO_2 and the decrease in intrathoracic pressure that accompany spontaneous ventilation with halothane partially reverse the depression in cardiac output, arterial blood pressure, and heart rate described above. Hypoxic drive is severely depressed by even low concentrations of halothane (0.1 MAC).

Halothane is considered a potent bronchodilator, as it often reverses asthma-induced bronchospasm. This action is not inhibited by β -adrenergic blocking agents. Halothane attenuates airway reflexes and relaxes bronchial smooth muscle by inhibiting intracellular calcium mobilization. Halothane also depresses clearance of mucus from the respiratory tract (mucociliary function), promoting postoperative hypoxia and atelectasis.

C. Cerebral

By dilating cerebral vessels, halothane lowers cerebral vascular resistance and increases CBF. **Autoregulation**, the maintenance of constant CBF during changes in arterial blood pressure, is blunted. Concomitant rises in intracranial pressure can be prevented by establishing hyperventilation *prior to* administration of halothane. Cerebral activity is decreased, leading to electroencephalographic slowing and modest reductions in metabolic oxygen requirements.

D. Neuromuscular

Halothane relaxes skeletal muscle and potentiates nondepolarizing neuromuscular-blocking agents (NMBA). Like the other potent volatile anesthetics, it is a triggering agent of malignant hyperthermia.

E. Renal

Halothane reduces renal blood flow, glomerular filtration rate, and urinary output. Part of this decrease can be explained by a fall in arterial blood pressure and cardiac output. Because the reduction in renal blood flow is greater than the reduction in glomerular filtration rate, the filtration fraction is increased. Preoperative hydration limits these changes.

F. Hepatic

Halothane causes hepatic blood flow to decrease in proportion to the depression of cardiac output. Hepatic artery vasospasm has been reported during halothane anesthesia. The metabolism and clearance of some drugs (eg, fentanyl, phenytoin, verapamil) seem to be impaired by halothane. Other evidence of hepatic cellular dysfunction includes sulfobromophthalein (BSP) dye retention and minor liver transaminase elevations.

Biotransformation & Toxicity

Halothane is oxidized in the liver by a particular isozyme of CYP (2E1) to its principal metabolite, trifluoroacetic acid. This metabolism can be inhibited by pretreatment with disulfiram. Bromide, another oxidative metabolite, has been incriminated in (but is an improbable cause of) postanesthetic changes in mental status. In the absence of oxygen, reductive metabolism may result in a small amount of hepatotoxic end products that covalently bind to tissue macromolecules. This is more apt to occur following enzyme induction by phenobarbital. Elevated fluoride levels signal significant anaerobic metabolism.

Postoperative hepatic dysfunction has several causes: viral hepatitis, impaired hepatic perfusion, preexisting liver disease, hepatocyte hypoxia, sepsis, hemolysis, benign postoperative intrahepatic cholestasis, and drug-induced hepatitis. **8 Halothane hepatitis** is extremely rare (1 per 35,000 cases). Patients exposed to multiple halothane anesthetics at short intervals, middle-aged obese women, and

persons with a familial predisposition to halothane toxicity or a personal history of toxicity are considered to be at increased risk. Signs are mostly related to hepatic injury, such as increased serum alanine and aspartate transferase, elevated bilirubin (leading to jaundice), and encephalopathy.

The hepatic lesion seen in humans—centrilobular necrosis—also occurs in rats pretreated with an enzyme inducer (phenobarbital) and exposed to halothane under hypoxic conditions ($F_{iO_2} < 14\%$). This *halothane hypoxic model* implies hepatic damage from reductive metabolites or hypoxia.

More likely evidence points to an immune mechanism. For instance, some signs of the disease indicate an allergic reaction (eg, eosinophilia, rash, fever) and do not appear until a few days after exposure. Furthermore, an antibody that binds to hepatocytes previously exposed to halothane has been isolated from patients with halothane-induced hepatic dysfunction. This antibody response may involve liver microsomal proteins that have been modified by trifluoroacetic acid as the triggering antigens (trifluoroacetylated liver proteins such as microsomal carboxylesterase). As with halothane, other inhalational agents that undergo oxidative metabolism can likewise lead to hepatitis. However, newer agents undergo little to no metabolism, and therefore do not form trifluoroacetic acid protein adducts or produce the immune response leading to hepatitis.

Contraindications

It is prudent to withhold halothane from patients with unexplained liver dysfunction following previous anesthetic exposure.

Halothane, like all inhalational anesthetics, should be used with care in patients with intracranial mass lesions because of the possibility of intracranial hypertension secondary to increased cerebral blood volume and blood flow.

Hypovolemic patients and some patients with severe reductions in left ventricular function may not tolerate halothane's negative inotropic effects. Sensitization of the heart to catecholamines limits the usefulness of halothane when exogenous epinephrine is administered or in patients with pheochromocytoma.

Drug Interactions

The myocardial depression seen with halothane is exacerbated by β -adrenergic-blocking agents and calcium channel-blocking agents. Tricyclic antidepressants and monoamine oxidase inhibitors have been associated with fluctuations in blood pressure and arrhythmias, although neither represents an absolute contraindication. The combination of halothane and aminophylline has resulted in serious ventricular arrhythmias.

ISOFLURANE

Physical Properties

Isoflurane is a nonflammable volatile anesthetic with a pungent ethereal odor. Although it is a chemical isomer with the same molecular weight as enflurane, it has different physicochemical properties (see Table 8–3).

Effects on Organ Systems

A. Cardiovascular

Isoflurane causes minimal left ventricular depression *in vivo*. Cardiac output is maintained by a rise in heart rate due to partial preservation of carotid baroreflexes. Mild β -adrenergic stimulation increases skeletal muscle blood flow, decreases systemic vascular resistance, and lowers arterial blood pressure. Rapid increases in isoflurane concentration lead to transient increases in heart rate, arterial blood pressure, and plasma levels of norepinephrine. **9** Isoflurane dilates coronary arteries, but not nearly as potently as nitroglycerin or adenosine. Dilation of normal coronary arteries could theoretically divert blood away from fixed stenotic lesions, which was the basis for concern about coronary “steal” with this agent, a concern that has largely been forgotten.

B. Respiratory

Respiratory depression during isoflurane anesthesia resembles that of other volatile anesthetics, except that tachypnea is less pronounced. The net effect is a more pronounced fall in minute ventilation. Even low levels of isoflurane (0.1 MAC) blunt the normal ventilatory response to hypoxia and hypercapnia.

Despite a tendency to irritate upper airway reflexes, isoflurane is considered a good bronchodilator, but may not be as potent a bronchodilator as halothane.

C. Cerebral

At concentrations greater than 1 MAC, isoflurane increases CBF and intracranial pressure. These effects are thought to be less pronounced than with halothane and are reversed by hyperventilation. In contrast to halothane, the hyperventilation does not have to be instituted prior to the use of isoflurane to prevent intracranial hypertension. Isoflurane reduces cerebral metabolic oxygen requirements, and at 2 MAC, it produces an electrically silent electroencephalogram (EEG).

D. Neuromuscular

Isoflurane relaxes skeletal muscle.

E. Renal

Isoflurane decreases renal blood flow, glomerular filtration rate, and urinary output.

F. Hepatic

Total hepatic blood flow (hepatic artery and portal vein flow) may be reduced during isoflurane anesthesia. Hepatic oxygen supply is better maintained with isoflurane than with halothane, however, because hepatic artery perfusion is preserved. Liver function tests are usually not affected.

Biotransformation & Toxicity

Isoflurane is metabolized to trifluoroacetic acid. Although serum fluoride fluid levels may rise, nephrotoxicity is extremely unlikely, even in the presence of enzyme inducers. Prolonged sedation (>24 h at 0.1–0.6% isoflurane) of critically ill patients has resulted in elevated plasma fluoride levels (15–50 $\mu\text{mol/L}$) without evidence of renal impairment. Similarly, up to 20 MAC-hours of isoflurane may lead to fluoride levels exceeding 50 $\mu\text{mol/L}$ without detectable postoperative renal dysfunction. Its limited oxidative metabolism also minimizes any possible risk of significant hepatic dysfunction.

Contraindications

Isoflurane presents no unique contraindications. Patients with severe hypovolemia may not tolerate

its vasodilating effects. It can trigger malignant hyperthermia.

Drug Interactions

Epinephrine can be safely administered in doses up to 4.5 mcg/kg. Nondepolarizing NMBAs are potentiated by isoflurane.

DESFLURANE

Physical Properties

The structure of desflurane is very similar to that of isoflurane. In fact, the only difference is the substitution of a fluorine atom for isoflurane's chlorine atom. That "minor" change has profound effects on the physical properties of the drug, however. For instance, because the vapor pressure of desflurane at 20°C is 681 mm Hg, at high altitudes (eg, Denver, Colorado) it boils at room temperature. This problem necessitated the development of a special **10** desflurane vaporizer. Furthermore, the low solubility of desflurane in blood and body tissues causes a very rapid induction and emergence of anesthesia. Therefore, the alveolar concentration of desflurane approaches the inspired concentration much more rapidly than the other volatile agents, giving the anesthesiologist tighter control over anesthetic levels. **Wake-up times are approximately 50% less than those observed following isoflurane.** This is principally attributable to a blood/gas partition coefficient (0.42) that is even lower than that of nitrous oxide (0.47). Although desflurane is roughly one-fourth as potent as the other volatile agents, it is 17 times more potent than nitrous oxide. A high vapor pressure, an ultrashort duration of action, and moderate potency are the most characteristic features of desflurane.

Effects on Organ Systems

A. Cardiovascular

The cardiovascular effects of desflurane seem to be similar to those of isoflurane. Increasing the dose is associated with a decline in systemic vascular resistance that leads to a fall in arterial blood pressure. Cardiac output remains relatively unchanged or

slightly depressed at 1–2 MAC. There is a moderate rise in heart rate, central venous pressure, and pulmonary artery pressure that often does not become **11** apparent at low doses. Rapid increases in desflurane concentration lead to transient but sometimes worrisome elevations in heart rate, blood pressure, and catecholamine levels that are more pronounced than occur with isoflurane, particularly in patients with cardiovascular disease. These cardiovascular responses to rapidly increasing desflurane concentration can be attenuated by fentanyl, esmolol, or clonidine.

B. Respiratory

Desflurane causes a decrease in tidal volume and an increase in respiratory rate. There is an overall decrease in alveolar ventilation that causes a rise in resting PaCO_2 . Like other modern volatile anesthetic agents, desflurane depresses the ventilatory response to increasing PaCO_2 . Pungency and airway irritation during desflurane induction can be manifested by salivation, breath-holding, coughing, and laryngospasm. Airway resistance may increase in children with reactive airway susceptibility. These problems make desflurane a poor choice for inhalation induction.

C. Cerebral

Like the other volatile anesthetics, desflurane directly vasodilates the cerebral vasculature, increasing CBF, cerebral blood volume, and intracranial pressure at normotension and normocapnia. Countering the decrease in cerebral vascular resistance is a marked decline in the cerebral metabolic rate of oxygen (CMRO_2) that tends to cause cerebral vasoconstriction and moderate any increase in CBF. The cerebral vasculature remains responsive to changes in PaCO_2 , however, so that intracranial pressure can be lowered by hyperventilation. Cerebral oxygen consumption is decreased during desflurane anesthesia. Thus, during periods of desflurane-induced hypotension (mean arterial pressure = 60 mm Hg), CBF is adequate to maintain aerobic metabolism despite a low cerebral perfusion pressure. The effect on the EEG is similar to that of isoflurane. Initially, EEG frequency is increased, but as anesthetic depth is increased, EEG slowing

becomes manifest, leading to burst suppression at higher inhaled concentrations.

D. Neuromuscular

Desflurane is associated with a dose-dependent decrease in the response to train-of-four and tetanic peripheral nerve stimulation.

E. Renal

There is no evidence of any significant nephrotoxic effects caused by exposure to desflurane. However, as cardiac output declines, decreases in urine output and glomerular filtration should be expected with desflurane and all other anesthetics.

F. Hepatic

Hepatic function tests are generally unaffected by desflurane, assuming that organ perfusion is maintained perioperatively. Desflurane undergoes minimal metabolism, therefore the risk of anesthetic-induced hepatitis is likewise minimal. As with isoflurane and sevoflurane, hepatic oxygen delivery is generally maintained.

Biotransformation & Toxicity

Desflurane undergoes minimal metabolism in humans. Serum and urine inorganic fluoride levels following desflurane anesthesia are essentially unchanged from preanesthetic levels. There is insignificant percutaneous loss. Desflurane, more than other volatile anesthetics, is degraded by desiccated CO₂ absorbent (particularly barium hydroxide lime, but also sodium and potassium hydroxide) into potentially clinically significant levels of carbon monoxide. Carbon monoxide poisoning is difficult to diagnose under general anesthesia, but the presence of carboxyhemoglobin may be detectable by arterial blood gas analysis or lower than expected pulse oximetry readings (although still falsely high). Disposing of dried out absorbent or use of calcium hydroxide can minimize the risk of carbon monoxide poisoning.

Contraindications

Desflurane shares many of the contraindications of other modern volatile anesthetics: severe hypovolemia, malignant hyperthermia, and intracranial hypertension.

Drug Interactions

Desflurane potentiates nondepolarizing neuromuscular blocking agents to the same extent as isoflurane. Epinephrine can be safely administered in doses up to 4.5 mcg/kg as desflurane does not sensitize the myocardium to the arrhythmogenic effects of epinephrine. Although emergence is more rapid following desflurane anesthesia than after isoflurane anesthesia, switching from isoflurane to desflurane toward the end of anesthesia does not significantly accelerate recovery, nor does faster emergence translate into faster discharge times from the post-anesthesia care unit. Desflurane emergence has been associated with delirium in some pediatric patients.

SEVOFLURANE

Physical Properties

Like desflurane, sevoflurane is halogenated with fluorine. Sevoflurane's solubility in blood is slightly greater than desflurane ($\lambda_{b/g}$ 0.65 versus 0.42) (see Table 8–3). Nonpungency and rapid increases in alveolar anesthetic concentration make sevoflurane an excellent choice for smooth and rapid inhalation inductions in pediatric and adult patients. In fact, inhalation induction with 4% to 8% sevoflurane in a 50% mixture of nitrous oxide and oxygen can be achieved within 1 min. Likewise, its low blood solubility results in a rapid fall in alveolar anesthetic concentration upon discontinuation and a more rapid emergence compared with isoflurane (although not an earlier discharge from the post-anesthesia care unit). Sevoflurane's modest vapor pressure permits the use of a conventional variable bypass vaporizer.

Effects on Organ Systems

A. Cardiovascular

Sevoflurane mildly depresses myocardial contractility. Systemic vascular resistance and arterial blood pressure decline slightly less than with isoflurane or desflurane. Because sevoflurane causes little, if any, rise in heart rate, cardiac output is not maintained as well as with isoflurane or desflurane. Sevoflurane

may prolong the QT interval, the clinical significance of which is unknown. QT prolongation may be manifest 60 min following anesthetic emergence in infants.

B. Respiratory

Sevoflurane depresses respiration and reverses bronchospasm to an extent similar to that of isoflurane.

C. Cerebral

Similar to isoflurane and desflurane, sevoflurane causes slight increases in CBF and intracranial pressure at normocarbina, although some studies show a decrease in cerebral blood flow. High concentrations of sevoflurane (>1.5 MAC) may impair autoregulation of CBF, thus allowing a drop in CBF during hemorrhagic hypotension. This effect on CBF autoregulation seems to be less pronounced than with isoflurane. Cerebral metabolic oxygen requirements decrease, and seizure activity has not been reported.

D. Neuromuscular

Sevoflurane produces adequate muscle relaxation for intubation of children following an inhalation induction.

E. Renal

Sevoflurane slightly decreases renal blood flow. Its metabolism to substances associated with impaired renal tubule function (eg, decreased concentrating ability) is discussed below.

F. Hepatic

Sevoflurane decreases portal vein blood flow, but increases hepatic artery blood flow, thereby maintaining total hepatic blood flow and oxygen delivery. It is generally not associated with immune-mediated anesthetic hepatotoxicity

Biotransformation & Toxicity

The liver microsomal enzyme P-450 (specifically the 2E1 isoform) metabolizes sevoflurane at a rate one-fourth that of halothane (5% versus 20%), but 10 to 25 times that of isoflurane or desflurane and may be induced with ethanol or phenobarbital pretreatment. The potential nephrotoxicity of the resulting

rise in inorganic fluoride (F^-) was discussed earlier. Serum fluoride concentrations exceed $50 \mu\text{mol/L}$ in approximately 7% of patients who receive sevoflurane, yet clinically significant renal dysfunction has not been associated with sevoflurane anesthesia. The overall rate of sevoflurane metabolism is 5%, or 10 times that of isoflurane. Nonetheless, there has been no association with peak fluoride levels following sevoflurane and any renal concentrating abnormality.

Alkali such as barium hydroxide lime or soda lime (but not calcium hydroxide) can degrade sevoflurane, producing another proven (at least in rats) nephrotoxic end product (*compound A*, fluoromethyl-2,2-difluoro-1-[trifluoromethyl]vinyl ether). Accumulation of compound A increases with increased respiratory gas temperature, low-flow anesthesia, dry barium hydroxide absorbent (Baralyme), high sevoflurane concentrations, and anesthetics of long duration.

Most studies have not associated sevoflurane with any detectable postoperative impairment of renal function that would indicate toxicity or injury. Nonetheless, some clinicians recommend that fresh gas flows be at least 2 L/min for anesthetics lasting more than a few hours and that sevoflurane not be used in patients with preexisting renal dysfunction.

Sevoflurane can also be degraded into hydrogen fluoride by metal and environmental impurities present in manufacturing equipment, glass bottle packaging, and anesthesia equipment. Hydrogen fluoride can produce an acid burn on contact with respiratory mucosa. The risk of patient injury has been substantially reduced by inhibition of the degradation process by adding water to sevoflurane during the manufacturing process and packaging it in a special plastic container. The manufacturer has also distributed a "Dear Provider" letter warning of isolated incidents of fire in the respiratory circuits of anesthesia machines with desiccated CO_2 absorbent when sevoflurane was used.

Contraindications

Contraindications include severe hypovolemia, susceptibility to malignant hyperthermia, and intracranial hypertension.

Drug Interactions

Like other volatile anesthetics, sevoflurane potentiates NMBAs. It does not sensitize the heart to catecholamine-induced arrhythmias.

XENON

Xenon is a “noble” gas that has long been known to have anesthetic properties. It is an inert element that does not form chemical bonds. Xenon is scavenged from the atmosphere through a costly distillation process. It is an odorless, nonexplosive, naturally occurring gas with a MAC of .71 and a blood/gas coefficient of 0.115, giving it very fast onset and emergence parameters. As previously mentioned, xenon’s anesthetic effects seem to be mediated by NMDA inhibition by competing with glycine at the glycine binding site. Xenon seems to have little effect on cardiovascular, hepatic, or renal systems and has been found to be protective against neuronal ischemia. As a natural element, it has no effect upon the ozone layer compared with another NMDA antagonist, nitrous oxide. Cost and limited availability have prevented its widespread use.

Intravenous Anesthetics

KEY CONCEPTS

- 1 Repetitive administration of barbiturates (eg, infusion of thiopental for “barbiturate coma” and brain protection) saturates the peripheral compartments, minimizing any effect of redistribution, and rendering the duration of action more dependent on elimination. This is an example of context sensitivity.
- 2 Barbiturates constrict the cerebral vasculature, causing a decrease in cerebral blood flow, cerebral blood volume, and intracranial pressure.
- 3 Although apnea may be relatively uncommon after benzodiazepine induction, even small intravenous doses of diazepam and midazolam have resulted in respiratory arrest.
- 4 In contrast to other anesthetic agents, ketamine increases arterial blood pressure, heart rate, and cardiac output, particularly after rapid bolus injections.
- 5 Induction doses of etomidate transiently inhibit enzymes involved in cortisol and aldosterone synthesis. Etomidate was often used in the past for ICU sedation before reports of its consistent ability to produce adrenocortical suppression in that circumstance appeared.
- 6 Propofol formulations can support the growth of bacteria, so sterile technique must be observed in preparation and handling. Propofol should be administered within 6 h of opening the ampule.

General anesthesia began with inhaled agents but now can be induced and maintained with drugs that enter the patient through a wide range of routes. Drug administration can be oral, rectal, transdermal, transmucosal, intramuscular, or intravenous for the purpose of producing or enhancing an anesthetic state. Preoperative sedation of adults is usually accomplished by way of oral or intravenous routes. Induction of general anesthesia in adults usually includes intravenous drug administration. Effective topical anesthesia with EMLA (eutectic mixture of local anesthetic) cream, LMX (plain lidocaine cream 4% and 5%), or 2% lidocaine jelly has increased the ease of intravenous inductions in children. Maintenance of general anesthesia is

feasible with a total intravenous anesthesia (TIVA) technique. This chapter focuses on the intravenous agents used to produce hypnosis, including barbiturates, benzodiazepines, ketamine, etomidate, and propofol.

BARBITURATES

Mechanisms of Action

Barbiturates depress the reticular activating system in the brainstem, which controls multiple vital functions, including consciousness. In clinical concentrations, barbiturates more potently affect the function of nerve synapses than axons. Their primary

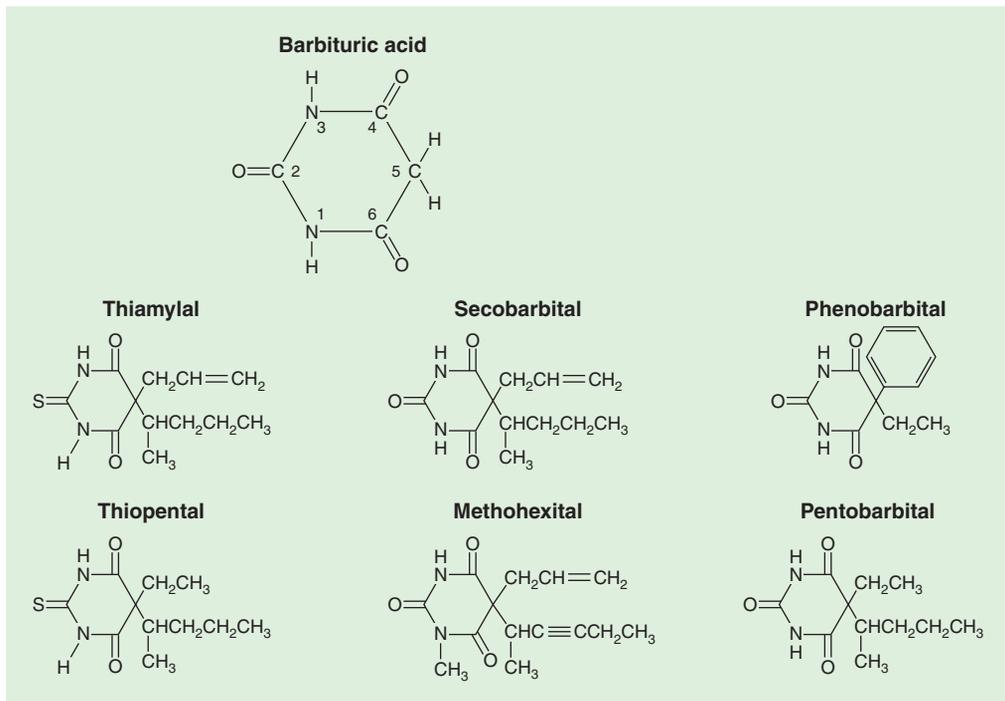

FIGURE 9-1 Barbiturates share the structure of barbituric acid and differ in the C₂, C₅, and N₁ substitutions.

mechanism of action is believed to be through binding to the γ -aminobutyric acid type A (GABA_A) receptor. Barbiturates potentiate the action of GABA in increasing the duration of openings of a chloride-specific ion channel.

Structure–Activity Relationships

Barbiturates are derived from barbituric acid (Figure 9–1). Substitution at carbon C₅ determines hypnotic potency and anticonvulsant activity. A long-branched chain conveys more potency than does a short straight chain. Likewise, the phenyl group in *phenobarbital* is anticonvulsive, whereas the methyl group in *methohexital* is not. Replacing the oxygen at C₂ (*oxybarbiturates*) with a sulfur atom (*thio-barbiturates*) increases lipid solubility. As a result, thiopental and thiamylal have a greater potency, more rapid onset of action, and shorter durations of action (after a single “sleep dose”) than pentobarbital. The sodium salts of the barbiturates are water soluble but markedly alkaline (pH of 2.5% thiopental >10) and relatively unstable (2-week shelf-life for

2.5% thiopental solution). Concentrations greater than recommended cause an unacceptable incidence of pain on injection and venous thrombosis.

Pharmacokinetics

A. Absorption

In clinical anesthesiology, thiopental, thiamylal, and methohexital were frequently administered intravenously for induction of general anesthesia in adults and children (prior to the introduction of propofol). Rectal thiopental or, more often, methohexital has been used for induction in children, and intramuscular (or oral) pentobarbital was often used in the past for premedication of all age groups.

B. Distribution

The duration of sleep doses of the highly lipid-soluble barbiturates (thiopental, thiamylal, and methohexital) is determined by redistribution, not by metabolism or elimination. For example, although thiopental is highly protein bound (80%), its great lipid solubility and high nonionized fraction (60%)

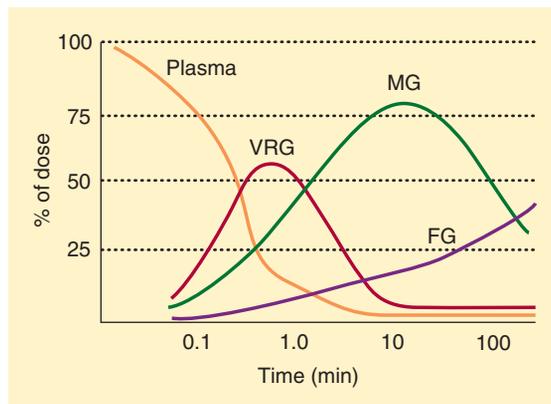

FIGURE 9-2 Distribution of thiopental from plasma to the vessel-rich group (VRG; brain, heart, liver, kidney, endocrine glands), to the muscle group (MG), and finally to the fat group (FG). (Modified and reproduced, with permission, from Price HL et al: The uptake of thiopental by body tissues and its relation to the duration of narcosis. *Clin Pharmacol Ther* 1960;1:16.)

account for rapid brain uptake (within 30 s). If the central compartment is contracted (eg, hypovolemic shock), if the serum albumin is low (eg, severe liver disease or malnutrition), or if the nonionized fraction is increased (eg, acidosis), larger brain and heart concentrations will be achieved for a given dose. Redistribution to the peripheral compartment—specifically, the muscle group—lowers plasma and brain concentration to 10% of peak levels within 20–30 min (Figure 9-2). This pharmacokinetic profile correlates with clinical experience—patients typically lose consciousness within 30 s and awaken within 20 min.

The minimal induction dose of thiopental will depend on body weight and age. Reduced induction doses are required for elderly patients primarily due to slower redistribution. In contrast to the rapid initial distribution half-life of a few minutes, elimination of thiopental is prolonged (elimination half-life ranges of 10–12 h). Thiamylal and methohexital have similar distribution patterns, whereas less lipid-soluble barbiturates have much longer distribution half-lives and durations of action after a sleep dose. Repetitive administration of barbiturates (eg, infusion of thiopental for “barbiturate coma” and brain protection) saturates the peripheral compartments,

minimizing any effect of redistribution, and rendering the duration of action more dependent on elimination. This is an example of context sensitivity.

C. Biotransformation

Barbiturates are principally biotransformed via hepatic oxidation to inactive water-soluble metabolites. Because of greater hepatic extraction, methohexital is cleared by the liver more rapidly than thiopental. Although redistribution is responsible for the awakening from a single sleep dose of any of these lipid-soluble barbiturates, full recovery of psychomotor function is more rapid following methohexital due to its enhanced metabolism.

D. Excretion

Increased protein binding decreases barbiturate glomerular filtration, whereas increased lipid solubility tends to increase renal tubular reabsorption. Except for the less protein-bound and less lipid-soluble agents such as phenobarbital, renal excretion is limited to water-soluble end products of hepatic biotransformation. Methohexital is excreted in the feces.

Effects on Organ Systems

A. Cardiovascular

Intravenous bolus induction doses of barbiturates cause a decrease in blood pressure and an increase in heart rate. Hemodynamic responses to barbiturates are reduced by slower rates of induction. Depression of the medullary vasomotor center produces vasodilation of peripheral capacitance vessels, which increases peripheral pooling of blood, mimicking a reduced blood volume. Tachycardia following administration is probably due to a central vagolytic effect and reflex responses to decreases in blood pressure. Cardiac output is often maintained by an increased heart rate and increased myocardial contractility from compensatory baroreceptor reflexes. Sympathetically induced vasoconstriction of resistance vessels (particularly with intubation under light planes of general anesthesia) may actually increase peripheral vascular resistance. However, in situations where the baroreceptor response will be blunted or absent (eg, hypovolemia, congestive heart failure, β -adrenergic blockade), **cardiac output and arterial blood pressure may fall dramatically due**

to uncompensated peripheral pooling of blood and direct myocardial depression. Patients with poorly controlled hypertension are particularly prone to wide swings in blood pressure during anesthesia induction. The cardiovascular effects of barbiturates therefore vary markedly, depending on rate of administration, dose, volume status, baseline autonomic tone, and preexisting cardiovascular disease. A slow rate of injection and adequate preoperative hydration attenuates or eliminates these changes in most patients.

B. Respiratory

Barbiturates depress the medullary ventilatory center, decreasing the ventilatory response to hypercapnia and hypoxia. Deep barbiturate sedation often leads to upper airway obstruction; apnea often follows an induction dose. During awakening, tidal volume and respiratory rate are decreased following barbiturate induction. Barbiturates incompletely depress airway reflex responses to laryngoscopy and intubation, and airway instrumentation may lead to bronchospasm (in asthmatic patients) or laryngospasm in lightly anesthetized patients.

C. Cerebral

2 Barbiturates constrict the cerebral vasculature, causing a decrease in cerebral blood flow, cerebral blood volume, and intracranial pressure. Intracranial pressure decreases to a greater extent than arterial blood pressure, so cerebral perfusion pressure (CPP) usually increases. (CPP

equals cerebral artery pressure minus the greater of jugular venous pressure or intracranial pressure.) Barbiturates induce a greater decline in cerebral oxygen consumption (up to 50% of normal) than in cerebral blood flow; therefore the decline in cerebral blood flow is not detrimental. Barbiturate-induced reductions in oxygen requirements and cerebral metabolic activity are mirrored by changes in the electroencephalogram (EEG), which progress from low-voltage fast activity with small doses to high-voltage slow activity, burst suppression, and electrical silence with larger doses. Barbiturates may protect the brain from transient episodes of focal ischemia (eg, cerebral embolism) but probably do not protect from global ischemia (eg, cardiac arrest). Abundant animal data document these effects but the clinical data are sparse and inconsistent. Furthermore, thiopental doses required to maintain EEG suppression (most often burst suppression or flat line) are associated with prolonged awakening, delayed extubation, and the need for inotropic support.

The degree of central nervous system depression induced by barbiturates ranges from mild sedation to unconsciousness, depending on the dose administered (**Table 9–1**). Some patients relate a taste sensation of garlic, onions, or pizza during induction with thiopental. Barbiturates do not impair the perception of pain. In fact, they sometimes appear to lower the pain threshold. Small doses occasionally cause a state of excitement and disorientation that can be disconcerting when sedation is the objective. Barbiturates do not produce

TABLE 9–1 Uses and dosages of common barbiturates.

Agent	Use	Route ¹	Concentration (%)	Dose (mg/kg)
Thiopental, thiamylal	Induction	IV	2.5	3–6

²Maximum dose is 150 mg.

muscle relaxation, and some induce involuntary skeletal muscle contractions (eg, methohexital). Relatively small doses of thiopental (50–100 mg intravenously) rapidly (but temporarily) control most grand mal seizures. Unfortunately, acute tolerance and physiological dependence on the sedative effect of barbiturates develop quickly.

D. Renal

Barbiturates reduce renal blood flow and glomerular filtration rate in proportion to the fall in blood pressure.

E. Hepatic

Hepatic blood flow is decreased. Chronic exposure to barbiturates has opposing effects on drug biotransformation. Induction of hepatic enzymes increases the rate of metabolism of some drugs, whereas binding of barbiturates to the cytochrome P-450 enzyme system interferes with the biotransformation of other drugs (eg, tricyclic antidepressants). Barbiturates promote aminolevulinic acid synthetase, which stimulates the formation of **porphyrin** (an intermediary in heme synthesis). This may precipitate acute intermittent porphyria or variegate porphyria in susceptible individuals.

F. Immunological

Anaphylactic or anaphylactoid allergic reactions are rare. Sulfur-containing thiobarbiturates evoke mast cell histamine release *in vitro*, whereas oxybarbiturates do not. For this reason, some anesthesiologists prefer induction agents other than thiopental or thiamylal in asthmatic or atopic patients, but the evidence for this choice is sparse. There is no question that airway instrumentation with light anesthesia is troublesome in patients with reactive airways.

Drug Interactions

Contrast media, sulfonamides, and other drugs that occupy the same protein-binding sites as thiopental may displace the barbiturate, increasing the amount of free drug available and potentiating the organ system effects of a given dose.

Ethanol, opioids, antihistamines, and other central nervous system depressants potentiate the sedative effects of barbiturates. The common clinical

impression that chronic alcohol abuse is associated with increased thiopental requirements during induction lacks scientific proof.

BENZODIAZEPINES

Mechanisms of Action

Benzodiazepines bind the same set of receptors in the central nervous system as barbiturates but bind to a different site on the receptors. Benzodiazepine binding to the GABA_A receptor increases the frequency of openings of the associated chloride ion channel. For example, benzodiazepine-receptor binding facilitates binding of GABA to its receptor. **Flumazenil** (an imidazobenzodiazepine) is a specific benzodiazepine-receptor antagonist that effectively reverses most of the central nervous system effects of benzodiazepines (see Chapter 17).

Structure–Activity Relationships

The chemical structure of benzodiazepines includes a benzene ring and a seven-member diazepine ring (**Figure 9–3**). Substitutions at various positions on these rings affect potency and biotransformation. The imidazole ring of midazolam contributes to its water solubility at low pH. Diazepam and lorazepam are insoluble in water so parenteral preparations contain propylene glycol, which can produce venous irritation.

Pharmacokinetics

A. Absorption

Benzodiazepines are commonly administered orally, intramuscularly, and intravenously to provide sedation or, less commonly, to induce general anesthesia (**Table 9–2**). Diazepam and lorazepam are well absorbed from the gastrointestinal tract, with peak plasma levels usually achieved in 1 and 2 h, respectively. Oral midazolam has not been approved by the U.S. Food and Drug Administration, nevertheless this route of administration has been popular for pediatric premedication. Likewise, intranasal (0.2–0.3 mg/kg), buccal (0.07 mg/kg), and sublingual (0.1 mg/kg) midazolam provide effective preoperative sedation.

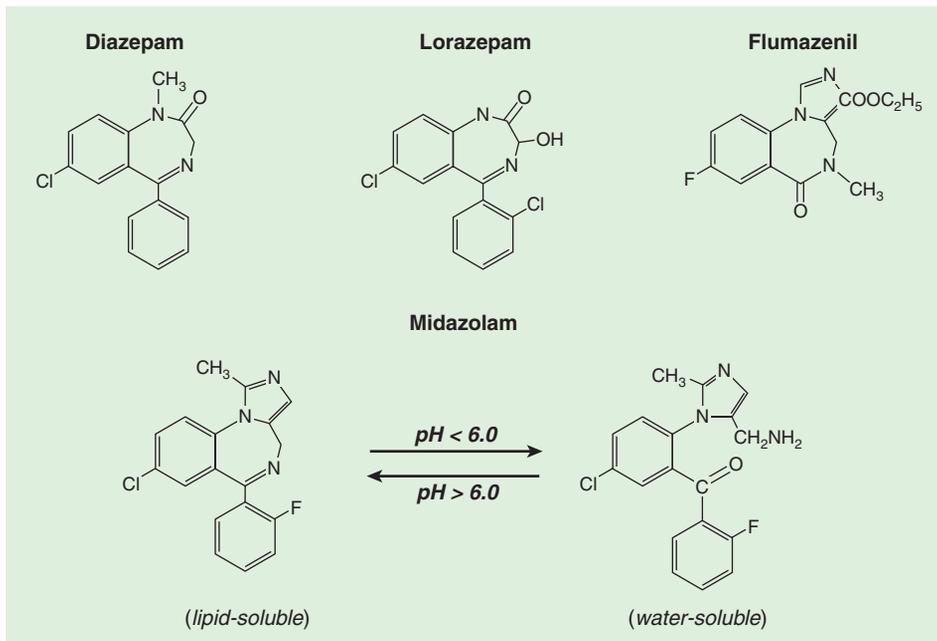

FIGURE 9-3 The structures of commonly used benzodiazepines and their antagonist, flumazenil, share a seven-member diazepine ring. (Modified and reproduced,

with permission, from White PF: Pharmacologic and clinical aspects of preoperative medication. *Anesth Analg* 1986;65:963. With permission from the International Anesthesia Research Society.)

Intramuscular injections of diazepam are painful and unreliably absorbed. In contrast, midazolam and lorazepam are well absorbed after intramuscular injection, with peak levels achieved in 30 and 90 min, respectively. Induction of general anesthesia with midazolam is convenient only with intravenous administration.

TABLE 9-2 Uses and doses of commonly used benzodiazepines.

Agent	Use	Route ¹	Dose (mg/kg)
Diazepam	Premedication	Oral	0.2–0.5 ²
	Sedation	IV	0.04–0.2
Midazolam	Premedication	IM	0.07–0.15
	Sedation	IV	0.01–0.1
	Induction	IV	0.1–0.4
Lorazepam	Premedication	Oral	0.05

¹IV, intravenous; IM, intramuscular.

²Maximum dose is 15 mg.

B. Distribution

Diazepam is relatively lipid soluble and readily penetrates the blood–brain barrier. Although midazolam is water soluble at reduced pH, its imidazole ring closes at physiological pH, increasing its lipid solubility (see Figure 9-3). The moderate lipid solubility of lorazepam accounts for its slower brain uptake and onset of action. Redistribution is fairly rapid for the benzodiazepines (the initial distribution half-life is 3–10 min) and, like the barbiturates, is responsible for awakening. Although midazolam has been used as an induction agent, neither midazolam nor any other of the benzodiazepines can match the rapid onset and short duration of action of propofol or even thiopental. All three benzodiazepines are highly protein bound (90–98%).

C. Biotransformation

The benzodiazepines rely on the liver for biotransformation into water-soluble glucuronidated end products. The phase I metabolites of diazepam are pharmacologically active.

Slow hepatic extraction and a large volume of distribution (V_d) result in a long elimination half-life for diazepam (30 h). Although lorazepam also has a low hepatic extraction ratio, its lower lipid solubility limits its V_d , resulting in a shorter elimination half-life (15 h). Nonetheless, the clinical duration of lorazepam is often quite prolonged due to increased receptor affinity. These differences between lorazepam and diazepam illustrate the low utility of individual pharmacokinetic half-lives in guiding clinical practice. Midazolam shares diazepam's V_d , but its elimination half-life (2 h) is the shortest of the group because of its increased hepatic extraction ratio.

D. Excretion

The metabolites of benzodiazepine biotransformation are excreted chiefly in the urine. Enterohepatic circulation produces a secondary peak in diazepam plasma concentration 6–12 h following administration. Kidney failure may lead to prolonged sedation in patients receiving larger doses of midazolam due to the accumulation of a conjugated metabolite (α -hydroxymidazolam).

Effects on Organ Systems

A. Cardiovascular

The benzodiazepines display minimal cardiovascular depressant effects even at general anesthetic doses, except when they are coadministered with opioids (these agents interact to produce myocardial depression and arterial hypotension). Benzodiazepines given alone decrease arterial blood pressure, cardiac output, and peripheral vascular resistance slightly, and sometimes increase heart rate. Intravenous midazolam tends to reduce blood pressure and peripheral vascular resistance more than diazepam. Changes in heart rate variability during midazolam sedation suggest decreased vagal tone (ie, drug-induced vagolysis).

B. Respiratory

Benzodiazepines depress the ventilatory response to CO_2 . This depression is usually insignificant unless the drugs are administered intravenously or in association with other respiratory depressants. Although **3** apnea may be relatively uncommon after benzodiazepine induction, even small intravenous

doses of diazepam and midazolam have resulted in respiratory arrest. The steep dose–response curve, slightly prolonged onset (compared with propofol or thiopental), and potency of midazolam necessitate careful titration to avoid overdosage and apnea. Ventilation must be monitored in all patients receiving intravenous benzodiazepines, and resuscitation equipment must be immediately available.

C. Cerebral

Benzodiazepines reduce cerebral oxygen consumption, cerebral blood flow, and intracranial pressure but not to the extent the barbiturates do. They are effective in preventing and controlling grand mal seizures. Oral sedative doses often produce anterograde amnesia, a useful premedication property. The mild muscle-relaxing property of these drugs is mediated at the spinal cord level, not at the neuromuscular junction. The antianxiety, amnesic, and sedative effects seen at lower doses progress to stupor and unconsciousness at induction doses. Compared with propofol or thiopental, induction with benzodiazepines is associated with a slower rate of loss of consciousness and a longer recovery. Benzodiazepines have no direct analgesic properties.

Drug Interactions

Cimetidine binds to cytochrome P-450 and reduces the metabolism of diazepam. Erythromycin inhibits metabolism of midazolam and causes a two- to threefold prolongation and intensification of its effects. Heparin displaces diazepam from protein-binding sites and increases the free drug concentration.

As previously mentioned, the combination of opioids and benzodiazepines markedly reduces arterial blood pressure and peripheral vascular resistance. This synergistic interaction has often been observed in patients with ischemic or valvular heart disease who often receive benzodiazepines for premedication and during induction of anesthesia with opioids.

Benzodiazepines reduce the minimum alveolar concentration of volatile anesthetics as much as 30%.

Ethanol, barbiturates, and other central nervous system depressants potentiate the sedative effects of the benzodiazepines.

KETAMINE

Mechanisms of Action

Ketamine has multiple effects throughout the central nervous system, inhibiting polysynaptic reflexes in the spinal cord as well as excitatory neurotransmitter effects in selected areas of the brain. In contrast to the depression of the reticular activating system induced by the barbiturates, ketamine functionally “dissociates” the thalamus (which relays sensory impulses from the reticular activating system to the cerebral cortex) from the limbic cortex (which is involved with the awareness of sensation). Clinically, this state of dissociative anesthesia may cause the patient to appear conscious (eg, eye opening, swallowing, muscle contracture) but unable to process or respond to sensory input. Ketamine has been demonstrated to be an *N*-methyl-D-aspartate (NMDA) receptor (a subtype of the glutamate receptor) antagonist.

Structure–Activity Relationships

Ketamine (Figure 9-4) is a structural analogue of phencyclidine (an anesthetic that has been used in veterinary medicine, and a drug of abuse). It is one-tenth as potent, yet retains many

of phencyclidine’s psychotomimetic effects. Ketamine is used for intravenous induction of anesthesia, particularly in settings where its tendency to produce sympathetic stimulation are useful (hypovolemia, trauma). When intravenous access is lacking, ketamine is useful for intramuscular induction of general anesthesia in children and uncooperative adults. Ketamine can be combined with other agents (eg, propofol or midazolam) in small bolus doses or infusions for deep conscious sedation during nerve blocks, endoscopy, etc. Even subanesthetic doses of ketamine may cause hallucinogenic effects but usually do not do so in clinical practice, where many patients will have received at least a small dose of midazolam (or a related agent) for amnesia and sedation. The increased anesthetic potency and decreased psychotomimetic side effects of one isomer (S[+] versus R[-]) are the result of stereospecific receptors. The single S(+) stereoisomer preparation is not available in the United States (but widely available throughout the world), and it has considerably greater affinity than the racemic mixture for the NMDA receptor as well as several-fold greater potency as a general anesthetic.

Pharmacokinetics

A. Absorption

Ketamine has been administered orally, nasally, rectally, subcutaneously, and epidurally, but in usual clinical practice it is given intravenously or intramuscularly (Table 9-3). Peak plasma levels are usually achieved within 10–15 min after intramuscular injection.

B. Distribution

Ketamine is more lipid soluble and less protein bound than thiopental. These characteristics, along with ketamine-induced increase in cerebral blood flow and cardiac output, lead to rapid brain uptake and subsequent redistribution (the distribution half-life is 10–15 min). Awakening is due to redistribution from brain to peripheral compartments.

C. Biotransformation

Ketamine is biotransformed in the liver to several metabolites, one of which (norketamine) retains

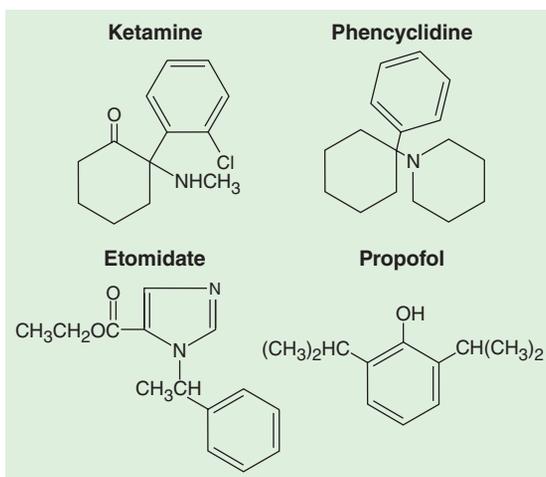

FIGURE 9-4 The structures of ketamine, etomidate, and propofol. Note the similarities between ketamine and phencyclidine.

TABLE 9–3 Uses and doses of ketamine, etomidate, and propofol.

Agent	Use	Route ¹	Dose

	Sedation ²	IV	3–5 mg/kg 2.5–15 mcg/kg/min
Etomidate	Induction	IV	0.2–0.5 mg/kg
Propofol	Induction	IV	1–2.5 mg/kg
	Maintenance infusion	IV	50–200 mcg/kg/min
	Sedation infusion	IV	25–100 mcg/kg/min

¹IV, intravenous; IM, intramuscular.

²Almost always in combination with propofol.

anesthetic activity. Induction of hepatic enzymes only partially explains the tolerance that patients who receive multiple doses of ketamine will develop. Extensive hepatic uptake (hepatic extraction ratio of 0.9) explains ketamine's relatively short elimination half-life (2 h).

D. Excretion

End products of ketamine biotransformation are excreted renally.

Effects on Organ Systems

A. Cardiovascular

4 In contrast to other anesthetic agents, ketamine increases arterial blood pressure, heart rate, and cardiac output (**Table 9–4**), particularly after rapid bolus injections. These indirect cardiovascular effects are due to central stimulation of the sympathetic nervous system and inhibition of the reuptake of norepinephrine after release at nerve terminals. Accompanying these changes are increases in pulmonary artery pressure and myocardial work. For these reasons, large bolus injections of ketamine should be administered cautiously in patients with coronary artery disease, uncontrolled hypertension, congestive heart failure, or arterial aneurysms. The **direct myocardial depressant** effects of large doses of ketamine, probably due to inhibition of calcium transients, are unmasked by sympathetic blockade (eg, spinal cord transection) or exhaustion of catecholamine stores (eg, severe end-stage shock). On the other hand, ketamine's **indirect stimulatory effects** may be beneficial to patients with acute shock.

B. Respiratory

Ventilatory drive is minimally affected by induction doses of ketamine, although rapid intravenous bolus

TABLE 9–4 Summary of nonvolatile anesthetic effects on organ systems.¹

¹HR, heart rate; MAP, mean arterial pressure; Vent, ventilatory drive; B'dil, bronchodilation; CBF, cerebral blood flow; CMRO₂, cerebral oxygen consumption; ICP, intracranial pressure; 0, no effect; 0/↑, no change or mild increase; ↓, decrease (mild, moderate, marked); ↑, increase (mild, moderate, marked).

²Minimal change in CBF and ICP when coadministered with other agents (see text).

administration or combinations of ketamine with opioids occasionally produce apnea. Racemic ketamine is a potent bronchodilator, making it a good induction agent for asthmatic patients; however, S(+) ketamine produces minimal bronchodilation. Upper airway reflexes remain largely intact, but partial airway obstruction may occur, and patients at increased risk for aspiration pneumonia (“full stomachs”) should be intubated during ketamine general anesthesia (see Case Discussion, Chapter 17). The increased salivation associated with ketamine can be attenuated by premedication with an anticholinergic agent such as glycopyrrolate

C. Cerebral

The received dogma about ketamine is that it increases cerebral oxygen consumption, cerebral blood flow, and intracranial pressure. These effects would seem to preclude its use in patients with space-occupying intracranial lesions such as occur with head trauma; however, recent publications offer convincing evidence that when combined with a benzodiazepine (or another agent acting on the same GABA receptor system) and controlled ventilation, but not with nitrous oxide, ketamine is *not* associated with increased intracranial pressure. Myoclonic activity is associated with increased subcortical electrical activity, which is not apparent on surface EEG. Undesirable psychotomimetic side effects (eg, disturbing dreams and delirium) during emergence and recovery are less common in children and in patients premedicated with benzodiazepines or those in whom ketamine is combined with propofol in a TIVA technique. Of the nonvolatile agents, ketamine comes closest to being a “complete” anesthetic as it induces analgesia, amnesia, and unconsciousness.

Drug Interactions

Ketamine interacts synergistically (more than additive) with volatile anesthetics but in an additive way with propofol, benzodiazepines, and other GABA-receptor-mediated agents. In animal experiments nondepolarizing neuromuscular blocking agents are minimally potentiated by ketamine (see Chapter 11). Diazepam and midazolam attenuate ketamine’s cardiostimulatory effects and diazepam prolongs ketamine’s elimination half-life.

α -Adrenergic and β -adrenergic antagonists (and other agents and techniques that diminish sympathetic stimulation) unmask the direct myocardial depressant effects of ketamine, which are normally overwhelmed by sympathetic stimulation. Concurrent infusion of ketamine and propofol, often in a fixed infusion rate ratio of 1:10, has achieved great popularity for sedation with local and regional anesthesia, particularly in office-based settings.

ETOMIDATE

Mechanisms of Action

Etomidate depresses the reticular activating system and mimics the inhibitory effects of GABA. Specifically, etomidate—particularly the R(+) isomer—appears to bind to a subunit of the GABA_A receptor, increasing the receptor’s affinity for GABA. Unlike barbiturates, etomidate may have disinhibitory effects on the parts of the nervous system that control extrapyramidal motor activity. This disinhibition offers a potential explanation for the 30–60% incidence of myoclonus with etomidate induction of anesthesia.

Structure–Activity Relationships

Etomidate contains a carboxylated imidazole and is structurally unrelated to other anesthetic agents (see Figure 9–4). The imidazole ring provides water solubility in acidic solutions and lipid solubility at physiological pH. Therefore etomidate is dissolved in propylene glycol for injection. This solution often causes pain on injection that can be lessened by a prior intravenous injection of lidocaine.

Pharmacokinetics

A. Absorption

Etomidate is available only for intravenous administration and is used primarily for induction of general anesthesia (see Table 9–3). It is sometimes used for brief production of deep (unconscious) sedation such as prior to placement of retrobulbar blocks.

B. Distribution

Although it is highly protein bound, etomidate is characterized by a very rapid onset of action due to its great lipid solubility and large nonionized fraction

at physiological pH. Redistribution is responsible for decreasing the plasma concentration to awakening levels. Etomidate plasma kinetics are well explained by a two-compartment model.

C. Biotransformation

Hepatic microsomal enzymes and plasma esterases rapidly hydrolyze etomidate to an inactive metabolite.

D. Excretion

The end products of etomidate hydrolysis are primarily excreted in the urine.

Effects on Organ Systems

A. Cardiovascular

Etomidate has minimal effects on the cardiovascular system. A mild reduction in peripheral vascular resistance is responsible for a slight decline in arterial blood pressure. Myocardial contractility and cardiac output are usually unchanged. Etomidate does not release histamine. However, etomidate by itself, even in large doses, produces relatively light anesthesia for laryngoscopy, and marked increases in heart rate and blood pressure may be recorded when etomidate provides the only anesthetic depth for intubation.

B. Respiratory

Ventilation is affected less with etomidate than with barbiturates or benzodiazepines. Even induction doses usually do not result in apnea unless opioids have also been administered.

C. Cerebral

Etomidate decreases cerebral metabolic rate, cerebral blood flow, and intracranial pressure. Because of minimal cardiovascular effects, CPP is well maintained. Although changes on EEG resemble those associated with barbiturates, etomidate increases the amplitude of somatosensory evoked potentials. Postoperative nausea and vomiting are more common following etomidate than following propofol or barbiturate induction. Etomidate lacks analgesic properties.

D. Endocrine

5 Induction doses of etomidate transiently inhibit enzymes involved in cortisol and aldosterone synthesis. It was used in the past for sedation

in the intensive care unit (ICU) before reports of its consistent ability to produce adrenocortical suppression in that circumstance appeared. Long-term infusion and **adrenocortical suppression** were associated with an increased mortality rate in critically ill (particularly septic) patients.

Drug Interactions

Fentanyl increases the plasma level and prolongs the elimination half-life of etomidate. Opioids decrease the myoclonus characteristic of an etomidate induction.

PROPOFOL

Mechanisms of Action

Propofol induction of general anesthesia may involve facilitation of inhibitory neurotransmission mediated by GABA_A receptor binding. Propofol allosterically increases binding affinity of GABA for the GABA_A receptor. This receptor, as previously noted, is coupled to a chloride channel, and activation of the receptor leads to hyperpolarization of the nerve membrane. Propofol (like most general anesthetics) binds multiple ion channels and receptors. Propofol actions are not reversed by the specific benzodiazepine antagonist flumazenil.

Structure–Activity Relationships

Propofol consists of a phenol ring substituted with two isopropyl groups (see Figure 9–4). Propofol is not water soluble, but a 1% aqueous solution (10 mg/mL) is available for intravenous administration as an oil-in-water emulsion containing soybean oil, glycerol, and egg lecithin. A history of egg allergy does not necessarily contraindicate the use of propofol because most egg allergies involve a reaction to egg white (egg albumin), whereas egg lecithin is extracted from egg yolk. This formulation will often cause pain during injection that can be decreased by prior injection of lidocaine or less effectively by mixing lidocaine with propofol prior to injection (2 mL of 1% lidocaine in 18 mL propofol). Propofol formulations can support the growth of bacteria, so sterile technique must be observed in preparation and handling. Propofol should be administered within 6 h of opening the

ampule. Sepsis and death have been linked to contaminated propofol preparations. Current formulations of propofol contain 0.005% disodium edetate or 0.025% sodium metabisulfite to help retard the rate of growth of microorganisms; however, these additives do not render the product “antimicrobially preserved” under United States Pharmacopeia standards.

Pharmacokinetics

A. Absorption

Propofol is available only for intravenous administration for the induction of general anesthesia and for moderate to deep sedation (see Table 9–3).

B. Distribution

Propofol has a rapid onset of action. Awakening from a single bolus dose is also rapid due to a very short initial distribution half-life (2–8 min). Most investigators believe that recovery from propofol is more rapid and is accompanied by less “hangover” than recovery from methohexital, thiopental, ketamine, or etomidate. This makes it a good agent for outpatient anesthesia. A smaller induction dose is recommended in elderly patients because of their smaller V_d . Age is also a key factor determining required propofol infusion rates for TIVA. In countries other than the United States, a device called the Diprifusor is often used to provide target (concentration) controlled infusion of propofol. The user must enter the patient’s age and weight and the desired target concentration. The device uses these data, a microcomputer, and standard pharmacokinetic parameters to continuously adjust the infusion rate.

C. Biotransformation

The clearance of propofol exceeds hepatic blood flow, implying the existence of extrahepatic metabolism. This exceptionally high clearance rate probably contributes to relatively rapid recovery after continuous infusions. Conjugation in the liver results in inactive metabolites that are eliminated by renal clearance. The pharmacokinetics of propofol do not appear to be affected by obesity, cirrhosis, or kidney failure. Use of propofol infusion for long-term sedation of children who are critically ill or young adult

neurosurgical patients has been associated with sporadic cases of lipemia, metabolic acidosis, and death, the so-termed *propofol infusion syndrome*.

D. Excretion

Although metabolites of propofol are primarily excreted in the urine, chronic kidney failure does not affect clearance of the parent drug.

Effects on Organ Systems

A. Cardiovascular

The major cardiovascular effect of propofol is a decrease in arterial blood pressure due to a drop in systemic vascular resistance (inhibition of sympathetic vasoconstrictor activity), preload, and cardiac contractility. Hypotension following induction is usually reversed by the stimulation accompanying laryngoscopy and intubation. Factors associated with propofol-induced hypotension include large doses, rapid injection, and old age. Propofol markedly impairs the normal arterial baroreflex response to hypotension. Rarely, a marked drop in preload may lead to a vagally mediated reflex bradycardia. Changes in heart rate and cardiac output are usually transient and insignificant in healthy patients but may be severe in patients at the extremes of age, those receiving β -adrenergic blockers, or those with impaired ventricular function. Although myocardial oxygen consumption and coronary blood flow usually decrease comparably, coronary sinus lactate production increases in some patients, indicating some mismatch between myocardial oxygen supply and demand.

B. Respiratory

Propofol is a profound respiratory depressant that usually causes apnea following an induction dose. Even when used for conscious sedation in sub-anesthetic doses, propofol inhibits hypoxic ventilatory drive and depresses the normal response to hypercarbia. As a result, only properly educated and qualified personnel should administer propofol for sedation. Propofol-induced depression of upper airway reflexes exceeds that of thiopental, allowing intubation, endoscopy, or laryngeal mask placement in the absence of neuromuscular blockade. Although propofol can cause histamine release, induction with propofol is accompanied by a lower incidence of

wheezing in asthmatic and nonasthmatic patients compared with barbiturates or etomidate.

C. Cerebral

Propofol decreases cerebral blood flow and intracranial pressure. In patients with elevated intracranial pressure, propofol can cause a critical reduction in CPP (<50 mm Hg) unless steps are taken to support mean arterial blood pressure. Propofol and thiopental probably provide a similar degree of cerebral protection during experimental focal ischemia. Unique to propofol are its antipruritic properties. Its antiemetic effects (requiring a blood propofol concentration of 200 ng/mL) provide yet another reason for it to be a preferred drug for outpatient anesthesia. Induction is occasionally accompanied by excitatory phenomena such as muscle twitching, spontaneous movement, opisthotonus, or hiccups. Although these reactions may occasionally mimic tonic-clonic seizures, propofol has anticonvulsant properties and has been used successfully to terminate status epilepticus. Propofol may be safely administered to epileptic patients. Propofol decreases intraocular pressure. Tolerance does not develop after long-term propofol infusions. Propofol is an uncommon agent of physical dependence or addiction; however, both anesthesia personnel and medically untrained individuals have died while using propofol inappropriately to induce sleep in nonsurgical settings.

Drug Interactions

Fentanyl and alfentanil concentrations may be increased with concomitant administration of propofol. Many clinicians administer a small amount of midazolam (eg, 30 mcg/kg) prior to induction with propofol; midazolam can reduce the required propofol dose by more than 10%.

FOSPROPOFOL

Fospropofol is a water-soluble prodrug that is metabolized in vivo to propofol, phosphate, and formaldehyde. It has been released in the United States and other countries based on studies showing that it produces more complete amnesia and better conscious sedation for endoscopy than midazolam plus fentanyl. It has a slower onset and

slower recovery than propofol, offering little reason for anesthesiologists to use fospropofol in place of propofol. The place (if any) of fospropofol relative to other competing agents has not yet been established in clinical practice.

CASE DISCUSSION

Premedication of the Surgical Patient

An extremely anxious 17-year-old woman presents for dilation and curettage. She demands to be asleep before going to the operating room and does not want to remember anything.

What are the goals of administering preoperative medication?

Anxiety is a normal response to impending surgery. Diminishing anxiety is usually the major goal of preoperative medication. For many patients, the preoperative interview with the anesthesiologist allays fears more effectively than sedative drugs. Preoperative medication may also provide relief of preoperative pain or perioperative amnesia.

There may also be specific medical indications for preoperative medication: prophylaxis against postoperative nausea and vomiting (5-HT₃s) and against aspiration pneumonia (eg, antacids), prevention of allergic reactions (eg, antihistamines), or decreasing upper airway secretions (eg, anticholinergics). The goals of preoperative medication depend on many factors, including the health and emotional status of the patient, the proposed surgical procedure, and the anesthetic plan. For this reason, the choice of anesthetic premedication must be individualized and must follow a thorough preoperative evaluation.

Do all patients require preoperative medication?

No—customary levels of preoperative anxiety do not harm most patients. Some patients dread intramuscular injections, and others find altered states of consciousness more unpleasant than nervousness. If the surgical procedure is brief, the effects of some sedatives may extend into the postoperative period and prolong recovery time. This is particularly troublesome for patients undergoing

ambulatory surgery. Specific contraindications for sedative premedication include severe lung disease, hypovolemia, impending airway obstruction, increased intracranial pressure, and depressed baseline mental status. Premedication with sedative drugs should never be given before informed consent has been obtained.

Which patients are most likely to benefit from preoperative medication?

Some patients are quite anxious despite the preoperative interview. Separation of young children from their parents is often a traumatic ordeal, particularly if they have endured multiple prior surgeries. Medical conditions such as coronary artery disease or hypertension may be aggravated by psychological stress.

How does preoperative medication influence the induction of general anesthesia?

Some medications often given preoperatively (eg, opioids) decrease anesthetic requirements and can smooth induction. However, intravenous administration of these medications just prior to induction is a more reliable method of achieving the same benefits.

What governs the choice among the preoperative medications commonly administered?

After the goals of premedication have been determined, the clinical effects of the agents dictate choice. For instance, in a patient experiencing preoperative pain from a femoral fracture, the analgesic effects of an opioid (eg, fentanyl, morphine, hydromorphone) will decrease the discomfort associated with transportation to the operating room and positioning on the operating room table. On the other hand, respiratory depression, orthostatic hypotension, and nausea and vomiting may result from opioid premedication.

Benzodiazepines relieve anxiety, often provide amnesia, and are relatively free of side effects; however, they are not analgesics. Diazepam and

lorazepam are available orally. Intramuscular midazolam has a rapid onset (30 min) and short duration (90 min), but intravenous midazolam has an even better pharmacokinetic profile.

Which factors must be considered in selecting the anesthetic premedication for this patient?

First, it must be made clear to the patient that in most centers, lack of necessary equipment and concern for patient safety preclude anesthesia being induced in the preoperative holding room. Long-acting agents such as morphine or lorazepam are poor choices for an outpatient procedure. Diazepam can also affect mental function for several hours. One alternative is to establish an intravenous line in the preoperative holding area and titrate small doses of midazolam using slurred speech as an end point. At that time, the patient can be taken to the operating room. Vital signs—particularly respiratory rate—must be continuously monitored.

Analgesic Agents

KEY CONCEPTS

- 1 The accumulation of morphine metabolites (morphine 3-glucuronide and morphine 6-glucuronide) in patients with kidney failure has been associated with narcosis and ventilatory depression lasting several days.
- 2 Rapid administration of larger doses of opioids (particularly fentanyl, sufentanil, remifentanil, and alfentanil) can induce chest wall rigidity severe enough to prevent adequate bag-and-mask ventilation.
- 3 Prolonged dosing of opioids can produce “opioid-induced hyperalgesia,” in which patients become more sensitive to painful stimuli. Infusion of large doses of (in particular) remifentanil during general anesthesia can produce acute tolerance, in which much larger than usual doses of opioids are required for postoperative analgesia.
- 4 The neuroendocrine stress response to surgical stimulation is measured in terms of the secretion of specific hormones, including catecholamines, antidiuretic hormone, and cortisol. Large doses of opioids block the release of these hormones in response to surgery more completely than volatile anesthetics.
- 5 Aspirin is unique in that it irreversibly inhibits COX-1 by acetylating a serine residue in the enzyme. The irreversible nature of its inhibition underlies the nearly 1-week duration of its clinical effects (eg, return of platelet aggregation to normal) after drug discontinuation.

Regardless of how expertly surgical and anesthetic procedures are performed, appropriate prescription of analgesic drugs, especially opioids and cyclooxygenase (COX) inhibitors, can make the difference between a satisfied and an unsatisfied postoperative patient. Studies have shown that outcomes can be improved when analgesia is provided in a “multimodal” format (typically emphasizing COX inhibitors and local anesthetic techniques while minimizing opioid use) as one part of a well-defined and well-organized plan for postoperative care (see Chapter 48).

OPIOIDS

Mechanisms of Action

Opioids bind to specific receptors located throughout the central nervous system and other tissues. Four major opioid receptor types have been identified ([Table 10-1](#)): mu (μ , with subtypes μ_1 and μ_2), kappa (κ), delta (δ), and sigma (σ). All opioid receptors couple to G proteins; binding of an agonist to an opioid receptor causes membrane hyperpolarization. Acute opioid effects are mediated by inhibition of adenylyl cyclase (reductions in intracellular cyclic

TABLE 10–1 Classification of opioid receptors.¹

¹Note: The relationships among receptor, clinical effect, and agonist are more complex than indicated in this table. For example, pentazocine is an antagonist at μ receptors, a partial agonist at κ receptors, and an agonist at σ receptors.

²Endogenous opioid.

adenosine monophosphate concentrations) and activation of phospholipase C. Opioids inhibit voltage-gated calcium channels and activate inwardly rectifying potassium channels. Opioid effects vary based on the duration of exposure, and opioid tolerance leads to changes in opioid responses.

Although opioids provide some degree of sedation and (in many species) can produce general anesthesia when given in large doses, they are principally used to provide analgesia. The properties of specific opioids depend on which receptor is bound (and in the case of spinal and epidural administration of opioids, the location in the neuraxis where the receptor is located) and the binding affinity of the drug. Agonist–antagonists (eg, nalbuphine, nalorphine, butorphanol, and pentazocine) have less efficacy than so-called full agonists (eg, fentanyl) and under some circumstances will antagonize the actions of full agonists. The pure opioid antagonists are discussed in Chapter 17.

The opioid drugs mimic endogenous compounds. Endorphins, enkephalins, and dynorphins are endogenous peptides that bind to opioid receptors. These three families of opioid peptides differ in their amino acid sequences, anatomic distributions, and receptor affinities.

Opioid receptor activation inhibits the pre-synaptic release and postsynaptic response to excitatory neurotransmitters (eg, acetylcholine, substance P) from nociceptive neurons. The cellular mechanism for this action was described at the beginning of this chapter. Transmission of pain impulses can be *selectively* modified at the level of the dorsal horn of the spinal cord with intrathecal or epidural administration of opioids. Opioid receptors also respond to systemically administered opioids. Modulation through a descending inhibitory pathway from the periaqueductal gray matter to the dorsal horn of the spinal cord may also play a role in opioid analgesia. Although opioids exert their greatest effect within the central nervous system, opiate receptors have also been identified on somatic and sympathetic peripheral nerves. Certain opioid side effects (eg, depression of gastrointestinal motility) are the result of opioid binding to receptors in peripheral tissues (eg, the wall of the gastrointestinal tract), and there are now selective antagonists for opioid actions outside the central nervous system (alvimopan and oral naltrexone). The distribution of opioid receptors on axons of primary sensory nerves and the clinical importance of these receptors (if present) remains speculative, despite the persisting practice of compounding of opioids in local anesthetic solutions applied to peripheral nerves.

Structure–Activity Relationships

Opioid receptor binding is a property shared by a chemically diverse group of compounds. Nonetheless, there are common structural characteristics, which are shown in **Figure 10–1**. As is true for most classes of drugs, small molecular changes can convert an agonist into an antagonist. The levorotatory isomers are generally more potent than the dextrorotatory opioid isomers.

Pharmacokinetics

A. Absorption

Rapid and complete absorption follows the intramuscular injection of hydromorphone, morphine, or meperidine, with peak plasma levels usually reached after 20–60 min. Oral transmucosal fentanyl citrate absorption (fentanyl “lollipop”) provides rapid onset of analgesia and sedation in patients who are not good candidates for conventional oral, intravenous, or intramuscular dosing of opioids.

The low molecular weight and high lipid solubility of fentanyl also favor transdermal absorption (the transdermal fentanyl “patch”). The amount of fentanyl absorbed per unit of time depends on the surface area of skin covered by the patch and also on local skin conditions (eg, blood flow). The time required to establish a reservoir of drug in the upper dermis delays by several hours the achievement of effective blood concentrations. Serum concentrations of fentanyl reach a plateau within 14–24 h of application (with peak levels occurring after a longer delay in elderly than in younger patients) and remain constant for up to 72 h. Continued absorption from the dermal reservoir accounts for persisting measurable serum levels many hours after patch removal. Fentanyl patches are most often used for outpatient management of chronic pain and are particularly appropriate for patients who require continuous opioid dosing but cannot take the much less expensive, but equally efficacious, oral agents such as methadone.

A wide variety of opioids are effective by oral administration, including oxycodone, hydrocodone (most often in combination with acetaminophen), codeine, tramadol, morphine, hydromorphone, and methadone. These agents are much used for outpatient pain management.

Fentanyl is often administered in small doses (10–25 mcg) with local anesthetics for spinal anesthesia, and adds to the analgesia when included with local anesthetics in epidural infusions. Morphine in doses between 0.1 and 0.5 mg and hydromorphone in doses between 0.05 and 0.2 mg provide 12–18 hours of analgesia after intrathecal administration. Morphine and hydromorphone are commonly included in local anesthetic solutions infused for postoperative epidural analgesia. Extended-release

TABLE 10–2 Physical characteristics of opioids that determine distribution.¹

Agent	Nonionized Fraction	Protein Binding	Lipid Solubility

epidural morphine (DepoDur) is administered as a single epidural dose (5–15 mg), the effects of which persist for 48 h.

B. Distribution

Table 10–2 summarizes the physical characteristics that determine distribution and tissue binding of opioid analgesics. After intravenous administration, the distribution half-lives of all of the opioids are fairly rapid (5–20 min). The low fat solubility of morphine slows passage across the blood–brain barrier, however, so that its onset of action is slow and its duration of action is prolonged. This contrasts with the increased lipid solubility of fentanyl and sufentanil, which are associated with a faster onset and shorter duration of action **when administered in small doses**. Interestingly, alfentanil has a more rapid onset of action and shorter duration of action than fentanyl following a bolus injection, even though it is less lipid soluble than fentanyl. The high nonionized fraction of alfentanil at physiological pH and its small volume of distribution (V_d) increase the amount of drug (as a percentage of the administered dose) available for binding in the brain.

Significant amounts of lipid-soluble opioids can be retained by the lungs (first-pass uptake); as systemic concentrations fall they will return to the bloodstream. The amount of pulmonary uptake is reduced by prior accumulation of other drugs, increased by a history of tobacco use, and decreased by concurrent inhalation anesthetic administration.

Unbinding of opioid receptors and redistribution (of drug from effect sites) terminate the clinical effects of all opioids. After smaller doses of the lipid-soluble drugs (eg, fentanyl or sufentanil), redistribution alone is the driver for reducing blood concentrations, whereas after larger doses biotransformation becomes an important driver in reducing plasma levels below those that have clinical effects. Thus, the time required for fentanyl or sufentanil concentrations to decrease by half is *context sensitive*; in other words, the half-time depends on the total dose of drug and duration of exposure (see Chapter 7).

C. Biotransformation

With the exception of remifentanyl, all opioids depend primarily on the liver for biotransformation and are metabolized by the cytochrome P (CYP) system, conjugated in the liver, or both. Because of the high hepatic extraction ratio of opioids, their clearance depends on liver blood flow. The small V_d of alfentanil contributes to a short elimination half-life (1.5 h). Morphine and hydromorphone undergo conjugation with glucuronic acid to form, in the former case, morphine 3-glucuronide and morphine 6-glucuronide, and in the latter case, hydromorphone 3-glucuronide. Meperidine is *N*-demethylated to normeperidine, an active metabolite associated with seizure activity, particularly after very large meperidine doses. The end products of fentanyl, sufentanil, and alfentanil are inactive. Norfentanyl, the metabolite of fentanyl, can be measured in urine long after the native compound is no longer detectable in blood to determine chronic fentanyl ingestion. This has its greatest importance in diagnosing fentanyl abuse.

Codeine is a prodrug that becomes active after it is metabolized by CYP to morphine. Tramadol similarly must be metabolized by CYP to *O*-desmethyltramadol to be active. Oxycodone is metabolized by CYP to series of active compounds that are less potent than the parent one.

The ester structure of remifentanyl makes it susceptible to hydrolysis (in a manner similar to esmolol) by nonspecific esterases in red blood cells and tissue (see Figure 10–1), yielding a terminal elimination half-life of less than 10 min. Remifentanyl biotransformation is rapid and the duration of a

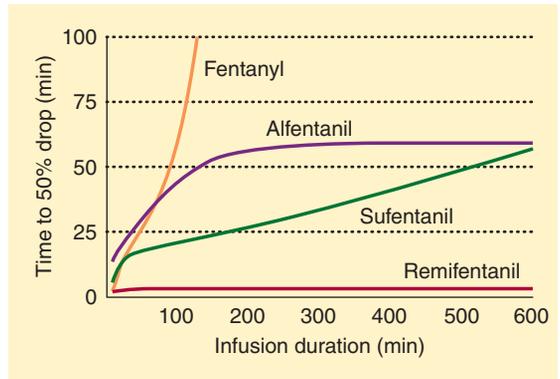

FIGURE 10-2 In contrast to other opioids, the time necessary to achieve a 50% decrease in the plasma concentration of remifentanyl (its **context-sensitive half-time**) is very short and is not influenced by the duration of the infusion. (Reproduced, with permission, from Egan TD: The pharmacokinetics of the new short-acting opioid remifentanyl [GI87084B] in healthy adult male volunteers. *Anesthesiology* 1993;79:881.)

remifentanyl infusion has little effect on wake-up time (Figure 10–2). The context-sensitive half-time of remifentanyl remains approximately 3 min regardless of the dose or duration of infusion. In its lack of accumulation remifentanyl differs from other currently available opioids. Hepatic dysfunction requires no adjustment in remifentanyl dosing. Finally, patients with pseudocholinesterase deficiency have a normal response to remifentanyl (as also appears true for esmolol).

D. Excretion

The end products of morphine and meperidine biotransformation are eliminated by the kidneys, with less than 10% undergoing biliary excretion. Because 5–10% of morphine is excreted unchanged in the urine, kidney failure prolongs morphine duration of action. The accumulation of morphine metabolites (morphine 3-glucuronide and morphine 6-glucuronide) in patients with kidney failure has been associated with prolonged narcosis and ventilatory depression. In fact, morphine 6-glucuronide is a more potent and longer-lasting opioid agonist than morphine. As previously noted, normeperidine at increased concentrations may produce seizures; these are not reversed by naloxone. Renal dysfunction increases the likelihood of toxic effects

from normeperidine accumulation. However, both morphine and meperidine have been used safely and successfully in patients with kidney failure. Metabolites of sufentanil are excreted in urine and bile. The main metabolite of remifentanil is eliminated in urine, is several thousand times less potent than its parent compound, and thus is unlikely to produce any clinical opioid effects.

Effects on Organ Systems

A. Cardiovascular

In general, opioids have few direct effects on the heart. Meperidine tends to increase heart rate (it is structurally similar to atropine and was originally synthesized as an atropine replacement), whereas larger doses of morphine, fentanyl, sufentanil, remifentanil, and alfentanil are associated with a vagus nerve-mediated bradycardia. With the exception of meperidine (and only then at very large doses), the opioids do not depress cardiac contractility provided they are administered alone (which is almost never the circumstance in surgical anesthetic settings). Nonetheless, arterial blood pressure often falls as a result of bradycardia, venodilation, and decreased sympathetic reflexes, sometimes requiring vasopressor support. These effects are more pronounced when opioids are administered in combination with benzodiazepines, in which case drugs such as sufentanil and fentanyl can be associated with reduced cardiac output. Bolus doses of meperidine, hydromorphone, and morphine evoke histamine release in some individuals that can lead to profound drops in systemic vascular resistance and arterial blood pressure. The potential hazards of histamine release can be minimized in susceptible patients by infusing opioids slowly or by pretreatment with H_1 and H_2 antagonists, or both. The end effects of histamine release can be reversed by infusion of intravenous fluid and vasopressors.

Intraoperative hypertension during large-dose opioid anesthesia or nitrous oxide–opioid anesthesia is common. Such hypertension is often attributed to inadequate anesthetic depth, thus it is conventionally treated by the addition of other anesthetic agents (benzodiazepines, propofol, or potent inhaled agents). If depth of anesthesia is adequate and hypertension persists, vasodilators or other antihypertensives may be used. The inherent cardiac

stability provided by opioids is greatly diminished in actual practice when other anesthetic drugs, including nitrous oxide, benzodiazepines, propofol, or volatile agents, are typically added. The end result of polypharmacy can include myocardial depression.

B. Respiratory

Opioids depress ventilation, particularly respiratory rate. Thus, monitoring of respiratory rate provides a convenient, simple way of detecting early respiratory depression in patients receiving opioid analgesia. Opioids increase the partial pressure of carbon dioxide (P_{aCO_2}) and blunt the response to a CO_2 challenge, resulting in a shift of the CO_2 response curve downward and to the right (Figure 10–3). These effects result from opioid binding to neurons in the respiratory centers of the brainstem. **The apneic threshold—the greatest P_{aCO_2} at which a patient remains apneic—rises, and hypoxic drive is decreased.** Morphine and meperidine can cause histamine-induced bronchospasm in susceptible patients. **Rapid administration of larger doses of opioids (particularly fentanyl, sufentanil, remifentanil, and alfentanil) can induce chest wall rigidity severe enough to prevent adequate bag-and-mask ventilation.** This centrally

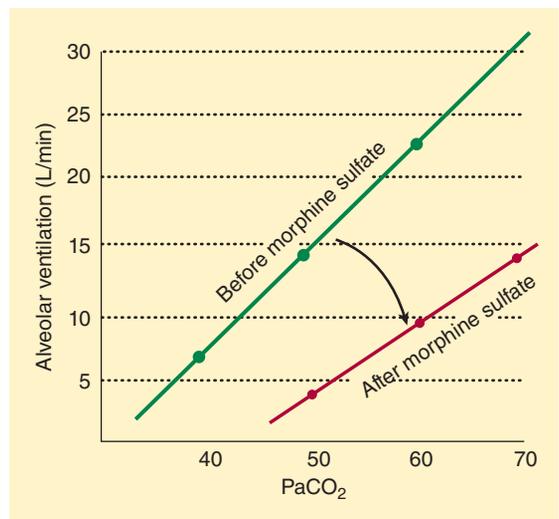

FIGURE 10–3 Opioids depress ventilation. This is graphically displayed by a shift of the CO_2 curve downward and to the right.

mediated muscle contraction is effectively treated with neuromuscular blocking agents. This problem is rarely seen now that large-dose opioid anesthesia is less often used in cardiovascular anesthesia practice. Opioids can effectively blunt the bronchoconstrictive response to airway stimulation such as occurs during tracheal intubation.

C. Cerebral

The effects of opioids on cerebral perfusion and intracranial pressure must be separated from any effects of opioids on Paco_2 . In general, opioids reduce cerebral oxygen consumption, cerebral blood flow, cerebral blood volume, and intracranial pressure, but to a much lesser extent than barbiturates, propofol, or benzodiazepines. These effects will occur during maintenance of normocarbica by artificial ventilation; however, there are some reports of mild—but transient and almost certainly unimportant—increases in cerebral artery blood flow velocity and intracranial pressure following opioid boluses in patients with brain tumors or head trauma. If combined with hypotension, the resulting fall in cerebral perfusion pressure *could* be deleterious to patients with abnormal intracranial pressure–volume relationships. Nevertheless, the important clinical message is that any trivial opioid-induced increase in intracranial pressure would likely be much less important than the much more likely large increases in intracranial pressure associated with intubation that might be observed in an inadequately anesthetized patient (from whom opioids were withheld). Opioids usually have almost no effects on the electroencephalogram (EEG), although large doses are associated with slow δ -wave activity. There are curious sporadic case reports that large doses of fentanyl may rarely cause seizure activity; however, some of these apparent seizures have been retrospectively diagnosed as severe opioid-induced muscle rigidity. EEG activation and seizures have been associated with the meperidine metabolite normeperidine, as previously noted.

Stimulation of the medullary chemoreceptor trigger zone is responsible for opioid-induced nausea and vomiting. Curiously, nausea and vomiting are more common following smaller (analgesic) than very large (anesthetic) doses of opioids. Prolonged oral

dosing of opioids or infusion of large doses of remifentanyl during general anesthesia can produce the phenomenon of opioid-induced tolerance. Repeated dosing of opioids will reliably produce tolerance, a phenomenon in which larger doses are required to produce the same response. This is not the same as physical dependence or addiction, which may also be associated with repeated opioid administration.

3 Prolonged dosing of opioids can also produce “opioid-induced hyperalgesia,” in which patients become more sensitive to painful stimuli. Infusion of large doses of (in particular) remifentanyl during general anesthesia can produce acute tolerance, in which much larger than usual doses of opioids will be required for postoperative analgesia. Relatively large doses of opioids are required to render patients unconscious (Table 10-3). Regardless of the dose, however, opioids will not reliably produce amnesia. Parenteral opioids have been the mainstay of pain control for more than a century. The relatively recent use of opioids in epidural and intrathecal spaces has revolutionized acute and chronic pain management (see Chapters 47 and 48).

Unique among the commonly used opioids, meperidine has minor local anesthetic qualities, particularly when administered into the subarachnoid space. Meperidine’s clinical use as a local anesthetic has been limited by its relatively low potency and propensity to cause typical opioid side effects (nausea, sedation, and pruritus) at the doses required to induce local anesthesia. **Intravenous meperidine (10–25 mg) is more effective than morphine or fentanyl for decreasing shivering in the postanesthetic care unit and meperidine appears to be the best agent for this indication.**

D. Gastrointestinal

Opioids slow gastrointestinal motility by binding to opioid receptors in the gut and reducing peristalsis. Biliary colic may result from opioid-induced contraction of the sphincter of Oddi. Biliary spasm, which can mimic a common bile duct stone on cholangiography, is reversed with the opioid antagonist naloxone or glucagon. Patients receiving long-term opioid therapy (eg, for cancer pain) usually become tolerant to many of the side effects but rarely to constipation. This is the basis for

TABLE 10–3 Uses and doses of common opioids.

Agent	Use	Route ¹	Dose ²
Morphine	Postoperative analgesia	IM	0.05–0.2 mg/kg
		IV	0.03–0.15 mg/kg
Hydromorphone	Postoperative analgesia	IM	0.02–0.04 mg/kg
		IV	0.01–0.02 mg/kg
Fentanyl	Intraoperative anesthesia	IV	2–50 mcg/kg
	Postoperative analgesia	IV	0.5–1.5 mcg/kg
Sufentanil	Intraoperative anesthesia	IV	0.25–20 mcg/kg
Alfentanil	Intraoperative anesthesia	IV	8–100 mcg/kg
	Loading dose		
	Maintenance infusion	IV	0.5–3 mcg/kg/min
Remifentanil	Intraoperative anesthesia	IV	1.0 mcg/kg
	Loading dose		
	Maintenance infusion	IV	0.5–20 mcg/kg/min
	Postoperative analgesia/sedation	IV	0.05–0.3 mcg/kg/min

¹IM, intramuscular; IV, intravenous.

²Note: The wide range of opioid doses reflects a large therapeutic index and depends upon which other anesthetics are simultaneously administered. For obese patients, dose should be based on ideal body weight or lean body mass, not total body weight. Tolerance can develop rapidly (ie, within 2 h) during IV infusion of opioids, necessitating higher infusion rates. Dose correlates with other variables besides body weight that need to be considered (eg, age). The relative potencies of fentanyl, sufentanil, and alfentanil are estimated to be 1:9:1/7.

the recent development of the peripheral opioid antagonists methylnaltrexone and alvimopan, and for their salutary effects in promoting motility in patients with opioid bowel syndrome, those receiving chronic opioid treatment of cancer pain, and those receiving intravenous opioids after abdominal surgery.

E. Endocrine

4 The neuroendocrine stress response to surgical stimulation is measured in terms of the secretion of specific hormones, including catecholamines, antidiuretic hormone, and cortisol. Large doses of opioids (typically fentanyl or sufentanil) block the release of these hormones in response to surgery more completely than volatile anesthetics. Although much discussed, the actual clinical outcome benefit produced by attenuating the stress response, even in high-risk cardiac patients, remains speculative (and possibly nonexistent).

Drug Interactions

The combination of meperidine and monoamine oxidase inhibitors should be avoided as it may result

in hypertension, hypotension, hyperpyrexia, coma, or respiratory arrest. The cause of this catastrophic interaction is incompletely understood. (The results of failure to appreciate this drug interaction in the celebrated Libby Zion case led to changes in work rules for house officers in the United States.)

Propofol, barbiturates, benzodiazepines, and other central nervous system depressants can have synergistic cardiovascular, respiratory, and sedative effects with opioids.

The biotransformation of alfentanil may be impaired following treatment with erythromycin, leading to prolonged sedation and respiratory depression.

CYCLOOXYGENASE INHIBITORS

Mechanisms of Action

Many over-the-counter nonsteroidal antiinflammatory agents (NSAIDs) work through inhibition of cyclooxygenase (COX), the key step in prostaglandin synthesis. COX catalyzes the production of prostaglandin H₂ from arachidonic acid. The two forms

of the enzyme, COX-1 and COX-2, have differing distribution in tissue. COX-1 receptors are widely distributed throughout the body, including the gut and platelets. COX-2 is produced in response to inflammation.

COX-1 and COX-2 enzymes differ further in the size of their binding sites: the COX-2 site can accommodate larger molecules that are restricted from binding at the COX-1 site. This distinction is in part responsible for selective COX-2 inhibition. Agents that inhibit COX nonselectively (eg, aspirin) will control fever, inflammation, pain, and thrombosis. COX-2 selective agents (eg, acetaminophen [paracetamol], celecoxib, etoricoxib) can be used perioperatively without concerns about platelet inhibition or gastrointestinal upset. Curiously, while COX-1 inhibition decreases thrombosis, selective COX-2 inhibition increases the risk of heart attack, thrombosis, and stroke.

Aspirin, the first of the so-called NSAIDs, formerly was used as an antipyretic and analgesic. Now it is used almost exclusively for prevention of thrombosis in susceptible individuals or for treatment of acute myocardial infarction. Aspirin is unique in that it irreversibly inhibits COX-1 by acetylating a serine residue in the enzyme. The irreversible nature of its inhibition underlies the nearly 1-week duration of its clinical effects (eg, return of platelet aggregation to normal) after drug discontinuation.

The first relatively selective COX-2 agent to be developed was acetaminophen (paracetamol). Curiously, this agent, while effective for analgesia, produces almost no effects on inflammation relative to other COX-2 selective agents. With few exceptions, the COX inhibitors are oral agents. Acetaminophen and ketorolac are available in an intravenous form for perioperative use.

Multimodal analgesia typically includes the use of COX inhibitors, regional or local anesthesia techniques, and other approaches aimed at reducing the requirement for opioids in postoperative patients. The hope is that reduced exposure to opioids will hasten and improve recovery from surgical procedures.

Structure–Activity Relationships

The COX enzyme is inhibited by an unusually diverse group of compounds that can be grouped

into salicylic acids (eg, aspirin), acetic acid derivatives (eg, ketorolac), propionic acid derivatives (eg, ibuprofen), heterocyclics (eg, celecoxib), and others. Thus a conventional discussion of structure to potency (and other factors) is not useful for these chemicals, other than to note that the heterocyclics tend to be the compounds with the greatest selectivity for the COX-2 rather than COX-1 form of the enzyme.

Pharmacokinetics

A. Absorption

All COX inhibitors (save for ketorolac) are well absorbed after oral administration and all will typically achieve their peak blood concentrations in less than 3 hours. Some COX inhibitors are formulated for topical application (eg, as a gel to be applied over joints or as liquid drops to be instilled on the eye).

B. Distribution

After absorption, COX inhibitors are highly bound by plasma proteins, chiefly albumin. Their lipid solubility allows them to readily permeate the blood–brain barrier to produce a central analgesia and antipyresis, and to penetrate joint spaces to produce (with the exception of acetaminophen) an anti-inflammatory effect.

C. Biotransformation

Most COX inhibitors undergo hepatic biotransformation. The agent with the most notable metabolite is acetaminophen which at toxic, increased doses yields sufficiently large concentrations of *N*-acetyl-*p*-benzoquinone imine to produce hepatic failure.

D. Excretion

Nearly all COX inhibitors are excreted in urine after biotransformation.

Effects on Organ Systems

A. Cardiovascular

COX inhibitors do not act directly on the cardiovascular system. Any cardiovascular effects result from the actions of these agents on coagulation. Prostaglandins maintain the patency of the ductus arteriosus, thus prostaglandin inhibitors have been administered to neonates to promote closure of a persistently patent ductus arteriosus.

B. Respiratory

At appropriate clinical doses, none of the COX inhibitors have effects on respiration or lung function. Aspirin overdosage has complex effects on acid–base balance and respiration.

C. Gastrointestinal

The classical complication of COX-1 inhibition is gastrointestinal upset. In its most extreme form this can cause upper gastrointestinal bleeding. Both complications result from direct actions of the drug, in the former case, on protective effects of prostaglandins in the mucosa, and in the latter case, on the combination of mucosal effects and inhibition of platelet aggregation.

Acetaminophen abuse or overdosage is a common cause of fulminant hepatic failure resulting in need for hepatic transplantation in western societies.

Neuromuscular Blocking Agents

KEY CONCEPTS

- 1 It is important to realize that muscle relaxation does not ensure unconsciousness, amnesia, or analgesia.
- 2 Depolarizing muscle relaxants act as acetylcholine (ACh) receptor agonists, whereas nondepolarizing muscle relaxants function as competitive antagonists.
- 3 Because depolarizing muscle relaxants are not metabolized by acetylcholinesterase, they diffuse away from the neuromuscular junction and are hydrolyzed in the plasma and liver by another enzyme, pseudocholinesterase (nonspecific cholinesterase, plasma cholinesterase, or butyrylcholinesterase).
- 4 With the exception of mivacurium, nondepolarizing agents are not significantly metabolized by either acetylcholinesterase or pseudocholinesterase. Reversal of their blockade depends on redistribution, gradual metabolism, and excretion of the relaxant by the body, or administration of specific reversal agents (eg, cholinesterase inhibitors) that inhibit acetylcholinesterase enzyme activity.
- 5 Muscle relaxants owe their paralytic properties to mimicry of ACh. For example, succinylcholine consists of two joined ACh molecules.
- 6 Compared with patients with low enzyme levels or heterozygous atypical enzyme in whom blockade duration is doubled or tripled, patients with homozygous atypical enzyme will have a very long blockade (eg, 4–8 h) following succinylcholine administration.
- 7 Succinylcholine is considered contraindicated in the routine management of children and adolescents because of the risk of hyperkalemia, rhabdomyolysis, and cardiac arrest in children with undiagnosed myopathies.
- 8 Normal muscle releases enough potassium during succinylcholine-induced depolarization to raise serum potassium by 0.5 mEq/L. Although this is usually insignificant in patients with normal baseline potassium levels, a life-threatening potassium elevation is possible in patients with burn injury, massive trauma, neurological disorders, and several other conditions.
- 9 Doxacurium, pancuronium, vecuronium, and pipecuronium are partially excreted by the kidneys, and their action is prolonged in patients with renal failure.
- 10 Cirrhotic liver disease and chronic renal failure often result in an increased volume of distribution and a lower plasma concentration for a given dose of water-soluble drugs, such as muscle relaxants. On the other hand, drugs dependent on hepatic or renal excretion may demonstrate prolonged clearance. Thus, depending on

—Continued next page

Continued—

the drug, a greater initial dose—but smaller maintenance doses—might be required in these diseases.

- 11 Atracurium and cisatracurium undergo degradation in plasma at physiological pH and temperature by organ-independent Hofmann elimination. The resulting metabolites (a monoquaternary acrylate and laudanosine) have no intrinsic neuromuscular blocking effects.
- 12 Hypertension and tachycardia may occur in patients given pancuronium. These cardiovascular effects are caused by the combination of vagal blockade and

catecholamine release from adrenergic nerve endings.

- 13 Long-term administration of vecuronium to patients in intensive care units has resulted in prolonged neuromuscular blockade (up to several days), possibly from accumulation of its active 3-hydroxy metabolite, changing drug clearance, or the development of a polyneuropathy.
- 14 Rocuronium (0.9–1.2 mg/kg) has an onset of action that approaches succinylcholine (60–90 s), making it a suitable alternative for rapid-sequence inductions, but at the cost of a much longer duration of action.

Skeletal muscle relaxation can be produced by deep inhalational anesthesia, regional nerve block, or neuromuscular blocking agents (commonly called *muscle relaxants*). In 1942, Harold Griffith published the results of a study using an extract of curare (a South American arrow poison) during anesthesia. Following the introduction of succinylcholine as a “new approach to muscular relaxation,” these agents rapidly became a routine part of the anesthesiologist’s drug arsenal. However, as noted by Beecher and Todd in 1954: “[m]uscle relaxants given inappropriately may provide the surgeon with optimal [operating] conditions in . . . a patient [who] is paralyzed but not anesthetized—a state [that] is **1** wholly unacceptable for the patient.” In other words, muscle relaxation does not ensure unconsciousness, amnesia, or analgesia. This chapter reviews the principles of neuromuscular transmission and presents the mechanisms of action, physical structures, routes of elimination, recommended dosages, and side effects of several muscle relaxants.

Neuromuscular Transmission

Association between a motor neuron and a muscle cell occurs at the neuromuscular junction (Figure 11-1). The cell membranes of the neuron and

muscle fiber are separated by a narrow (20-nm) gap, the synaptic cleft. As a nerve’s action potential depolarizes its terminal, an influx of calcium ions through voltage-gated calcium channels into the nerve cytoplasm allows storage vesicles to fuse with the terminal plasma membrane and release their contents

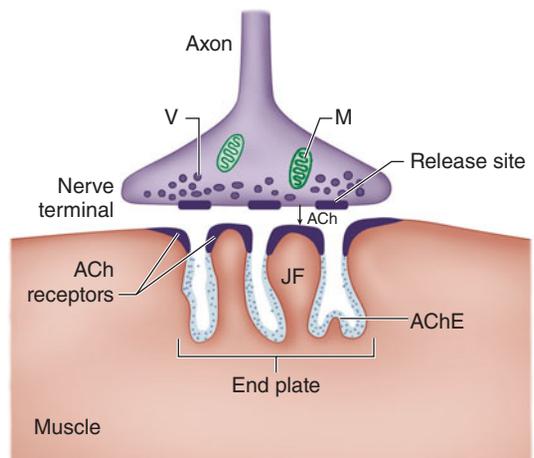

FIGURE 11-1 The neuromuscular junction. V, transmitter vesicle; M, mitochondrion; ACh, acetylcholine; AChE, acetylcholinesterase; JF, junctional folds. (Reproduced, with permission, from Drachman DB: Myasthenia gravis. *N Engl J Med* 1978;298:135.)

(acetylcholine [ACh]). The ACh molecules diffuse across the synaptic cleft to bind with nicotinic cholinergic receptors on a specialized portion of the muscle membrane, the motor end-plate. Each neuromuscular junction contains approximately 5 million of these receptors, but activation of only about 500,000 receptors is required for normal muscle contraction.

The structure of ACh receptors varies in different tissues and at different times in development. Each ACh receptor in the neuromuscular junction normally consists of five protein subunits; two α subunits; and single β , δ , and ϵ subunits. Only the two identical α subunits are capable of binding ACh molecules. If both binding sites are occupied by ACh, a conformational change in the subunits briefly (1 ms) opens an ion channel in the core of the receptor (Figure 11-2). The channel will not open if ACh binds on only one site. In contrast to the normal (or

mature) junctional ACh receptor, another isoform contains a γ subunit instead of the ϵ subunit. This isoform is referred to as the fetal or immature receptor because it is in the form initially expressed in fetal muscle. It is also often referred to as extrajunctional because, unlike the mature isoform, it may be located anywhere in the muscle membrane, inside or outside the neuromuscular junction when expressed in adults.

Cations flow through the open ACh receptor channel (sodium and calcium in; potassium out), generating an **end-plate potential**. The contents of a single vesicle, a quantum of ACh (10^4 molecules per quantum), produce a miniature end-plate potential. The number of quanta released by each nerve impulse, normally at least 200, is very sensitive to extracellular ionized calcium concentration; increasing calcium concentration increases the

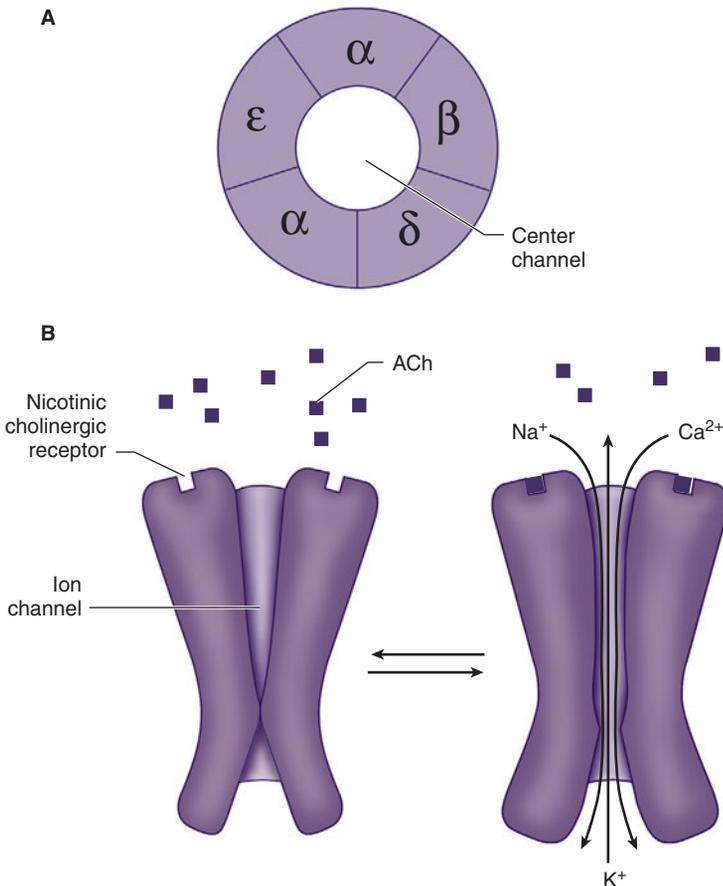

FIGURE 11-2 **A:** Structure of the ACh receptor. Note the two α subunits that actually bind ACh and the center channel. **B:** Binding of ACh to receptors on muscle end-plate causes channel opening and ion flux.

number of quanta released. When enough receptors are occupied by ACh, the end-plate potential will be sufficiently strong to depolarize the perijunctional membrane. Voltage-gated sodium channels within this portion of the muscle membrane open when a threshold voltage is developed across them, as opposed to end-plate receptors that open when ACh is applied (Figure 11-3). Perijunctional areas of muscle membrane have a higher density of these sodium channels than other parts of the membrane. The resulting action potential propagates along the muscle membrane and T-tubule system, opening sodium channels and releasing calcium from the sarcoplasmic reticulum. This intracellular calcium allows the contractile proteins actin and myosin to interact, bringing about muscle contraction. The

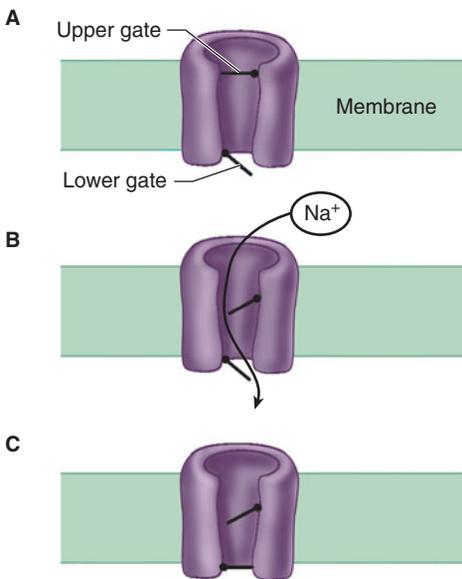

FIGURE 11-3 Schematic of the sodium channel. The sodium channel is a transmembrane protein that can be conceptualized as having two gates. Sodium ions pass only when both gates are open. Opening of the gates is time dependent and voltage dependent. The channel therefore possesses three functional states. At rest, the lower gate is open but the upper gate is closed (A). When the muscle membrane reaches threshold voltage depolarization, the upper gate opens and sodium can pass (B). Shortly after the upper gate opens the time-dependent lower gate closes (C). When the membrane repolarizes to its resting voltage, the upper gate closes and the lower gate opens (A).

amount of ACh released and the number of receptors subsequently activated will normally far exceed the minimum required for the initiation of an action potential. The nearly 10-fold margin of safety is lost in Eaton–Lambert myasthenic syndrome (decreased release of ACh) and myasthenia gravis (decreased number of receptors).

ACh is rapidly hydrolyzed into acetate and choline by the substrate-specific enzyme **acetylcholinesterase**. This enzyme (also called specific cholinesterase or true cholinesterase) is embedded into the motor end-plate membrane immediately adjacent to the ACh receptors. After unbinding ACh, the receptors' ion channels close, permitting the end-plate to repolarize. Calcium is resequestered in the sarcoplasmic reticulum, and the muscle cell relaxes.

Distinctions Between Depolarizing & Nondepolarizing Blockade

Neuromuscular blocking agents are divided into two classes: depolarizing and nondepolarizing (Table 11-1). This division reflects distinct differences in the mechanism of action, response to peripheral nerve stimulation, and reversal of block.

MECHANISM OF ACTION

Similar to ACh, all neuromuscular blocking agents are quaternary ammonium compounds whose positively charged nitrogen imparts an affinity to

TABLE 11-1 Depolarizing and nondepolarizing muscle relaxants.

Depolarizing	Nondepolarizing
Short-acting Succinylcholine	Short-acting Gantacurium ¹ Intermediate-acting Atracurium Cisatracurium Vecuronium Rocuronium Long-acting Pancuronium

¹Not yet commercially available in the United States.

nicotinic ACh receptors. Whereas most agents have two quaternary ammonium atoms, a few have one quaternary ammonium cation and one tertiary amine that is protonated at physiological pH.

Depolarizing muscle relaxants very closely resemble ACh and readily bind to ACh receptors, generating a muscle action potential. Unlike ACh, however, these drugs are *not* metabolized by acetylcholinesterase, and their concentration in the synaptic cleft does not fall as rapidly, resulting in a prolonged depolarization of the muscle end-plate.

Continuous end-plate depolarization causes muscle relaxation because opening of perijunctional sodium channels is time limited (sodium channels rapidly “inactivate” with continuing depolarization) (Figure 11–3). After the initial excitation and opening (Figure 11–3B), these sodium channels inactivate (Figure 11–3C) and cannot reopen until the end-plate repolarizes. The end-plate cannot repolarize as long as the depolarizing muscle relaxant continues to bind to ACh receptors; this is called a phase I block. After a period of time, prolonged end-plate depolarization can cause poorly understood changes in the ACh receptor that result in a phase II block, which clinically resembles that of nondepolarizing muscle relaxants.

Nondepolarizing muscle relaxants bind ACh receptors but are incapable of inducing the conformational change necessary for ion channel opening. Because ACh is prevented from binding to its receptors, no end-plate potential develops. Neuromuscular blockade occurs even if only one α subunit is blocked.

2 Thus, depolarizing muscle relaxants act as ACh receptor agonists, whereas nondepolarizing muscle relaxants function as competitive antagonists. This basic difference in mechanism of action explains their varying effects in certain disease states. For example, conditions associated with a chronic decrease in ACh release (eg, muscle denervation injuries) stimulate a compensatory increase in the number of ACh receptors within muscle membranes. These states also promote the expression of the immature (extrajunctional) isoform of the ACh receptor, which displays low channel conductance properties and prolonged open-channel time. This up-regulation causes an exaggerated response to depolarizing muscle relaxants (with more receptors being depolarized),

but a resistance to nondepolarizing relaxants (more receptors that must be blocked). In contrast, conditions associated with fewer ACh receptors (eg, down-regulation in myasthenia gravis) demonstrate a resistance to depolarizing relaxants and an increased sensitivity to nondepolarizing relaxants.

OTHER MECHANISMS OF NEUROMUSCULAR BLOCKADE

Some drugs may interfere with the function of the ACh receptor without acting as an agonist or antagonist. They interfere with normal functioning of the ACh receptor binding site or with the opening and closing of the receptor channel. These may include inhaled anesthetic agents, local anesthetics, and ketamine. The ACh receptor–lipid membrane interface may be an important site of action.

Drugs may also cause either closed or open channel blockade. During closed channel blockade, the drug physically plugs up the channel, preventing passage of cations whether or not ACh has activated the receptor. Open channel blockade is use dependent, because the drug enters and obstructs the ACh receptor channel only after it is opened by ACh binding. The clinical relevance of open channel blockade is unknown. Based on laboratory experiments, one would expect that increasing the concentration of ACh with a cholinesterase inhibitor would not overcome this form of neuromuscular blockade. Drugs that may cause channel block in the laboratory include neostigmine, some antibiotics, cocaine, and quinidine. Other drugs may impair the presynaptic release of ACh. Prejunctional receptors play a role in mobilizing ACh to maintain muscle contraction. Blocking these receptors can lead to a fading of the train-of-four response.

REVERSAL OF NEUROMUSCULAR BLOCKADE

3 Because succinylcholine is not metabolized by acetylcholinesterase, it unbinds the receptor and diffuses away from the neuromuscular junction

to be hydrolyzed in the plasma and liver by another enzyme, pseudocholinesterase (nonspecific cholinesterase, plasma cholinesterase, or butyrylcholinesterase). Fortunately, this is a fairly rapid process, because no specific agent to reverse a depolarizing blockade is available.

4 With the exception of the discontinued drug mivacurium, nondepolarizing agents are not metabolized by either acetylcholinesterase or pseudocholinesterase. Reversal of their blockade depends on unbinding the receptor, redistribution, metabolism, and excretion of the relaxant by the body, or administration of specific reversal agents (eg, cholinesterase inhibitors) that inhibit acetylcholinesterase enzyme activity. Because this inhibition increases the amount of ACh that is available at the neuromuscular junction and can compete with the nondepolarizing agent, clearly, the reversal agents are of no benefit in reversing a depolarizing block. In fact, by increasing neuromuscular junction ACh concentration and inhibiting pseudocholinesterase-induced metabolism of succinylcholine, *cholinesterase inhibitors can prolong neuromuscular blockade produced by succinylcholine*. The ONLY time neostigmine reverses neuromuscular block after succinylcholine is when there is a phase II block (fade of the train-of-four) AND sufficient time has passed for the circulating concentration of succinylcholine to be negligible.

Sugammadex, a cyclodextrin, is the first selective relaxant-binding agent; it exerts its reversal effect by forming tight complexes in a 1:1 ratio with steroidal nondepolarizing agents (vecuronium, rocuronium,). This drug has been in use in the European Union for the past few years, but is not yet commercially available in the United States.

The newer neuromuscular blocking agents, such as gantacurium, which are still under investigation, show promise as ultrashort-acting nondepolarizing agents; they undergo chemical degradation by rapid adduction with L-cysteine.

RESPONSE TO PERIPHERAL NERVE STIMULATION

The use of peripheral nerve stimulators to monitor neuromuscular function is discussed in

Chapter 6. Four patterns of electrical stimulation with supramaximal square-wave pulses are considered:

Tetany: A sustained stimulus of 50–100 Hz, usually lasting 5 sec.

Single twitch: A single pulse 0.2 ms in duration.

Train-of-four: A series of four twitches in 2 s (2-Hz frequency), each 0.2 ms long.

Double-burst stimulation (DBS): Three short (0.2 ms) high-frequency stimulations separated by a 20-ms interval (50 Hz) and followed 750 ms later by two (DBS_{3,2}) or three (DBS_{3,3}) additional impulses.

The occurrence of fade, a gradual diminution of evoked response during prolonged or repeated nerve stimulation, is indicative of a nondepolarizing block ([Table 11–2](#)), or of a phase II block if only succinylcholine has been administered. Fade may be due to a prejunctional effect of nondepolarizing relaxants that reduces the amount of ACh in the nerve terminal available for release during stimulation (blockade of ACh mobilization). Adequate clinical recovery correlates well with the absence of fade. Because fade is more obvious during sustained tetanic stimulation or double-burst stimulation than following a train-of-four pattern or repeated twitches, the first two patterns are the preferred methods for determining adequacy of recovery from a nondepolarizing block.

The ability of tetanic stimulation during a partial nondepolarizing block to increase the evoked response to a subsequent twitch is termed posttetanic potentiation. This phenomenon may relate to a transient increase in ACh mobilization following tetanic stimulation.

In contrast, a phase I depolarization block from succinylcholine does not exhibit fade during tetanus or train-of-four; neither does it demonstrate posttetanic potentiation. With longer infusions of succinylcholine, however, the quality of the block will sometimes change to resemble a nondepolarizing block (phase II block).

Newer quantitative methods of assessment of neuromuscular blockade, such as acceleromyography, permit determination of exact train-of-four ratios, as opposed to subjective interpretations. Acceleromyography may reduce the incidence of

TABLE 11–2 Evoked responses during depolarizing (phase I and phase II) and nondepolarizing block.

Normal Evoked Stimulus	Depolarizing Block		
	Phase I	Phase II	Nondepolarizing Block
Train-of-four	Constant but diminished	Fade	Fade
Tetany	Constant but diminished	Fade	Fade
Double-burst stimulation (DBS _{3,2})	Constant but diminished	Fade	Fade

unexpected postoperative residual neuromuscular blockade.

Depolarizing Muscle Relaxants

SUCCINYLCHOLINE

The only depolarizing muscle relaxant in clinical use today is succinylcholine.

Physical Structure

5 Succinylcholine—also called diacetylcholine or suxamethonium—consists of two joined ACh molecules (Figure 11–4). This structure underlies succinylcholine’s mechanism of action, side effects, and metabolism.

Metabolism & Excretion

The popularity of succinylcholine is due to its rapid onset of action (30–60 s) and short duration

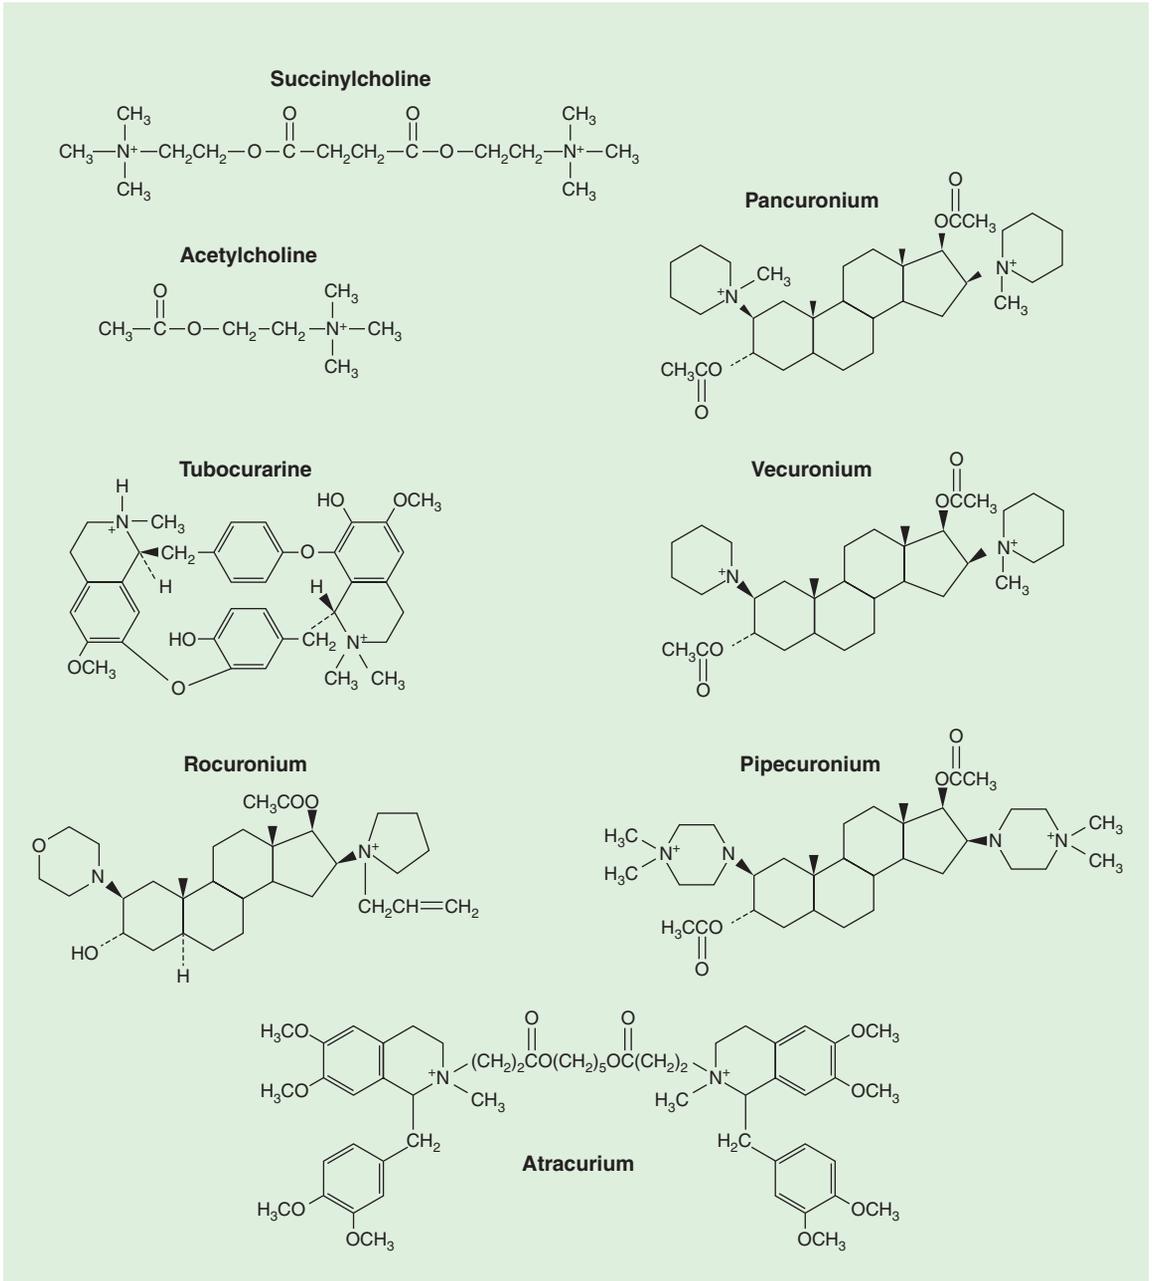

FIGURE 11-4 Chemical structures of neuromuscular blocking agents.

of action (typically less than 10 min). Its rapid onset of action relative to other neuromuscular blockers is largely due to the relative overdose that is usually administered. Succinylcholine, like

all neuromuscular blockers, has a small volume of distribution due to its very low lipid solubility, and this also underlies a rapid onset of action. As succinylcholine enters the circulation, most of it is

rapidly metabolized by pseudocholinesterase into succinylmonocholine. This process is so efficient that only a small fraction of the injected dose ever reaches the neuromuscular junction. As drug levels fall in blood, succinylcholine molecules diffuse away from the neuromuscular junction, limiting the duration of action. However, this duration of action can be prolonged by high doses, infusion of succinylcholine, or abnormal metabolism. The latter may result from hypothermia, reduced pseudocholinesterase levels, or a genetically aberrant enzyme. Hypothermia decreases the rate of hydrolysis. Reduced levels of pseudocholinesterase (measured as units per liter) accompany pregnancy, liver disease, renal failure, and certain drug therapies (Table 11-3). Reduced pseudocholinesterase levels generally produce only modest prolongation of succinylcholine's actions (2–20 min).

One in 25–30 patients of European extraction is a heterozygote with one normal and one abnormal (atypical) pseudocholinesterase gene, resulting in a slightly prolonged block (20–30 min). Even fewer (1 in 3000) patients have two copies of the most prevalent abnormal gene (homozygous atypical) that produce an enzyme with little or no affinity for **6** succinylcholine. In contrast to the doubling or tripling of blockade duration seen in

patients with low enzyme levels or heterozygous atypical enzyme, patients with homozygous atypical enzyme will have a *very* long blockade (eg, 4–8 h) following administration of succinylcholine. Of the recognized abnormal pseudocholinesterase genes, the dibucaine-resistant (variant) allele, which produces an enzyme with 1/100 of normal affinity for succinylcholine, is the most common. Other variants include fluoride-resistant and silent (no activity) alleles.

Dibucaine, a local anesthetic, inhibits normal pseudocholinesterase activity by 80%, but inhibits atypical enzyme activity by only 20%. Serum from an individual who is heterozygous for the atypical enzyme is characterized by an intermediate 40% to 60% inhibition. The percentage of inhibition of pseudocholinesterase activity is termed the **dibucaine number**. A patient with normal pseudocholinesterase has a dibucaine number of 80; a homozygote for the most common abnormal allele will have a dibucaine number of 20. The dibucaine number measures pseudocholinesterase function, not the amount of enzyme. Therefore, adequacy of pseudocholinesterase can be determined in the laboratory quantitatively in units per liter (a minor factor) and qualitatively by dibucaine number (the major factor). **Prolonged paralysis from succinylcholine caused by abnormal pseudocholinesterase (atypical cholinesterase) should be treated with continued mechanical ventilation and sedation until muscle function returns to normal by clinical signs. Such unседated patients do NOT appreciate unnecessary, repetitive use of nerve stimulation when all members of a department come by to confirm the diagnosis.**

Drug Interactions

The effects of muscle relaxants can be modified by concurrent drug therapy (Table 11-4). Succinylcholine is involved in two interactions deserving special comment.

A. Cholinesterase Inhibitors

Although cholinesterase inhibitors reverse nondepolarizing paralysis, they markedly prolong a depolarizing phase I block by two mechanisms. By inhibiting acetylcholinesterase, they lead to a

TABLE 11-3 Drugs known to decrease pseudocholinesterase activity.

Drug	Description
Echothiophate	Organophosphate use for glaucoma
Neostigmine Pyridostigmine	Cholinesterase inhibitors
Phenelzine	Monoamine oxidase inhibitor
Cyclophosphamide	Antineoplastic agent
Metoclopramide	Antiemetic/prokinetic agent
Esmolol	β-Blocker
Pancuronium	Nondepolarizing muscle relaxant
Oral contraceptives	Various agents

TABLE 11-4 Potentiation (+) and resistance (–) of neuromuscular blocking agents by other drugs.

Drug	Effect on Depolarizing Blockade	Effect on Nondepolarizing Blockade	Comments
Antibiotics	+	+	Streptomycin, aminoglycosides, kanamycin, neomycin, colistin, polymyxin, tetracycline, lincomycin, clindamycin
Anticonvulsants	?	–	Phenytoin, carbamazepine, primidone, sodium valproate
Antiarrhythmics	+	+	Quinidine, calcium channel blockers
Cholinesterase inhibitors	+	–	Neostigmine, pyridostigmine
Dantrolene	?	+	Used in treatment of malignant hyperthermia (has quaternary ammonium group)
Inhalational anesthetics	+	+	Volatile anesthetics
Ketamine	?	+	
Local anesthetics	+	+	High doses only
Lithium carbonate	+	?	Prolongs onset and duration of succinylcholine
Magnesium sulfate	+	+	Doses used to treat preeclampsia and eclampsia of pregnancy

higher ACh concentration at the nerve terminal, which intensifies depolarization. They also reduce the hydrolysis of succinylcholine by inhibiting pseudocholinesterase. Organophosphate pesticides, for example, cause an irreversible inhibition of acetylcholinesterase and can prolong the action of succinylcholine by 20–30 min. Echothiophate eye drops, used in the past for glaucoma, can markedly prolong succinylcholine by this mechanism.

B. Nondepolarizing Relaxants

In general, small doses of nondepolarizing relaxants antagonize a depolarizing phase I block. Because the drugs occupy some ACh receptors, depolarization by succinylcholine is partially prevented.

If enough depolarizing agent is administered to develop a phase II block, a nondepolarizer will potentiate paralysis.

Dosage

Because of the rapid onset, short duration, and low cost of succinylcholine, many clinicians believe

that it is still a good choice for routine intubation in adults. The usual adult dose of succinylcholine for intubation is 1–1.5 mg/kg intravenously. Doses as small as 0.5 mg/kg will often provide acceptable intubating conditions if a defasciculating dose of a nondepolarizing agent is not used. Repeated small boluses (10 mg) or a succinylcholine drip (1 g in 500 or 1000 mL, titrated to effect) can be used during surgical procedures that require brief but intense paralysis (eg, otolaryngological endoscopies). Neuromuscular function should be frequently monitored with a nerve stimulator to prevent overdosing and to watch for phase II block. The availability of intermediate-acting nondepolarizing muscle relaxants has reduced the popularity of succinylcholine infusions. In the past, these infusions were a mainstay of ambulatory practice in the United States.

Because succinylcholine is not lipid soluble, it has a small volume of distribution. Per kilogram, infants and neonates have a larger extracellular space than adults. Therefore, dosage requirements for

pediatric patients are often greater than for adults. If succinylcholine is administered *intramuscularly* to children, a dose as high as 4–5 mg/kg does not always produce complete paralysis.

Succinylcholine should be stored under refrigeration (2–8°C), and should generally be used within 14 days after removal from refrigeration and exposure to room temperature.

Side Effects & Clinical Considerations

Succinylcholine is a relatively safe drug—assuming that its many potential complications are understood and avoided. Because of the risk of **7** hyperkalemia, rhabdomyolysis, and cardiac arrest in children with undiagnosed myopathies, succinylcholine is considered relatively contraindicated in the routine management of children and adolescent patients. Most clinicians have also abandoned the *routine* use of succinylcholine for adults. Succinylcholine is still useful for rapid sequence induction and for short periods of intense paralysis because none of the presently available nondepolarizing muscle relaxants can match its very rapid onset and short duration.

A. Cardiovascular

Because of the resemblance of muscle relaxants to ACh, it is not surprising that they affect cholinergic receptors in addition to those at the neuromuscular junction. The entire parasympathetic nervous system and parts of the sympathetic nervous system (sympathetic ganglia, adrenal medulla, and sweat glands) depend on ACh as a neurotransmitter.

Succinylcholine not only stimulates nicotinic cholinergic receptors at the neuromuscular junction, it stimulates all ACh receptors. The cardiovascular actions of succinylcholine are therefore very complex. Stimulation of nicotinic receptors in parasympathetic and sympathetic ganglia, and muscarinic receptors in the sinoatrial node of the heart, can increase or decrease blood pressure and heart rate. Low doses of succinylcholine can produce negative chronotropic and inotropic effects, but higher doses usually increase heart rate and contractility and elevate circulating catecholamine levels. In most patients, the hemodynamic consequences are

inconsequential in comparison to the effects of the induction agent and laryngoscopy.

Children are particularly susceptible to profound bradycardia following administration of succinylcholine. Bradycardia will sometimes occur in adults when a second bolus of succinylcholine is administered approximately 3–8 min after the first dose. The dogma (based on no real evidence) is that the succinylcholine metabolite, succinylmonocholine, sensitizes muscarinic cholinergic receptors in the sinoatrial node to the second dose of succinylcholine, resulting in bradycardia. Intravenous atropine (0.02 mg/kg in children, 0.4 mg in adults) is normally given prophylactically to children prior to the first and subsequent doses, and *usually* before a second dose of succinylcholine is given to adults. Other arrhythmias, such as nodal bradycardia and ventricular ectopy, have been reported.

B. Fasciculations

The onset of paralysis by succinylcholine is usually signaled by visible motor unit contractions called fasciculations. These can be prevented by pretreatment with a small dose of nondepolarizing relaxant. Because this pretreatment usually antagonizes a depolarizing block, a larger dose of succinylcholine is required (1.5 mg/kg). Fasciculations are typically not observed in young children and elderly patients.

C. Hyperkalemia

8 Normal muscle releases enough potassium during succinylcholine-induced depolarization to increase serum potassium by 0.5 mEq/L. Although this is usually insignificant in patients with normal baseline potassium levels, it can be life-threatening in patients with preexisting hyperkalemia. The increase in potassium in patients with burn injury, massive trauma, neurological disorders, and several other conditions (**Table 11-5**) can be large and catastrophic. Hyperkalemic cardiac arrest can prove to be quite refractory to routine cardiopulmonary resuscitation, requiring calcium, insulin, glucose, bicarbonate, and even cardiopulmonary bypass to support the circulation while reducing serum potassium levels.

TABLE 11-5 Conditions causing susceptibility to succinylcholine-induced hyperkalemia.

Burn injury
Massive trauma
Severe intraabdominal infection
Spinal cord injury
Encephalitis
Stroke
Guillain-Barré syndrome
Severe Parkinson's disease
Tetanus
Prolonged total body immobilization
Ruptured cerebral aneurysm
Polyneuropathy
Closed head injury
Hemorrhagic shock with metabolic acidosis
Myopathies (eg, Duchenne's dystrophy)

Following denervation injuries (spinal cord injuries, larger burns), the immature isoform of the ACh receptor may be expressed inside and outside the neuromuscular junction (up-regulation). These extrajunctional receptors allow succinylcholine to effect widespread depolarization and extensive potassium release. Life-threatening potassium release is *not* reliably prevented by pretreatment with a nondepolarizer. The risk of hyperkalemia usually seems to peak in 7–10 days following the injury, but the exact time of onset and the duration of the risk period vary. The risk of hyperkalemia from succinylcholine is minimal in the first 2 days after spinal cord or burn injury.

D. Muscle Pains

Patients who have received succinylcholine have an increased incidence of postoperative myalgia. The efficacy of nondepolarizing pretreatment is controversial. Administration of rocuronium (0.06–0.1 mg/kg) prior to succinylcholine has been reported to be effective in preventing fasciculations and reducing postoperative myalgias. The relationship between fasciculations and postoperative myalgias is also inconsistent. The myalgias are theorized to be due to the initial unsynchronized contraction of muscle groups; myoglobinemia and increases in serum creatine kinase can be detected following administration of succinylcholine. Perioperative

use of nonsteroidal antiinflammatory drugs may reduce the incidence and severity of myalgias.

E. Intra gastric Pressure Elevation

Abdominal wall muscle fasciculations increase intra gastric pressure, which is offset by an increase in lower esophageal sphincter tone. Therefore, despite being much discussed, there is no evidence that the risk of gastric reflux or pulmonary aspiration is increased by succinylcholine.

F. Intraocular Pressure Elevation

Extraocular muscle differs from other striated muscle in that it has multiple motor end-plates on each cell. Prolonged membrane depolarization and contraction of extraocular muscles following administration of succinylcholine transiently raise intraocular pressure and theoretically could compromise an injured eye. However, there is no evidence that succinylcholine leads to worsened outcome in patients with “open” eye injuries. The elevation in intraocular pressure is not always prevented by pretreatment with a nondepolarizing agent.

G. Masseter Muscle Rigidity

Succinylcholine transiently increases muscle tone in the masseter muscles. Some difficulty may initially be encountered in opening the mouth because of incomplete relaxation of the jaw. A marked increase in tone preventing laryngoscopy is abnormal and can be a premonitory sign of malignant hyperthermia.

H. Malignant Hyperthermia

Succinylcholine is a potent triggering agent in patients susceptible to malignant hyperthermia, a hypermetabolic disorder of skeletal muscle (see Chapter 52). Although some of the signs and symptoms of neuroleptic malignant syndrome (NMS) resemble those of malignant hyperthermia, the pathogenesis is completely different and there is no need to avoid use of succinylcholine in patients with NMS.

I. Generalized Contractions

Patients afflicted with myotonia may develop myoclonus after administration of succinylcholine.

J. Prolonged Paralysis

As discussed above, patients with reduced levels of normal pseudocholinesterase may have a longer than normal duration of action, whereas patients with atypical pseudocholinesterase will experience markedly prolonged paralysis.

K. Intracranial Pressure

Succinylcholine may lead to an activation of the electroencephalogram and slight increases in cerebral blood flow and intracranial pressure in some patients. Muscle fasciculations stimulate muscle stretch receptors, which subsequently increase cerebral activity. The increase in intracranial pressure can be attenuated by maintaining good airway control and instituting hyperventilation. It can also be prevented by pretreating with a nondepolarizing muscle relaxant and administering intravenous lidocaine (1.5–2.0 mg/kg) 2–3 min prior to intubation. The effects of intubation on intracranial pressure far outweigh any increase caused by succinylcholine, and succinylcholine is NOT contraindicated for rapid sequence induction of patients with intracranial mass lesions or other causes of increased intracranial pressure.

L. Histamine Release

Slight histamine release may be observed following succinylcholine in some patients.

Nondepolarizing Muscle Relaxants

Unique Pharmacological Characteristics

In contrast to depolarizing muscle relaxants, there is a wide selection of nondepolarizing muscle relaxants (Tables 11–6 and 11–7). Based on their chemical structure, they can be classified as benzylisoquinolinium, steroidal, or other compounds. It is often said that choice of a particular drug depends on its unique characteristics, which are often related to its structure; however, for most patients, the differences among the intermediate-acting neuromuscular blockers are inconsequential. In general, steroidal compounds can be vagolytic, but this property is most notable with pancuronium and clinically unimportant with vecuronium or rocuronium. Benzylisoquinolines tend to release histamine. Because of structural similarities, an allergic history to one muscle relaxant strongly suggests the possibility of allergic reactions to other muscle relaxants, particularly those in the same chemical class.

A. Suitability for Intubation

None of the currently available nondepolarizing muscle relaxants equals succinylcholine's rapid onset of action or short duration. However, the

¹Not commercially available in the United States.

²No longer available in the United States.

onset of nondepolarizing relaxants can be quickened by using either a larger dose or a priming dose. The ED₉₅ of any drug is the effective dose of a drug in 95% of individuals. For neuromuscular blockers, one often specifies the dose that produces 95% twitch depression in 50% of individuals. One to two times the ED₉₅ or twice the dose that produces 95% twitch depression is usually used for intubation. Although a larger intubating dose speeds onset, it exacerbates side effects and prolongs the duration of blockade. For example, a dose of 0.15 mg/kg of pancuronium may produce intubating conditions in 90 sec, but at the cost of more pronounced tachycardia—and a block that may be irreversible (by neostigmine) for more than 60 min. The consequence of a long duration of action is the ensuing difficulty in completely reversing the blockade and a subsequent increased incidence of postoperative pulmonary complications. As a general rule, the more potent the nondepolarizing muscle relaxant, the slower its speed of onset; the “explanatory dogma” is that greater potency necessitates a smaller dose, with fewer total drug molecules, which in turn, decreases the rate of drug binding opportunities at the neuromuscular junction.

The introduction of short- and intermediate-acting agents has resulted in the greater use of priming doses. Theoretically, giving 10% to 15% of the usual intubating dose 5 min before induction will occupy enough receptors so that paralysis will quickly follow when the balance of relaxant is administered. Use of a priming dose can produce conditions suitable for intubation as soon as 60 sec following administration of rocuronium or 90 sec following administration of other intermediate-acting nondepolarizers. A priming dose does not *usually* lead to clinically significant paralysis, which requires that 75% to 80% of the receptors be blocked (a neuromuscular margin of safety). In some patients, however, the priming dose produces distressing dyspnea, diplopia, or dysphagia; in such instances, the patient should be reassured, and induction of anesthesia should proceed without delay. Priming can additionally cause measureable deterioration in respiratory function (eg, decreased forced vital capacity) and may lead to oxygen desaturation in patients with marginal pulmonary reserve. These negative side effects are more common in older, sicker patients.

Muscle groups vary in their sensitivity to muscle relaxants. For example, the laryngeal

muscles—whose relaxation is important during intubation—recover from blockade more quickly than the adductor pollicis, which is commonly monitored by the peripheral nerve stimulator.

B. Suitability for Preventing Fasciculations

To prevent fasciculations and myalgias, 10% to 15% of a nondepolarizer intubating dose can be administered 5 min before succinylcholine. When administered only shortly before succinylcholine, myalgias, but not fasciculations, will be inhibited. Although most nondepolarizers have been successfully used for this purpose, tubocurarine and rocuronium have been most popular (precurarization); tubocurarine is no longer available in the United States.

C. Maintenance Relaxation

Following intubation, muscle paralysis may need to be maintained to facilitate surgery, (eg, abdominal operations), to permit a reduced depth of anesthesia, or to control ventilation. There is great variability among patients in response to muscle relaxants. Monitoring neuromuscular function with a nerve stimulator helps to prevent over- and underdosing and to reduce the likelihood of serious residual muscle paralysis in the recovery room. Maintenance doses, whether by intermittent boluses or continuous infusion (Table 11–7), should be guided by the nerve stimulator *and* clinical signs (eg, spontaneous respiratory efforts or movement). In some instances, clinical signs may precede twitch recovery because of differing sensitivities to muscle relaxants between muscle groups or technical problems with the nerve stimulator. Some return of neuromuscular transmission should be evident prior to administering each maintenance dose, if the patient needs to resume spontaneous ventilation at the end of the anesthetic. When an infusion is used for maintenance, the rate should be adjusted at or just above the rate that allows some return of neuromuscular transmission so that drug effects can be monitored.

D. Potentiation by Inhalational Anesthetics

Volatile agents decrease nondepolarizer dosage requirements by at least 15%. The actual degree of this postsynaptic augmentation depends on both the

inhalational anesthetic (desflurane > sevoflurane > isoflurane and enflurane > halothane > N₂O/O₂/narcotic) and the muscle relaxant employed (pancuronium > vecuronium and atracurium).

E. Potentiation by Other Nondepolarizers

Some combinations of nondepolarizers produce a greater than additive (synergistic) neuromuscular blockade. The lack of synergism (ie, the drugs are only additive) by closely related compounds (eg, vecuronium and pancuronium) lends credence to the theory that synergism results from slightly differing mechanisms of action.

F. Autonomic Side Effects

In clinical doses, the nondepolarizers differ in their relative effects on nicotinic and muscarinic cholinergic receptors. Some older agents (tubocurarine and, to a lesser extent, metocurine) blocked autonomic ganglia, reducing the ability of the sympathetic nervous system to increase heart contractility and rate in response to hypotension and other intraoperative stresses. In contrast, pancuronium (and gallamine) block vagal muscarinic receptors in the sinoatrial node, resulting in tachycardia. All newer nondepolarizing relaxants, including atracurium, cisatracurium, vecuronium, and rocuronium, are devoid of significant autonomic effects in their recommended dosage ranges.

G. Histamine Release

Histamine release from mast cells can result in bronchospasm, skin flushing, and hypotension from peripheral vasodilation. Both atracurium and mivacurium are capable of triggering histamine release, particularly at higher doses. Slow injection rates and H₁ and H₂ antihistamine pretreatment ameliorate these side effects.

H. Hepatic Clearance

Only pancuronium and vecuronium are metabolized to any significant degree by the liver. Active metabolites likely contribute to their clinical effect. Vecuronium and rocuronium depend heavily on biliary excretion. Clinically, liver failure prolongs pancuronium and rocuronium blockade, with less effect on vecuronium, and no effect on pipercuronium. Atracurium, cisatracurium, and

mivacurium, although extensively metabolized, depend on extrahepatic mechanisms. Severe liver disease does not significantly affect clearance of atracurium or cisatracurium, but the associated decrease in pseudocholinesterase levels may slow the metabolism of mivacurium.

I. Renal Excretion

9 Doxacurium, pancuronium, vecuronium, and pipecuronium are partially excreted by the kidneys, and their action is prolonged in patients with renal failure. The elimination of atracurium, cisatracurium, mivacurium, and rocuronium is independent of kidney function.

General Pharmacological Characteristics

Some variables affect all nondepolarizing muscle relaxants.

A. Temperature

Hypothermia prolongs blockade by decreasing metabolism (eg, mivacurium, atracurium, and cisatracurium) and delaying excretion (eg, pancuronium and vecuronium).

B. Acid–Base Balance

Respiratory acidosis potentiates the blockade of most nondepolarizing relaxants and antagonizes its reversal. This could prevent complete neuromuscular recovery in a hypoventilating postoperative patient. Conflicting findings regarding the neuromuscular effects of other acid–base changes may be due to coexisting alterations in extracellular pH, intracellular pH, electrolyte concentrations, or structural differences between drugs (eg, monoquaternary versus bisquaternary; steroidal versus isoquinolinium).

C. Electrolyte Abnormalities

Hypokalemia and hypocalcemia augment a nondepolarizing block. The responses of patients with hypercalcemia are unpredictable. Hypermagnesemia, as may be seen in preeclamptic patients being managed with magnesium sulfate (or after intravenous magnesium administered in the operating room), potentiates a nondepolarizing blockade by competing with calcium at the motor end-plate.

TABLE 11-8 Additional considerations in special populations.

Pediatric	Succinylcholine – should not be used routinely Nondepolarizing agents – faster onset Vecuronium – long-acting in neonates
Elderly	Decreased clearance – prolonged duration, except with cisatracurium
Obese	Dosage 20% more than lean body weight; onset unchanged Prolonged duration, except with cisatracurium
Hepatic disease	Increased volume of distribution Pancuronium and vecuronium – prolonged elimination due to hepatic metabolism and biliary excretion Cisatracurium – unchanged Pseudocholinesterase decreased; prolonged action may be seen with succinylcholine in severe disease
Renal failure	Vecuronium – prolonged Rocuronium – relatively unchanged Cisatracurium – safest alternative
Critically ill	Myopathy, polyneuropathy, nicotinic acetylcholine receptor up-regulation

D. Age

Neonates have an increased sensitivity to nondepolarizing relaxants because of their immature neuromuscular junctions (**Table 11-8**). This sensitivity does not necessarily decrease dosage requirements, as the neonate's greater extracellular space provides a larger volume of distribution.

E. Drug Interactions

As noted earlier, many drugs augment nondepolarizing blockade (see **Table 11-4**). They have multiple sites of interaction: prejunctional structures, postjunctional cholinergic receptors, and muscle membranes.

F. Concurrent Disease

The presence of neurological or muscular disease can have profound effects on an individual's response **10** to muscle relaxants (**Table 11-9**). Cirrhotic liver disease and chronic renal failure often result in an increased volume of distribution and a lower plasma concentration for a given dose of

TABLE 11-9 Diseases with altered responses to muscle relaxants.

Disease	Response to Depolarizers	Response to Nondepolarizers
Amyotrophic lateral sclerosis	Contracture	Hypersensitivity
Autoimmune disorders Systemic lupus erythematosus Polymyositis Dermatomyositis	Hypersensitivity	Hypersensitivity
Burn injury	Hyperkalemia	Resistance
Cerebral palsy	Slight hypersensitivity	Resistance
Familial periodic paralysis (hyperkalemic)	Myotonia and hyperkalemia	Hypersensitivity?
Guillain-Barré syndrome	Hyperkalemia	Hypersensitivity
Hemiplegia	Hyperkalemia	Resistance on affected side
Muscular denervation (peripheral nerve injury)	Hyperkalemia and contracture	Normal response or resistance
Muscular dystrophy (Duchenne type)	Hyperkalemia and malignant hyperthermia	Hypersensitivity
Myasthenia gravis	Resistance	Hypersensitivity
Myasthenic syndrome	Hypersensitivity	Hypersensitivity
Myotonia Dystrophica Congenital Paramyotonia	Generalized muscular contractions	Normal or hypersensitivity
Severe chronic infection Tetanus Botulism	Hyperkalemia	Resistance

water-soluble drugs, such as muscle relaxants. On the other hand, drugs dependent on hepatic or renal excretion may demonstrate prolonged clearance (Table 11-8). Thus, depending on the drug chosen, a greater initial (loading) dose—but smaller maintenance doses—might be required in these diseases.

G. Muscle Groups

The onset and intensity of blockade vary among muscle groups. This may be due to differences in blood flow, distance from the central circulation, or different fiber types. Furthermore, the relative sensitivity of a muscle group may depend on the choice of muscle relaxant. In general, the diaphragm, jaw, larynx, and facial muscles (orbicularis oculi) respond to and recover from muscle relaxation sooner than the thumb. Although they are a fortuitous safety feature,

persistent diaphragmatic contractions can be disconcerting in the face of complete adductor pollicis paralysis. Glottic musculature is also quite resistant to blockade, as is often confirmed during laryngoscopy. The ED₉₅ for laryngeal muscles is nearly two times that for the adductor pollicis muscle. Good intubating conditions are usually associated with visual loss of the orbicularis oculi twitch response.

Considering the multitude of factors influencing the duration and magnitude of muscle relaxation, it becomes clear that an individual's response to neuromuscular blocking agents should be monitored. Dosage recommendations, including those in this chapter, should be considered guidelines that require modification for individual patients. Wide variability in sensitivity to nondepolarizing muscle relaxants is often encountered in clinical practice.

ATRACURIUM

Physical Structure

Like all muscle relaxants, atracurium has a quaternary group; however, a benzyloisoquinoline structure is responsible for its unique method of degradation. The drug is a mixture of 10 stereoisomers.

Metabolism & Excretion

Atracurium is so extensively metabolized that its pharmacokinetics are independent of renal and hepatic function, and less than 10% is excreted unchanged by renal and biliary routes. Two separate processes are responsible for metabolism.

A. Ester Hydrolysis

This action is catalyzed by nonspecific esterases, not by acetylcholinesterase or pseudocholinesterase.

B. Hofmann Elimination

A spontaneous nonenzymatic chemical breakdown occurs at physiological pH and temperature.

Dosage

A dose of 0.5 mg/kg is administered intravenously for intubation. After succinylcholine, intraoperative relaxation is achieved with 0.25 mg/kg initially, then in incremental doses of 0.1 mg/kg every 10–20 min. An infusion of 5–10 mcg/kg/min can effectively replace intermittent boluses.

Although dosage requirements do not significantly vary with age, atracurium may be shorter acting in children and infants than in adults.

Atracurium is available as a solution of 10 mg/mL. It must be stored at 2–8°C, as it loses 5% to 10% of its potency for each month it is exposed to room temperature. At room temperature, it should be used within 14 days to preserve potency.

Side Effects & Clinical Considerations

Atracurium triggers dose-dependent histamine release that becomes significant at doses above 0.5 mg/kg.

A. Hypotension and Tachycardia

Cardiovascular side effects are unusual unless doses in excess of 0.5 mg/kg are administered. Atracurium may also cause a transient drop in systemic vascular

resistance and an increase in cardiac index independent of any histamine release. A slow rate of injection minimizes these effects.

B. Bronchospasm

Atracurium should be avoided in asthmatic patients. Severe bronchospasm is occasionally seen in patients without a history of asthma.

C. Laudanosine Toxicity

Laudanosine, a tertiary amine, is a breakdown product of atracurium's Hofmann elimination and has been associated with central nervous system excitation, resulting in elevation of the minimum alveolar concentration and even precipitation of seizures. Concerns about laudanosine are probably irrelevant unless a patient has received an extremely large total dose or has hepatic failure. Laudanosine is metabolized by the liver and excreted in urine and bile.

D. Temperature and pH Sensitivity

Because of its unique metabolism, atracurium's duration of action can be markedly prolonged by hypothermia and to a lesser extent by acidosis.

E. Chemical Incompatibility

Atracurium will precipitate as a free acid if it is introduced into an intravenous line containing an alkaline solution such as thiopental.

F. Allergic Reactions

Rare anaphylactoid reactions to atracurium have been described. Proposed mechanisms include direct immunogenicity and acrylate-mediated immune activation. IgE-mediated antibody reactions directed against substituted ammonium compounds, including muscle relaxants, have been described. Reactions to acrylate, a metabolite of atracurium and a structural component of some dialysis membranes, have also been reported in patients undergoing hemodialysis.

CISATRACURIUM

Physical Structure

Cisatracurium is a stereoisomer of atracurium that is four times more potent. Atracurium contains approximately 15% cisatracurium.

Metabolism & Excretion

11 Like atracurium, cisatracurium undergoes degradation in plasma at physiological pH and temperature by organ-independent Hofmann elimination. The resulting metabolites (a monoquaternary acrylate and laudanosine) have no neuromuscular blocking effects. Because of cisatracurium's greater potency, the amount of laudanosine produced for the same extent and duration of neuromuscular blockade is much less than with atracurium. Nonspecific esterases are not involved in the metabolism of cisatracurium. Metabolism and elimination are independent of renal or liver failure. Minor variations in pharmacokinetic patterns due to age result in no clinically important changes in duration of action.

Dosage

Cisatracurium produces good intubating conditions following a dose of 0.1–0.15 mg/kg within 2 min and results in muscle blockade of intermediate duration. The typical maintenance infusion rate ranges from 1.0–2.0 mcg/kg/min. Thus, it is more potent than atracurium.

Cisatracurium should be stored under refrigeration (2–8°C) and should be used within 21 days after removal from refrigeration and exposure to room temperature.

Side Effects & Clinical Considerations

Unlike atracurium, cisatracurium does not produce a consistent, dose-dependent increase in plasma histamine levels following administration. Cisatracurium does not alter heart rate or blood pressure, nor does it produce autonomic effects, even at doses as high as eight times ED_{95} .

Cisatracurium shares with atracurium the production of laudanosine, pH and temperature sensitivity, and chemical incompatibility.

PANCURONIUM

Physical Structure

Pancuronium consists of a steroid ring on which two modified ACh molecules are positioned (a bisquaternary relaxant). The steroid ring serves as a “spacer” between the two quaternary amines. Pancuronium

resembles ACh enough to bind (but not activate) the nicotinic ACh receptor.

Metabolism & Excretion

Pancuronium is metabolized (deacetylated) by the liver to a limited degree. Its metabolic products have some neuromuscular blocking activity. Excretion is primarily renal (40%), although some of the drug is cleared by the bile (10%). Not surprisingly, elimination of pancuronium is slowed and neuromuscular blockade is prolonged by renal failure. Patients with cirrhosis may require a larger initial dose due to an increased volume of distribution but have reduced maintenance requirements because of a decreased rate of plasma clearance.

Dosage

A dose of 0.08–0.12 mg/kg of pancuronium provides adequate relaxation for intubation in 2–3 min. Intraoperative relaxation is achieved by administering 0.04 mg/kg initially followed every 20–40 min by 0.01 mg/kg.

Children may require moderately larger doses of pancuronium. Pancuronium is available as a solution of 1 or 2 mg/mL and is stored at 2–8°C but may be stable for up to 6 months at normal room temperature.

Side Effects & Clinical Considerations

A. Hypertension and Tachycardia

12 These cardiovascular effects are caused by the combination of vagal blockade and sympathetic stimulation. The latter is due to a combination of ganglionic stimulation, catecholamine release from adrenergic nerve endings, and decreased catecholamine reuptake. Large bolus doses of pancuronium should be given with caution to patients in whom an increased heart rate would be particularly detrimental (eg, coronary artery disease, hypertrophic cardiomyopathy, aortic stenosis).

B. Arrhythmias

Increased atrioventricular conduction and catecholamine release increase the likelihood of ventricular arrhythmias in predisposed individuals. The combination of pancuronium, tricyclic antidepressants,

and halothane has been reported to be particularly arrhythmogenic.

C. Allergic Reactions

Patients who are hypersensitive to bromides may exhibit allergic reactions to pancuronium (pancuronium bromide).

VECURONIUM

Physical Structure

Vecuronium is pancuronium minus a quaternary methyl group (a monoquaternary relaxant). This minor structural change beneficially alters side effects without affecting potency.

Metabolism & Excretion

Vecuronium is metabolized to a small extent by the liver. It depends primarily on biliary excretion and secondarily (25%) on renal excretion. Although it is a satisfactory drug for patients with renal failure, its duration of action is somewhat prolonged. Vecuronium's brief duration of action is explained by its shorter elimination half-life and more rapid clearance compared with pancuronium. Long-term administration of vecuronium to patients in intensive care units has resulted in prolonged neuromuscular blockade (up to several days), possibly from accumulation of its active 3-hydroxy metabolite, changing drug clearance, and in some patients, leading to the development of a polyneuropathy. Risk factors seem to include female gender, renal failure, long-term or high-dose corticosteroid therapy, and sepsis. Thus, these patients must be closely monitored, and the dose of vecuronium carefully titrated. Long-term relaxant administration and the subsequent prolonged lack of ACh binding at the postsynaptic nicotinic ACh receptors may mimic a chronic denervation state and cause lasting receptor dysfunction and paralysis. Tolerance to nondepolarizing muscle relaxants can also develop after long-term use. Fortunately, the use of unnecessary paralysis has greatly declined in critical care units.

Dosage

Vecuronium is equipotent with pancuronium, and the intubating dose is 0.08–0.12 mg/kg. A dose

of 0.04 mg/kg initially followed by increments of 0.01 mg/kg every 15–20 min provides intraoperative relaxation. Alternatively, an infusion of 1–2 mcg/kg/min produces good maintenance of relaxation.

Age does not affect initial dose requirements, although subsequent doses are required less frequently in neonates and infants. Women seem to be approximately 30% more sensitive than men to vecuronium, as evidenced by a greater degree of blockade and longer duration of action (this has also been seen with pancuronium and rocuronium). The cause for this sensitivity may be related to gender-related differences in fat and muscle mass, protein binding, volume of distribution, or metabolic activity. The duration of action of vecuronium may be further prolonged in postpartum patients due to alterations in hepatic blood flow or liver uptake.

Side Effects & Clinical Considerations

A. Cardiovascular

Even at doses of 0.28 mg/kg, vecuronium is devoid of significant cardiovascular effects. Potentiation of opioid-induced bradycardia may be observed in some patients.

B. Liver Failure

Although it is dependent on biliary excretion, the duration of action of vecuronium is usually not significantly prolonged in patients with cirrhosis unless doses greater than 0.15 mg/kg are given. Vecuronium requirements are reduced during the anhepatic phase of liver transplantation.

ROCURONIUM

Physical Structure

This monoquaternary steroid analogue of vecuronium was designed to provide a rapid onset of action.

Metabolism & Excretion

Rocuronium undergoes no metabolism and is eliminated primarily by the liver and slightly by the kidneys. Its duration of action is not significantly affected by renal disease, but it is modestly

prolonged by severe hepatic failure and pregnancy. Because rocuronium does not have active metabolites, it may be a better choice than vecuronium in the rare patient requiring prolonged infusions in the intensive care unit setting. Elderly patients may experience a prolonged duration of action due to decreased liver mass.

Dosage

Rocuronium is less potent than most other steroidal muscle relaxants (potency seems to be inversely related to speed of onset). It requires 0.45–0.9 mg/kg intravenously for intubation and 0.15 mg/kg boluses for maintenance. A lower dose of 0.4 mg/kg may allow reversal as soon as 25 min after intubation. Intramuscular rocuronium (1 mg/kg for infants; 2 mg/kg for children) provides adequate vocal cord and diaphragmatic paralysis for intubation, but not until after 3–6 min (deltoid injection has a faster onset than quadriceps), and can be reversed after about 1 hr. The infusion requirements for rocuronium range from 5–12 mcg/kg/min. Rocuronium can produce a prolonged duration of action in elderly patients. Initial dosage requirements are modestly increased in patients with advanced liver disease, presumably due to a larger volume of distribution.

Side Effects & Clinical Considerations

14 Rocuronium (at a dose of 0.9–1.2 mg/kg) has an onset of action that *approaches* succinylcholine (60–90 s), making it a suitable alternative for rapid-sequence inductions, but at the cost of a much longer duration of action. This intermediate duration of action is comparable to vecuronium or atracurium.

Rocuronium (0.1 mg/kg) has been shown to be a rapid (90 s) and effective agent (decreased fasciculations and postoperative myalgias) for precurarization prior to administration of succinylcholine. It has slight vagolytic tendencies.

OTHER RELAXANTS

Muscle relaxants, primarily of historical interest, are either no longer manufactured or not clinically used. They include tubocurarine, metocurine,

gallamine, alcuronium, rapacuronium, and decamethonium. Tubocurarine, the first muscle relaxant used clinically, often produced hypotension and tachycardia through histamine release; its ability to block autonomic ganglia was of secondary importance. Histamine release could also produce or exacerbate bronchospasm. Tubocurarine is not metabolized significantly, and its elimination is primarily renal and secondarily biliary. Metocurine, a closely related agent, shares many of the side effects of tubocurarine. It is primarily dependent on renal function for elimination. Patients allergic to iodine (eg, shellfish allergies) could exhibit hypersensitivity to metocurine preparations, as they contain iodide. Gallamine has the most potent vagolytic properties of any relaxant, and it is entirely dependent on renal function for elimination. Alcuronium, a long-acting nondepolarizer with mild vagolytic properties, is also primarily dependent on renal function for elimination. Rapacuronium has a rapid onset of action, minimal cardiovascular side effects, and a short duration of action. It was withdrawn by the manufacturer following multiple reports of serious bronchospasm, including a few unexplained fatalities. Histamine release may have been a factor. Decamethonium was an older depolarizing agent.

More recently, doxacurium, pipecuronium, and mivacurium are no longer commercially available in the United States. Mivacurium is a benzylisoquinolinium derivative, which is metabolized by pseudocholinesterase; therefore, its duration of action may be prolonged in pathophysiological states that result in low pseudocholinesterase levels. The usual intubating dose is 0.2 mg/kg, with the steady state infusion rate being 4–10 mcg/kg/min. Mivacurium releases histamine to about the same degree as atracurium; the resulting cardiovascular effects can be minimized by slow injection. Doxacurium is a potent long-acting benzyloquinolinium compound that is primarily eliminated by renal excretion. Adequate intubating conditions are achieved in 5 min with 0.05 mg/kg. It is essentially devoid of cardiovascular and histamine-releasing side effects. Pipecuronium, on the other hand, is a bisquarternary steroidal compound similar to pancuronium, without the

vagolytic effects. Onset and duration of action are also similar to pancuronium; elimination is primarily through renal (70%) and biliary (20%) excretion. The usual intubating dose ranges from 0.06-0.1 mg/kg; its pharmacologic profile is relatively unchanged in elderly patients.

NEWER MUSCLE RELAXANTS

Gantacurium belongs to a new class of nondepolarizing neuromuscular blockers called chlorofumarates. It is provided as a lyophilized powder, because it is not stable as an aqueous solution; therefore, it requires reconstitution prior to administration. In preclinical trials, gantacurium demonstrated an ultrashort duration of action, similar to that of succinylcholine. Its pharmacokinetic profile is explained by the fact that it undergoes nonenzymatic degradation by two chemical mechanisms: rapid formation of inactive cysteine adduction product and ester hydrolysis. At a dose of 0.2 mg/kg (ED_{95}), the onset of action has been estimated to be 1-2 min, with a duration of blockade similar to that of succinylcholine. Its clinical duration of action ranged from 5-10 min; recovery can be accelerated by edrophonium, as well as by the administration of exogenous cysteine. Cardiovascular effects suggestive of histamine release were observed following the use of three times the ED_{95} dosage.

AV002 (CW002) is another investigational nondepolarizing agent. It is a benzylisoquinolinium fumarate ester-based compound with an intermediate duration of action that undergoes metabolism and elimination similar to that of gantacurium.

CASE DISCUSSION

Delayed Recovery from General Anesthesia

A 72-year-old man has undergone general anesthesia for transurethral resection of the prostate. Twenty minutes after conclusion of the procedure, he is still intubated and shows no evidence of spontaneous respiration or consciousness.

What is your general approach to this diagnostic dilemma?

Clues to the solution of complex clinical problems are usually found in a pertinent review of the medical and surgical history, the history of drug ingestions, the physical examination, and laboratory results. In this case, the perioperative anesthetic management should also be considered.

What medical illnesses predispose a patient to delayed awakening or prolonged paralysis?

Chronic hypertension alters cerebral blood flow autoregulation and decreases the brain's tolerance to episodes of hypotension. Liver disease reduces hepatic drug metabolism and biliary excretion, resulting in prolonged drug action. Reduced serum albumin concentrations increase free drug (active drug) availability. Hepatic encephalopathy can alter consciousness. Kidney disease decreases the renal excretion of many drugs. Uremia can also affect consciousness. Diabetic patients are prone to hypoglycemia and hyperosmotic, hyperglycemic, and nonketotic coma. A prior stroke or symptomatic carotid bruit increases the risk of intraoperative cerebral vascular accident. Right-to-left heart shunts, particularly in children with congenital heart disease, allow air emboli to pass directly from the venous circulation to the systemic (possibly cerebral) arterial circulation. A paradoxical air embolism can result in permanent brain damage. Severe hypothyroidism is associated with impaired drug metabolism and, rarely, myxedema coma.

Does an uneventful history of general anesthesia narrow the differential?

Hereditary atypical pseudocholinesterase is ruled out by uneventful prior general anesthesia, assuming succinylcholine was administered. Decreased levels of normal enzyme would not result in postoperative apnea unless the surgery was of very short duration. Malignant hyperthermia does not typically present as delayed awakening, although prolonged somnolence is not

unusual. Uneventful prior anesthetics do not, however, rule out malignant hyperthermia. Persons unusually sensitive to anesthetic agents (eg, geriatric patients) may have a history of delayed emergence.

How do drugs that a patient takes at home affect awakening from general anesthesia?

Drugs that decrease minimum alveolar concentration, such as methyldopa, predispose patients to anesthetic overdose. Acute ethanol intoxication decreases barbiturate metabolism and acts independently as a sedative. Drugs that decrease liver blood flow, such as cimetidine, will limit hepatic drug metabolism. Antiparkinsonian drugs and tricyclic antidepressants have anticholinergic side effects that augment the sedation produced by scopolamine. Long-acting sedatives, such as the benzodiazepines, can delay awakening.

Does anesthetic technique alter awakening?

Preoperative medications can affect awakening. In particular, anticholinergics (with the exception of glycopyrrolate, which does not cross the blood–brain barrier), opioids, and sedatives can interfere with postoperative recovery. Patients with low cardiac output may have delayed absorption of intramuscular injections.

Intraoperative hyperventilation is a common cause of postoperative apnea. Because volatile agents raise the apneic threshold, the P_{aCO_2} level at which spontaneous ventilation ceases, moderate postoperative hypoventilation may be required to stimulate the respiratory centers. Severe intraoperative hypotension or hypertension may lead to cerebral hypoxia and edema.

Hypothermia decreases minimum alveolar concentration, antagonizes muscle relaxation reversal, and limits drug metabolism. Arterial hypoxia or severe hypercapnia ($P_{aCO_2} > 70$ mm Hg) can alter consciousness.

Certain surgical procedures, such as carotid endarterectomy, cardiopulmonary bypass, and intracranial procedures, are associated with an

increased incidence of postoperative neurological deficits. Subdural hematomas can occur in severely coagulopathic patients. Transurethral resection of the prostate is associated with hyponatremia from the dilutional effects of absorbed irrigating solution.

What clues does a physical examination provide?

Pupil size is not always a reliable indicator of central nervous system integrity. Fixed and dilated pupils in the absence of anticholinergic medication or ganglionic blockade (eg, the formerly used hypotensive agent, trimethaphan), however, may be an ominous sign. Response to physical stimulation, such as a forceful jaw thrust, may differentiate somnolence from paralysis. Peripheral nerve stimulation also differentiates paralysis from coma.

What specific laboratory findings would you order?

Arterial blood gases and serum electrolytes, particularly sodium, may be helpful. Computed tomographic scanning may be necessary if unresponsiveness is prolonged. Increased concentrations of inhalational agent provided by respiratory gas analysis, as well as processed electroencephalogram (EEG) measurements, may assist in determining if the patient is still under the effects of anesthesia. Slow EEG signals can be indicative of both anesthesia and cerebral pathology. Processed EEG awareness monitors can also be employed with the realization that low numbers on the bispectral index can be caused both by anesthetic suppression of the EEG and ischemic brain injury.

What therapeutic interventions should be considered?

Supportive mechanical ventilation should be continued in the unresponsive patient. Naloxone, flumazenil, and physostigmine may be indicated, depending on the probable cause of the delayed emergence, if drug effects are suspected and reversal is considered both safe and desirable.

Cholinesterase Inhibitors & Other Pharmacologic Antagonists to Neuromuscular Blocking Agents

KEY CONCEPTS

- 1** The primary clinical use of cholinesterase inhibitors, also called anticholinesterases, is to reverse nondepolarizing muscle blockade.
- 2** Acetylcholine is the neurotransmitter for the entire parasympathetic nervous system (parasympathetic ganglions and effector cells), parts of the sympathetic nervous system (sympathetic ganglions, adrenal medulla, and sweat glands), some neurons in the central nervous system, and somatic nerves innervating skeletal muscle.
- 3** Neuromuscular transmission is blocked when nondepolarizing muscle relaxants compete with acetylcholine to bind to nicotinic cholinergic receptors. The cholinesterase inhibitors indirectly increase the amount of acetylcholine available to compete with the nondepolarizing agent, thereby reestablishing neuromuscular transmission.
- 4** In excessive doses, acetylcholinesterase inhibitors can paradoxically potentiate a nondepolarizing neuromuscular blockade. In addition, these drugs prolong the depolarization blockade of succinylcholine.
- 5** Any prolongation of action of a nondepolarizing muscle relaxant from renal or hepatic insufficiency will probably be accompanied by a corresponding increase in the duration of action of a cholinesterase inhibitor.
- 6** The time required to fully reverse a nondepolarizing block depends on several factors, including the choice and dose of cholinesterase inhibitor administered, the muscle relaxant being antagonized, and the extent of the blockade before reversal.
- 7** A reversal agent should be routinely given to patients who have received nondepolarizing muscle relaxants unless full reversal can be demonstrated or the postoperative plan includes continued intubation and ventilation.
- 8** In monitoring a patient's recovery from neuromuscular blockade, the suggested end points are sustained tetanus for 5 sec in response to a 100-Hz stimulus in anesthetized patients or sustained head lift in awake patients. If neither of these end points is achieved, the patient should remain intubated and ventilation should be continued.
- 9** Sugammadex exerts its effects by forming tight complexes in a 1:1 ratio with steroidal neuromuscular blocking agents.
- 10** Cysteine causes inactivation of gantacurium via metabolic degradation and adduct formation.

Incomplete reversal of neuromuscular blocking agents and residual post-procedure paralysis are associated with morbidity; therefore, careful evaluation of neuromuscular blockade and appropriate pharmacologic antagonism are strongly recommended whenever muscle relaxants are administered. The primary clinical use of cholinesterase inhibitors, also called anticholinesterases, is to reverse nondepolarizing muscle blockade. Some of these agents are also used to diagnose and treat myasthenia gravis. More recently, newer agents, such as cyclodextrins and cysteine, with superior ability to reverse neuromuscular blockade from specific agents, are being investigated with promising results. This chapter reviews cholinergic pharmacology and mechanisms of acetylcholinesterase inhibition and presents the clinical pharmacology of commonly used cholinesterase inhibitors (neostigmine, edrophonium, pyridostigmine, and physostigmine). It concludes with a brief description and mechanisms of action of some unique reversal agents.

Cholinergic Pharmacology

The term cholinergic refers to the effects of the neurotransmitter *acetylcholine*, as opposed to the adrenergic effects of *noradrenaline* (norepinephrine). Acetylcholine is synthesized in the nerve terminal by the enzyme cholineacetyltransferase, which catalyzes the reaction between acetylcoenzyme A and choline (Figure 12-1). After its release, acetylcholine is rapidly hydrolyzed by acetylcholinesterase (true cholinesterase) into acetate and choline.

Acetylcholine is the neurotransmitter for the entire parasympathetic nervous system (parasympathetic ganglions and effector cells), parts of the sympathetic nervous system (sympathetic ganglions, adrenal medulla, and sweat glands), some neurons in the central nervous system, and somatic nerves innervating skeletal muscle (Figure 12-2).

Cholinergic receptors have been subdivided into two major groups based on their reaction to the alkaloids muscarine and nicotine (Figure 12-3). Nicotine stimulates the autonomic ganglia and skeletal muscle receptors (nicotinic receptors), whereas muscarine activates end-organ effector cells in

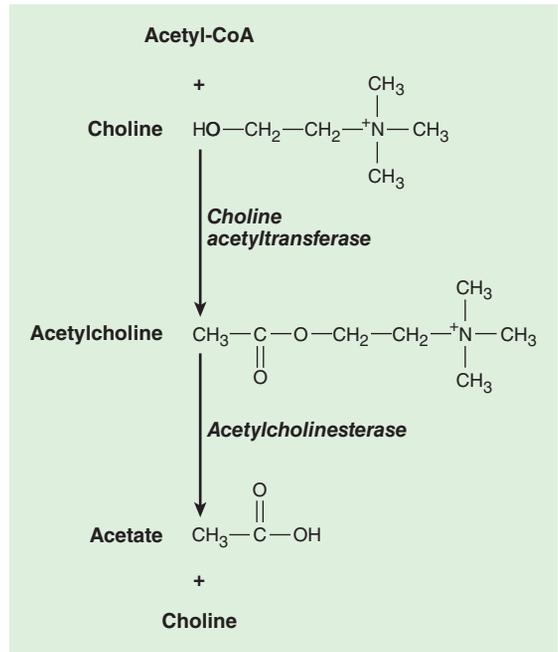

FIGURE 12-1 The synthesis and hydrolysis of acetylcholine.

bronchial smooth muscle, salivary glands, and the sinoatrial node (muscarinic receptors). The central nervous system has both nicotinic and muscarinic receptors. Nicotinic receptors are blocked by muscle relaxants (also called neuromuscular blockers), and muscarinic receptors are blocked by anticholinergic drugs, such as atropine. Although nicotinic and muscarinic receptors differ in their response to some agonists (eg, nicotine, muscarine) and some antagonists (eg, vecuronium vs atropine), they both respond to acetylcholine (Table 12-1). Clinically available cholinergic agonists resist hydrolysis by cholinesterase. Methacholine and bethanechol are primarily muscarinic agonists, whereas carbachol has both muscarinic and nicotinic agonist activities. Methacholine by inhalation has been used as a provocative test in asthma, bethanechol is used for bladder atony, and carbachol may be used topically for wide-angle glaucoma.

When reversing neuromuscular blockade, the primary goal is to maximize nicotinic transmission with a minimum of muscarinic side effects.

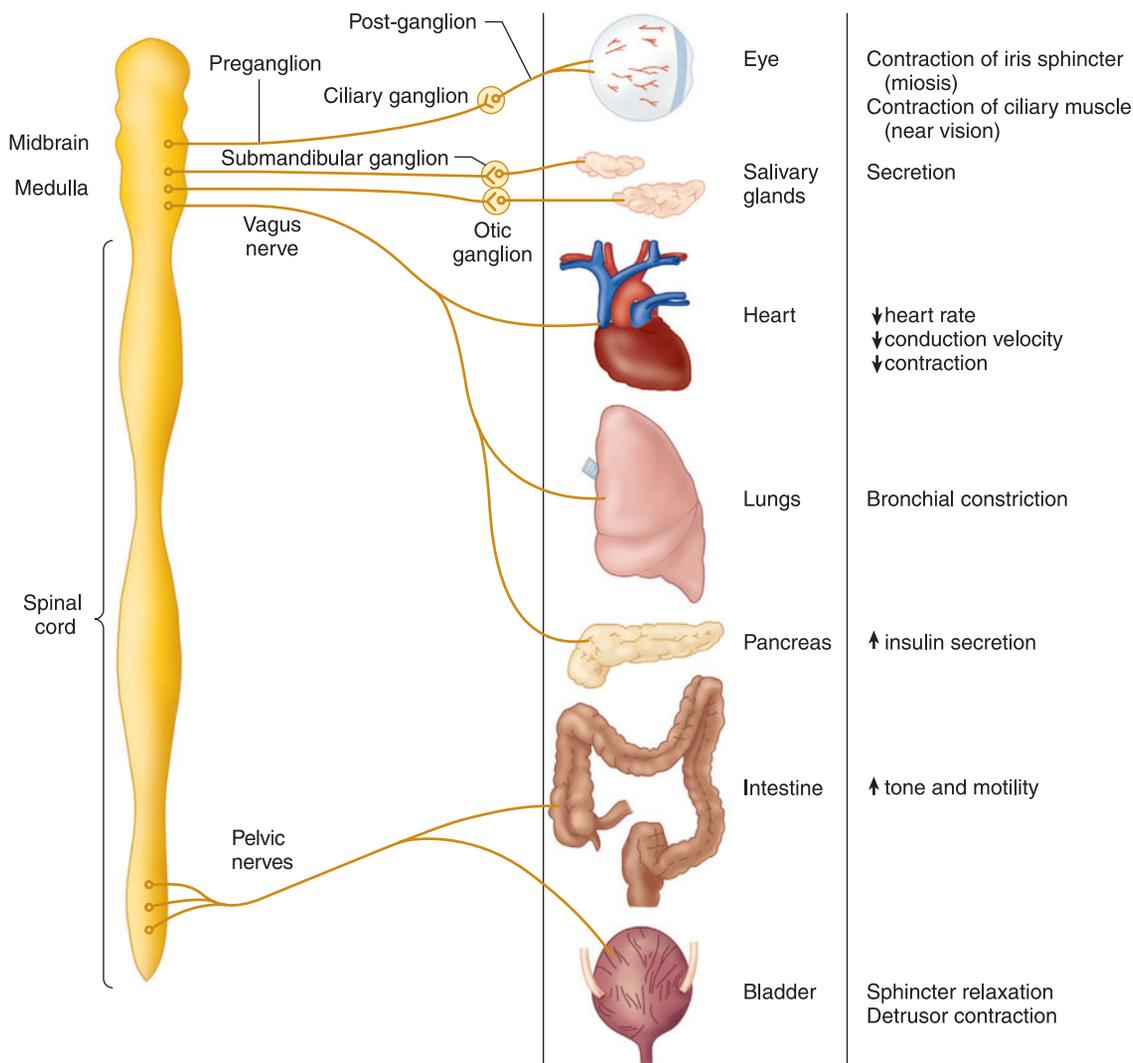

FIGURE 12-2 The parasympathetic nervous system uses acetylcholine as a preganglionic and postganglionic neurotransmitter.

MECHANISM OF ACTION

3 Normal neuromuscular transmission critically depends on acetylcholine binding to nicotinic cholinergic receptors on the motor endplate. Nondepolarizing muscle relaxants act by competing with acetylcholine for these binding sites, thereby blocking neuromuscular transmission. Reversal of blockade depends on gradual diffusion,

redistribution, metabolism, and excretion from the body of the nondepolarizing relaxant (*spontaneous reversal*), often assisted by the administration of specific reversal agents (*pharmacological reversal*). Cholinesterase inhibitors *indirectly* increase the amount of acetylcholine available to compete with the nondepolarizing agent, thereby reestablishing normal neuromuscular transmission.

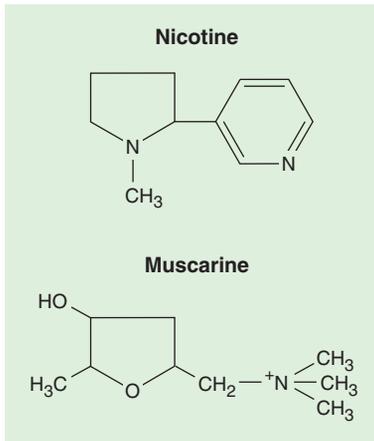

FIGURE 12-3 The molecular structures of nicotine and muscarine. Compare these alkaloids with acetylcholine (Figure 12-1).

Cholinesterase inhibitors inactivate acetylcholinesterase by reversibly binding to the enzyme. The stability of the bond influences the duration of action. The electrostatic attraction and hydrogen bonding of edrophonium are short-lived; the

covalent bonds of neostigmine and pyridostigmine are longer lasting.

Organophosphates, a special class of cholinesterase inhibitors, form very stable, irreversible bonds to the enzyme. They are used in ophthalmology and more commonly as pesticides. The clinical duration of the cholinesterase inhibitors used in anesthesia, however, is probably most influenced by the rate of drug disappearance from the plasma. Differences in duration of action can be overcome by dosage adjustments. Thus, the normally short duration of action of edrophonium can be partially overcome by increasing the dosage. Cholinesterase inhibitors are also used in the diagnosis and treatment of myasthenia gravis.

Mechanisms of action other than acetylcholinesterase inactivation may contribute to the restoration of neuromuscular function. Edrophonium seems to have prejunctional effects that enhance the release of acetylcholine. Neostigmine has a direct (but weak) agonist effect on nicotinic receptors. Acetylcholine mobilization and release by the nerve may also be enhanced (a presynaptic mechanism).

4 In excessive doses, acetylcholinesterase inhibitors paradoxically potentiate a nondepolarizing neuromuscular blockade. Standard dogma states that neostigmine in high doses may cause receptor channel blockade; however, clinical evidence of this is lacking. In addition, these drugs prolong the depolarization blockade of succinylcholine. Two mechanisms may explain this latter effect: an increase in acetylcholine (which increases motor end-plate depolarization) and inhibition of pseudocholinesterase activity. Neostigmine and to some extent pyridostigmine display some limited pseudocholinesterase-inhibiting activity, but their effect on acetylcholinesterase is much greater. Edrophonium has little or no effect on pseudocholinesterase. In large doses, neostigmine can cause a weak depolarizing neuromuscular blockade.

CLINICAL PHARMACOLOGY

General Pharmacological Characteristics

The increase in acetylcholine caused by cholinesterase inhibitors affects more than the nicotinic receptors of skeletal muscle (Table 12-2). Cholinesterase

TABLE 12-2 Muscarinic side effects of cholinesterase inhibitors.

Organ System	Muscarinic Side Effects
Cardiovascular	Decreased heart rate, bradyarrhythmias
Pulmonary	Bronchospasm, bronchial secretions
Cerebral	Diffuse excitation ¹
Gastrointestinal	Intestinal spasm, increased salivation
Genitourinary	Increased bladder tone
Ophthalmological	Pupillary constriction

¹Applies only to physostigmine.

inhibitors can act at cholinergic receptors of several other organ systems, including the cardiovascular and gastrointestinal systems.

Cardiovascular receptors—The predominant muscarinic effect on the heart is bradycardia that can progress to sinus arrest.

Pulmonary receptors—Muscarinic stimulation can result in bronchospasm (smooth muscle contraction) and increased respiratory tract secretions.

Cerebral receptors—Physostigmine is a cholinesterase inhibitor that crosses the blood–brain barrier and can cause diffuse activation of the electroencephalogram by stimulating muscarinic and nicotinic receptors within the central nervous system. Inactivation of nicotinic acetylcholine receptors in the central nervous system may play a role in the action of general anesthetics. Unlike physostigmine, cholinesterase inhibitors used to reverse neuromuscular blockers do not cross the blood–brain barrier.

Gastrointestinal receptors—Muscarinic stimulation increases peristaltic activity (esophageal, gastric, and intestinal) and glandular secretions (eg, salivary). Postoperative nausea, vomiting, and fecal

incontinence have been attributed to the use of cholinesterase inhibitors.

Unwanted muscarinic side effects are minimized by prior or concomitant administration of anticholinergic medications, such as atropine sulfate or glycopyrrolate. The duration of action is similar among the cholinesterase inhibitors. Clearance is due to both hepatic metabolism (25% to 50%) and renal excretion (50% to 75%). Thus, any prolongation of action of a nondepolarizing muscle relaxant from renal or hepatic insufficiency will probably be accompanied by a corresponding increase in the duration of action of a cholinesterase inhibitor.

As a rule, no amount of cholinesterase inhibitor can immediately reverse a block that is so intense that there is no response to tetanic peripheral nerve stimulation. Moreover, the absence of any palpable single twitches following 5 sec of tetanic stimulation at 50 Hz implies a very intensive blockade that cannot be reversed. Excessive doses of cholinesterase inhibitors may actually prolong recovery. Some evidence of spontaneous recovery (ie, the first twitch of the train-of-four [TOF]) should be present before reversal is attempted. The posttetanic count (the number of palpable twitches after tetanus) generally correlates with the time of return of the first twitch of the TOF and therefore the ability to reverse intense paralysis. For intermediate-acting agents, such as atracurium and vecuronium, a palpable posttetanic twitch appears about 10 min before spontaneous recovery of the first twitch of the TOF. In contrast, for longer-acting agents, such as pancuronium, the first twitch of the TOF appears about 40 min after a palpable posttetanic twitch.

The time required to fully reverse a nondepolarizing block depends on several factors, including the choice and dose of cholinesterase inhibitor administered, the muscle relaxant being antagonized, and the extent of the blockade before reversal. For example, reversal with edrophonium is usually faster than with neostigmine; large doses of neostigmine lead to faster reversal than small doses; intermediate-acting relaxants reverse sooner than long-acting relaxants; and a shallow block is easier to reverse than a deep block (ie, twitch height >10%). Intermediate-acting muscle relaxants

therefore require a lower dose of reversal agent (for the same degree of blockade) than long-acting agents, and concurrent excretion or metabolism provides a proportionally faster reversal of the short- and intermediate-acting agents. These advantages can be lost in conditions associated with severe end-organ disease (eg, the use of vecuronium in a patient with liver failure) or enzyme deficiencies (eg, mivacurium in a patient with homozygous atypical pseudocholinesterase). Depending on the dose of muscle relaxant that has been given, spontaneous recovery to a level adequate for pharmacological reversal may take more than 1 hr with long-acting muscle relaxants because of their insignificant metabolism and slow excretion. Factors associated with faster reversal are also associated with a lower incidence of residual paralysis in the recovery room and a lower risk of postoperative respiratory complications.

7 A reversal agent should be routinely given to patients who have received nondepolarizing muscle relaxants unless full reversal can be demonstrated or the postoperative plan includes continued intubation and ventilation. In the latter situation, adequate sedation must also be provided.

A peripheral nerve stimulator should also be used to monitor the progress and confirm the adequacy of reversal. In general, the higher the frequency of stimulation, the greater the sensitivity of

the test (100-Hz tetany > 50-Hz tetany or TOF > single-twitch height). Clinical signs of adequate reversal also vary in sensitivity (sustained head lift > inspiratory force > vital capacity > tidal volume).

8 Therefore, the suggested end points of recovery are sustained tetanus for 5 sec in response to a 100-Hz stimulus in anesthetized patients or sustained head or leg lift in awake patients. Newer quantitative methods for assessing recovery from neuromuscular blockade, such as acceleromyography, may further reduce the incidence of residual postoperative neuromuscular paralysis.

Specific Cholinesterase Inhibitors

NEOSTIGMINE

Physical Structure

Neostigmine consists of a carbamate moiety and a quaternary ammonium group (Figure 12-4). The former provides covalent bonding to acetylcholinesterase. The latter renders the molecule lipid insoluble, so that it cannot pass through the blood-brain barrier.

Dosage & Packaging

The maximum recommended dose of neostigmine is 0.08 mg/kg (up to 5 mg in adults), but smaller

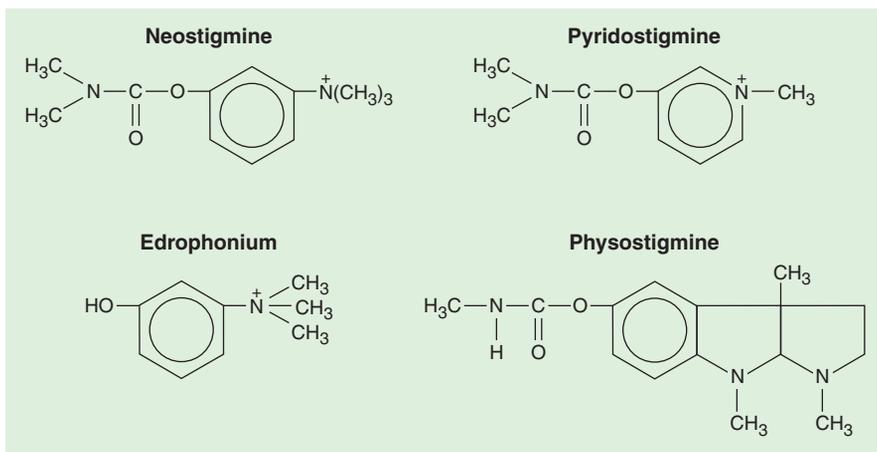

FIGURE 12-4 The molecular structures of neostigmine, pyridostigmine, edrophonium, and physostigmine.

TABLE 12-3 The choice and dose of cholinesterase inhibitor determine the choice and dose of anticholinergic.

Cholinesterase Inhibitor	Usual Dose of Cholinesterase Inhibitor	Recommended Anticholinergic	Usual Dose of Anticholinergic per mg of Cholinesterase Inhibitor
Neostigmine	0.04–0.08 mg/kg	Glycopyrrolate	0.2 mg
Pyridostigmine	0.1–0.25 mg/kg	Glycopyrrolate	0.05 mg
Edrophonium	0.5–1 mg/kg	Atropine	0.014 mg
Physostigmine ¹	0.01–0.03 mg/kg	Usually not necessary	NA

¹Not used to reverse muscle relaxants.

amounts often suffice and larger doses have also been given safely (Table 12-3). Neostigmine is most commonly packaged as 10 mL of a 1 mg/mL solution, although 0.5 mg/mL and 0.25 mg/mL concentrations are also available.

Clinical Considerations

The effects of neostigmine (0.04 mg/kg) are usually apparent in 5 min, peak at 10 min, and last more than 1 hr. If reversal is not complete in 10 min after 0.08 mg/kg, the time for full recovery of neuromuscular function will depend on the nondepolarizing agent used and the intensity of blockade. In practice, many clinicians use a dose of 0.04 mg/kg (or 2.5 mg) if the preexisting blockade is mild to moderate and a dose of 0.08 mg/kg (or 5 mg) if intense paralysis is being reversed. The duration of action is prolonged in geriatric patients. Muscarinic side effects are minimized by prior or concomitant administration of an anticholinergic agent. The onset of action of glycopyrrolate (0.2 mg glycopyrrolate per 1 mg of neostigmine) is similar to that of neostigmine and is associated with less tachycardia than is experienced with atropine (0.4 mg of atropine per 1 mg of neostigmine). It has been reported that neostigmine crosses the placenta, resulting in fetal bradycardia. Thus, *theoretically*, atropine may be a better choice of an anticholinergic agent than glycopyrrolate in pregnant patients receiving neostigmine, but there is no evidence that this makes any difference in patient outcomes. Neostigmine is also used to treat myasthenia gravis, urinary bladder atony, and paralytic ileus.

PYRIDOSTIGMINE

Physical Structure

Pyridostigmine is structurally similar to neostigmine except that the quaternary ammonium is incorporated into the phenol ring. Pyridostigmine shares neostigmine's covalent binding to acetylcholinesterase and its lipid insolubility.

Dosage & Packaging

Pyridostigmine is 20% as potent as neostigmine and may be administered in doses up to 0.25 mg/kg (a total of 20 mg in adults). It is available as a solution of 5 mg/mL.

Clinical Considerations

The onset of action of pyridostigmine is slower (10–15 min) than that of neostigmine, and its duration is slightly longer (>2 h). Glycopyrrolate (0.05 mg per 1 mg of pyridostigmine) or atropine (0.1 mg per 1 mg of pyridostigmine) must also be administered to prevent bradycardia. Glycopyrrolate is preferred because its slower onset of action better matches that of pyridostigmine, again resulting in less tachycardia.

EDROPHONIUM

Physical Structure

Because it lacks a carbamate group, edrophonium must rely on noncovalent bonding to the acetylcholinesterase enzyme. The quaternary ammonium group limits lipid solubility.

Dosage & Packaging

Edrophonium is less than 10% as potent as neostigmine. The recommended dosage is 0.5–1 mg/kg. Edrophonium is available as a solution containing 10 mg/mL; it is available with atropine as a combination drug (Enlon-Plus; 10 mg edrophonium and 0.14 mg atropine per mL).

Clinical Considerations

Edrophonium has the most rapid onset of action (1–2 min) and the shortest duration of effect of any of the cholinesterase inhibitors. Reduced doses should not be used, because longer-acting muscle relaxants may outlast the effects of edrophonium. Higher doses prolong the duration of action to more than 1 hr. Edrophonium may not be as effective as neostigmine at reversing intense neuromuscular blockade. In equipotent doses, muscarinic effects of edrophonium are less pronounced than those of neostigmine or pyridostigmine, requiring only half the amount of anticholinergic agent. Edrophonium's rapid onset is well matched to that of atropine (0.014 mg of atropine per 1 mg of edrophonium). Although glycopyrrolate (0.007 mg per 1 mg of edrophonium) can also be used, it should be given several minutes prior to edrophonium to avoid the possibility of bradycardia.

PHYSOSTIGMINE

Physical Structure

Physostigmine, a tertiary amine, has a carbamate group but no quaternary ammonium. Therefore, it is lipid soluble and is the only clinically available cholinesterase inhibitor that freely passes the blood–brain barrier.

Dosage & Packaging

The dose of physostigmine is 0.01–0.03 mg/kg. It is packaged as a solution containing 1 mg/mL.

Clinical Considerations

The lipid solubility and central nervous system penetration of physostigmine limit its usefulness as a reversal agent for nondepolarizing blockade, but make it effective in the treatment of central

anticholinergic toxicity caused by overdoses of atropine or scopolamine. In addition, it reverses some of the central nervous system depression and delirium associated with use of benzodiazepines and volatile anesthetics. Physostigmine (0.04 mg/kg) has been shown to be effective in preventing postoperative shivering. It reportedly partially antagonizes morphine-induced respiratory depression, presumably because morphine reduces acetylcholine release in the brain. These effects are transient, and repeated doses may be required. Bradycardia is infrequent in the recommended dosage range, but atropine should be immediately available. Because glycopyrrolate does not cross the blood–brain barrier, it will not reverse the central nervous system effects of physostigmine. Other possible muscarinic side effects include excessive salivation, vomiting, and convulsions. In contrast to other cholinesterase inhibitors, physostigmine is almost completely metabolized by plasma esterases, so renal excretion is not important.

OTHER CONSIDERATIONS

Recovery from neuromuscular blockade is influenced by the depth of block at the time of antagonism, clearance and half-life of the relaxant used, and other factors that affect neuromuscular blockade (Table 12–4), such as drugs and electrolyte

disturbances. In addition, some specific agents with the potential of reversing the neuromuscular blocking effects of nondepolarizing muscle relaxants merit brief discussion.

NON-CLASSIC REVERSAL AGENTS

Besides cholinesterase inhibitors, two unique drugs (sugammadex and L-cysteine) are currently under investigation in the United States; these agents act as selective antagonists of nondepolarizing neuromuscular blockade. Sugammadex is able to reverse aminosteroid-induced neuromuscular blockade, whereas cysteine has been shown to reverse the neuromuscular blocking effects of gantacurium and other fumarates.

SUGAMMADEX

Sugammadex is a novel selective relaxant-binding agent that is currently available for clinical use in Europe. It is a modified gamma-cyclodextrin (*su* refers to sugar, and *gammadex* refers to the structural molecule gamma-cyclodextrin).

Physical Structure

Its three-dimensional structure resembles a hollow truncated cone or doughnut with a hydrophobic cavity and a hydrophilic exterior. Hydrophobic interactions trap the drug (eg, rocuronium) in the cyclodextrin cavity (doughnut hole), resulting in tight formation of a water-soluble guest–host complex in a 1:1 ratio. This terminates the neuromuscular blocking action and restrains the drug in extracellular fluid where it cannot interact with nicotinic acetylcholine receptors. Sugammadex is essentially eliminated unchanged via the kidneys.

Clinical Considerations

Sugammadex has been administered in doses of 4–8 mg/kg. With an injection of 8 mg/kg, given 3 min after administration of 0.6 mg/kg of rocuronium, recovery of TOF ratio to 0.9 was observed within 2 min. It produces rapid and effective reversal of both shallow and profound

rocuronium-induced neuromuscular blockade in a consistent manner. Because of some concerns about hypersensitivity and allergic reactions, sugammadex has not yet been approved by the US Food and Drug Administration.

L-CYSTEINE

L-cysteine is an endogenous amino acid that is often added to total parenteral nutrition regimens to enhance calcium and phosphate solubility. The ultrashort-acting neuromuscular blocker, gantacurium, and other fumarates rapidly combine with L-cysteine *in vitro* to form less active degradation products (adducts). Exogenous administration of L-cysteine (10–50 mg/kg intravenously) given to anesthetized monkeys 1 min after these neuromuscular blocking agents abolished the block within 2–3 min; this antagonism was found to be superior to that produced by anticholinesterases. This unique method of antagonism by adduct formation and inactivation is still in the investigative stage, especially in terms of its safety and efficacy in humans.

CASE DISCUSSION

Respiratory Failure in the Recovery Room

A 66-year-old woman weighing 85 kg is brought to the recovery room following cholecystectomy. The anesthetic technique included the use of isoflurane and vecuronium for muscle relaxation. At the conclusion of the procedure, the anesthesiologist administered 6 mg of morphine sulfate for postoperative pain control and 3 mg of neostigmine with 0.6 mg of glycopyrrolate to reverse any residual neuromuscular blockade. The dose of cholinesterase inhibitor was empirically based on clinical judgment. Although the patient was apparently breathing normally on arrival in the recovery room, her tidal volume progressively diminished. Arterial blood gas measurements revealed a P_{aCO_2} of 62 mm Hg, a P_{aO_2} of 110 mm Hg, and a pH of 7.26 on a fraction of inspired oxygen (F_{IO_2}) of 40%.

Which drugs administered to this patient could explain her hypoventilation?

Isoflurane, morphine sulfate, and vecuronium all interfere with a patient's ability to maintain a normal ventilatory response to an elevated Paco_2 .

Why would the patient's breathing worsen in the recovery room?

Possibilities include the delayed onset of action of morphine sulfate, a lack of sensory stimulation in the recovery area, fatigue of respiratory muscles, and splinting as a result of upper abdominal pain.

Could the patient still have residual neuromuscular blockade?

If the dose of neostigmine was not determined by the response to a peripheral nerve stimulator, or if the recovery of muscle function was inadequately tested after the reversal drugs were given, persistent neuromuscular blockade is possible. Assume, for example, that the patient had minimal or no response to initial tetanic stimulation at 100 Hz. Even the maximal dose of neostigmine (5 mg) might not yet have adequately reversed the paralysis. Because of enormous patient variability, the response to peripheral nerve stimulation must always be monitored when intermediate- or long-acting muscle relaxants are administered. Even if partial reversal is achieved, paralysis may worsen if the patient hypoventilates. **Other factors (in addition to respiratory acidosis) that impair the reversal of nondepolarizing muscle relaxants include intense neuromuscular paralysis, electrolyte disturbances (hypermagnesemia, hypokalemia, and hypocalcemia), hypothermia (temperature $<32^\circ\text{C}$), drug interactions (see Table 11–4), metabolic alkalosis (from accompanying hypokalemia and hypocalcemia), and coexisting diseases (see Table 11–8).**

How could the extent of reversal be tested?

Tetanic stimulation is a sensitive but uncomfortable test of neuromuscular transmission in an

awake patient. Because of its shorter duration, double-burst stimulation is tolerated better than tetany by conscious patients. Many other tests of neuromuscular transmission, such as vital capacity and tidal volume, are insensitive as they may still seem normal when 70% to 80% of receptors are blocked. In fact, 70% of receptors may remain blocked despite an apparently normal response to TOF stimulation. The ability to sustain a head lift for 5 sec, however, indicates that fewer than 33% of receptors are occupied by muscle relaxant.

What treatment would you suggest?

Ventilation should be assisted to reduce the respiratory acidosis. Even if diaphragmatic function seems to be adequate, residual blockade can lead to airway obstruction and poor airway protection. More neostigmine (with an anticholinergic) could be administered up to a maximum recommended dose of 5 mg. If this does not adequately reverse paralysis, mechanical ventilation and airway protection should be instituted and continued until neuromuscular function is fully restored.

Anticholinergic Drugs

KEY CONCEPTS

- 1 The ester linkage is essential for effective binding of the anticholinergics to the acetylcholine receptors. This competitively blocks binding by acetylcholine and prevents receptor activation. The cellular effects of acetylcholine, which are mediated through second messengers, are inhibited.
- 2 Anticholinergics relax the bronchial smooth musculature, which reduces airway resistance and increases anatomic dead space.
- 3 Atropine has particularly potent effects on the heart and bronchial smooth muscle and is the most efficacious anticholinergic for treating bradyarrhythmias.
- 4 Ipratropium solution (0.5 mg in 2.5 mL) seems to be particularly effective in the treatment of acute chronic obstructive pulmonary disease when combined with a β -agonist drug (eg, albuterol).
- 5 Scopolamine is a more potent antisialagogue than atropine and causes greater central nervous system effects.
- 6 Because of its quaternary structure, glycopyrrolate cannot cross the blood–brain barrier and is almost devoid of central nervous system and ophthalmic activity.

One group of cholinergic antagonists has already been discussed: the nondepolarizing neuromuscular-blocking agents. These drugs act primarily at the nicotinic receptors in skeletal muscle. This chapter presents the pharmacology of drugs that block muscarinic receptors. Although the classification *anticholinergic* usually refers to this latter group, a more precise term would be *antimuscarinic*.

In this chapter, the mechanism of action and clinical pharmacology are introduced for three common anticholinergics: atropine, scopolamine, and glycopyrrolate. The clinical uses of these drugs in anesthesia relate to their effect on the cardiovascular, respiratory, cerebral, gastrointestinal, and other organ systems (Table 13–1).

MECHANISMS OF ACTION

Anticholinergics are esters of an aromatic acid combined with an organic base (Figure 13–1). The ester linkage is essential for effective binding of the anticholinergics to the acetylcholine receptors. **This competitively blocks binding by acetylcholine and prevents receptor activation.** The cellular effects of acetylcholine, which are mediated through second messengers, are inhibited. The tissue receptors vary in their sensitivity to blockade. In fact, muscarinic receptors are not homogeneous, and receptor subgroups have been identified including: neuronal (M_1), cardiac (M_2), and glandular (M_3) receptors.

CLINICAL PHARMACOLOGY

General Pharmacological Characteristics

In normal clinical doses, only muscarinic receptors are blocked by the anticholinergic drugs discussed in this chapter. The extent of the anticholinergic effect depends on the degree of baseline vagal tone. Several organ systems are affected.

A. Cardiovascular

Blockade of muscarinic receptors in the sinoatrial node produces tachycardia. This effect is especially useful in reversing bradycardia due to vagal reflexes (eg, baroreceptor reflex, peritoneal traction, or oculocardiac reflex). A transient slowing of heart rate in response to smaller intravenous doses of atropine (<0.4 mg) has been reported. The mechanism of this paradoxical response is unclear. Facilitation of

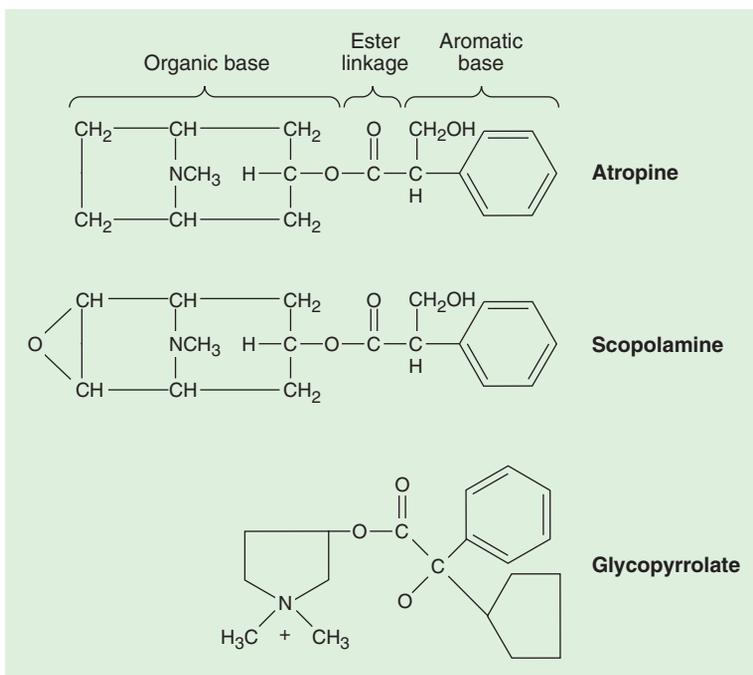

FIGURE 13-1 Physical structures of anticholinergic drugs.

conduction through the atrioventricular node shortens the P–R interval on the electrocardiogram and often decreases heart block caused by vagal activity. Atrial arrhythmias and nodal (junctional) rhythms occasionally occur. Anticholinergics generally have little effect on ventricular function or peripheral vasculature because of the paucity of direct cholinergic innervation of these areas despite the presence of cholinergic receptors. Presynaptic muscarinic receptors on adrenergic nerve terminals are known to inhibit norepinephrine release, so muscarinic antagonists may modestly enhance sympathetic activity. Large doses of anticholinergic agents can result in dilation of cutaneous blood vessels (atropine flush).

B. Respiratory

The anticholinergics inhibit the secretions of the respiratory tract mucosa, from the nose to the bronchi, a valuable property during airway endoscopic or **2** surgical procedures. Relaxation of the bronchial smooth musculature reduces airway resistance and increases anatomic dead space. These effects are particularly pronounced in patients with chronic obstructive pulmonary disease or asthma.

C. Cerebral

Anticholinergic medications can cause a spectrum of central nervous system effects ranging from stimulation to depression, depending on drug choice and dosage. Cerebral stimulation may present as excitation, restlessness, or hallucinations. Cerebral depression, including sedation and amnesia, are prominent after scopolamine. Physostigmine, a cholinesterase inhibitor that crosses the blood–brain barrier, promptly reverses anticholinergic actions on the brain.

D. Gastrointestinal

Salivary secretions are markedly reduced by anticholinergic drugs. Gastric secretions are also decreased, but larger doses are necessary. Decreased intestinal motility and peristalsis prolong gastric emptying time. Lower esophageal sphincter pressure is reduced. Overall, the anticholinergic drugs do not prevent aspiration pneumonia.

E. Ophthalmic

Anticholinergics cause mydriasis (pupillary dilation) and cycloplegia (an inability to accommodate

to near vision); acute angle-closure glaucoma is unlikely following systemic administration of most anticholinergic drugs.

F. Genitourinary

Anticholinergics may decrease ureter and bladder tone as a result of smooth muscle relaxation and lead to urinary retention, particularly in elderly men with prostatic hypertrophy.

G. Thermoregulation

Inhibition of sweat glands may lead to a rise in body temperature (atropine fever).

Specific Anticholinergic Drugs

ATROPINE

Physical Structure

Atropine is a tertiary amine. The naturally occurring levorotatory form is active, but the commercial mixture is racemic (Figure 13–1).

Dosage & Packaging

As a premedication, atropine is administered intravenously or intramuscularly in a range of 0.01–0.02 mg/kg, up to the usual adult dose of 0.4–0.6 mg. Larger intravenous doses up to 2 mg may be required to completely block the cardiac vagal nerves in treating severe bradycardia. Atropine sulfate is available in a multitude of concentrations.

Clinical Considerations

3 Atropine has particularly potent effects on the heart and bronchial smooth muscle and is the most efficacious anticholinergic for treating bradyarrhythmias. Patients with coronary artery disease may not tolerate the increased myocardial oxygen demand and decreased oxygen supply associated with the tachycardia caused by atropine. A derivative of atropine, ipratropium bromide, is available in a metered-dose inhaler for the treatment of bronchospasm. Its quaternary ammonium structure significantly **4** limits systemic absorption. Ipratropium solution (0.5 mg in 2.5 mL) seems to be particularly effective in the treatment of acute chronic obstructive pulmonary disease when combined with a β -agonist drug (eg, albuterol). The central nervous

system effects of atropine are minimal after the usual doses, even though this tertiary amine can rapidly cross the blood–brain barrier. Atropine has been associated with mild postoperative memory deficits, and toxic doses are usually associated with excitatory reactions. An intramuscular dose of 0.01–0.02 mg/kg reliably provides an antisialagogue effect. Atropine should be used cautiously in patients with narrow-angle glaucoma, prostatic hypertrophy, or bladder-neck obstruction.

SCOPOLAMINE

Physical Structure

Scopolamine, a tertiary amine, differs from atropine by the addition of an epoxide to the heterocyclic ring.

Dosage & Packaging

The premedication dose of scopolamine is the same as that of atropine, and it is usually given intramuscularly. Scopolamine hydrobromide is available as solutions containing 0.3, 0.4, and 1 mg/mL.

Clinical Considerations

5 Scopolamine is a more potent antisialagogue than atropine and causes greater central nervous system effects. Clinical dosages usually result in drowsiness and amnesia, although restlessness, dizziness, and delirium are possible. The sedative effects may be desirable for premedication but can interfere with awakening following short procedures. Scopolamine has the added virtue of preventing motion sickness. The lipid solubility allows transdermal absorption, and transdermal scopolamine has been used to prevent postoperative nausea and vomiting. Because of its pronounced ocular effects, scopolamine is best avoided in patients with closed-angle glaucoma.

GLYCOPYRROLATE

Physical Structure

Glycopyrrolate is a synthetic product that differs from atropine in being a quaternary amine and having both cyclopentane and a pyridine moieties in the compound.

Dosage & Packaging

The usual dose of glycopyrrolate is one-half that of atropine. For instance, the premedication dose is 0.005–0.01 mg/kg up to 0.2–0.3 mg in adults. Glycopyrrolate for injection is packaged as a solution of 0.2 mg/mL.

Clinical Considerations

6 Because of its quaternary structure, glycopyrrolate cannot cross the blood–brain barrier and is almost devoid of central nervous system and ophthalmic activity. Potent inhibition of salivary gland and respiratory tract secretions is the primary rationale for using glycopyrrolate as a premedication. Heart rate usually increases after intravenous—but not intramuscular—administration. Glycopyrrolate has a longer duration of action than atropine (2–4 h vs 30 min after intravenous administration).

CASE DISCUSSION

Central Anticholinergic Syndrome

An elderly patient is scheduled for enucleation of a blind, painful eye. Scopolamine, 0.4 mg intramuscularly, is administered as premedication. In the preoperative holding area, the patient becomes agitated and disoriented. The only other medication the patient has received is 1% atropine eye drops.

How many milligrams of atropine are in one drop of a 1% solution?

A 1% solution contains 1 g dissolved in 100 mL, or 10 mg/mL. Eyedroppers vary in the number of drops formed per milliliter of solution, but average 20 drops/mL. Therefore, one drop usually contains 0.5 mg of atropine.

How are ophthalmic drops systemically absorbed?

Absorption by vessels in the conjunctival sac is similar to subcutaneous injection. More rapid absorption is possible by the nasolacrimal duct mucosa.

What are the signs and symptoms of anticholinergic poisoning?

Reactions from an overdose of anticholinergic medication involve several organ systems. The central anticholinergic syndrome refers to central nervous system changes that range from unconsciousness to hallucinations. Agitation and delirium are not unusual in elderly patients. Other systemic manifestations include dry mouth, tachycardia, atropine flush, atropine fever, and impaired vision.

What other drugs possess anticholinergic activity that could predispose patients to the central anticholinergic syndrome?

Tricyclic antidepressants, antihistamines, and antipsychotics have antimuscarinic properties that could potentiate the side effects of anticholinergic drugs.

What drug is an effective antidote to anticholinergic overdose?

Cholinesterase inhibitors indirectly increase the amount of acetylcholine available to compete with anticholinergic drugs at the muscarinic receptor. Neostigmine, pyridostigmine, and edrophonium possess a quaternary ammonium group that prevents penetration of the blood–brain barrier. Physostigmine, a tertiary amine, is lipid soluble and

effectively reverses central anticholinergic toxicity. An initial dose of 0.01–0.03 mg/kg may have to be repeated after 15–30 min.

Should this case be canceled or allowed to proceed?

Enucleation to relieve a painful eye is clearly an elective procedure. The most important question that must be addressed for elective cases is whether the patient is optimally medically managed. In other words, would canceling surgery allow further fine-tuning of any medical problems? For example, if this anticholinergic overdose were accompanied by tachycardia, it would probably be prudent to postpone surgery in this elderly patient. On the other hand, if the patient's mental status responds to physostigmine and there seems to be no other significant anticholinergic side effects, surgery could proceed.

Adrenergic Agonists & Antagonists

KEY CONCEPTS

- 1 Adrenergic agonists can be categorized as direct or indirect. Direct agonists bind to the receptor, whereas indirect agonists increase endogenous neurotransmitter activity.
- 2 The primary effect of phenylephrine is peripheral vasoconstriction with a concomitant rise in systemic vascular resistance and arterial blood pressure.
- 3 Clonidine seems to decrease anesthetic and analgesic requirements and to provide sedation and anxiolysis.
- 4 Dexmedetomidine is a lipophilic α -methylol derivative with a higher affinity for α_2 -receptors than clonidine. It has sedative, analgesic, and sympatholytic effects that blunt many of the cardiovascular responses seen during the perioperative period.
- 5 Long-term use of these agents, particularly clonidine and dexmedetomidine, leads to supersensitization and up-regulation of receptors; with abrupt discontinuation of either drug, an acute withdrawal syndrome manifested by a hypertensive crisis can occur.
- 6 Ephedrine is commonly used as a vasopressor during anesthesia. As such, its administration should be viewed as a temporizing measure while the cause of hypotension is determined and remedied.
- 7 Small doses (approximately 2 mcg/kg/min) of dopamine (DA) have minimal adrenergic effects but activate dopaminergic receptors. Stimulation of these nonadrenergic receptors (specifically, DA_1 receptors) vasodilates the renal vasculature and promotes diuresis.
- 8 Favorable effects on myocardial oxygen balance are believed to make dobutamine a good choice for patients with the combination of congestive heart failure and coronary artery disease, particularly if peripheral vascular resistance is elevated. (There are some recent debates regarding this beneficial effect.)
- 9 Labetalol lowers blood pressure without reflex tachycardia because of its combination of α - and β -effects.
- 10 Esmolol is an ultrashort-acting selective β_1 -antagonist that reduces heart rate and, to a lesser extent, blood pressure.
- 11 Discontinuation of β -blocker therapy for 24–48 hr may trigger a withdrawal syndrome characterized by hypertension, tachycardia, and angina pectoris.

Adrenergic agonists and antagonists produce their clinical effects by interacting with the adrenergic receptors (ie, adrenoceptors). The clinical effects of these drugs can be deduced from an understanding of the adrenoceptor physiology and a knowledge of which receptors each drug activates or blocks.

ADRENOCEPTOR PHYSIOLOGY

The term “adrenergic” originally referred to the effects of epinephrine (*adrenaline*), although norepinephrine (*noradrenaline*) is the primary neurotransmitter responsible for most of the adrenergic activity of the sympathetic nervous system. With the exception of eccrine sweat glands and some blood vessels, norepinephrine is released by postganglionic sympathetic fibers at end-organ tissues (Figure 14-1). In contrast, acetylcholine is released by preganglionic sympathetic fibers and all parasympathetic fibers.

Norepinephrine is synthesized in the cytoplasm of sympathetic postganglionic nerve endings and stored in the vesicles (Figure 14-2). After release by a process of exocytosis, the action of norepinephrine is primarily terminated by reuptake into the postganglionic nerve ending (inhibited by tricyclic antidepressants), but also by diffusion from receptor sites, or via metabolism by monoamine oxidase (inhibited by monoamine oxidase inhibitors) and catechol-*O*-methyltransferase (Figure 14-3). Prolonged adrenergic activation leads to desensitization and hyporesponsiveness to further stimulation.

Adrenergic receptors are divided into two general categories: α and β . Each of these has been further subdivided into at least two subtypes: α_1 and α_2 , and β_1 , β_2 , and β_3 . The α -receptors have been further divided using molecular cloning techniques into α_{1A} , α_{1B} , α_{1D} , α_{2A} , α_{2B} , and α_{2C} . These receptors are linked to G proteins (Figure 14-4; Drs. Rodbell and Gilman received the Nobel Prize in physiology or medicine in 1994 for their discovery)—heterotrimeric receptors with α , β , and γ subunits. The different adrenoceptors are linked to specific G proteins, each with a unique effector, but each using guanosine triphosphate (GTP) as a cofactor. α_1 is linked to G_q , which activates phospholipases; α_2 is linked to

G_i , which inhibits adenylate cyclase, and β is linked to G_s , which activates adenylate cyclase.

α_1 -Receptors

α_1 -Receptors are postsynaptic adrenoceptors located in smooth muscle throughout the body (in the eye, lung, blood vessels, uterus, gut, and genitourinary system). Activation of these receptors increases intracellular calcium ion concentration, which leads to contraction of smooth muscles. Thus, α_1 -agonists are associated with mydriasis (pupillary dilation due to contraction of the radial eye muscles), bronchoconstriction, vasoconstriction, uterine contraction, and constriction of sphincters in the gastrointestinal and genitourinary tracts. α_1 -stimulation also inhibits insulin secretion and lipolysis. The myocardium possesses α_1 -receptors that have a positive inotropic effect, which might play a role in catecholamine-induced arrhythmia. During myocardial ischemia, enhanced α_1 -receptor coupling with agonists is observed. Nonetheless, the most important cardiovascular effect of α_1 -stimulation is vasoconstriction, which increases peripheral vascular resistance, left ventricular afterload, and arterial blood pressure.

α_2 -Receptors

In contrast to α_1 -receptors, α_2 -receptors are located primarily on the presynaptic nerve terminals. Activation of these adrenoceptors inhibits adenylate cyclase activity. This decreases the entry of calcium ions into the neuronal terminal, which limits subsequent exocytosis of storage vesicles containing norepinephrine. Thus, α_2 -receptors create a negative feedback loop that inhibits further norepinephrine release from the neuron. In addition, vascular smooth muscle contains postsynaptic α_2 -receptors that produce vasoconstriction. More importantly, stimulation of postsynaptic α_2 -receptors in the central nervous system causes sedation and reduces sympathetic outflow, which leads to peripheral vasodilation and lower blood pressure.

β_1 -Receptors

β -Adrenergic receptors are classified into β_1 , β_2 , and β_3 receptors. The catecholamines, norepinephrine,

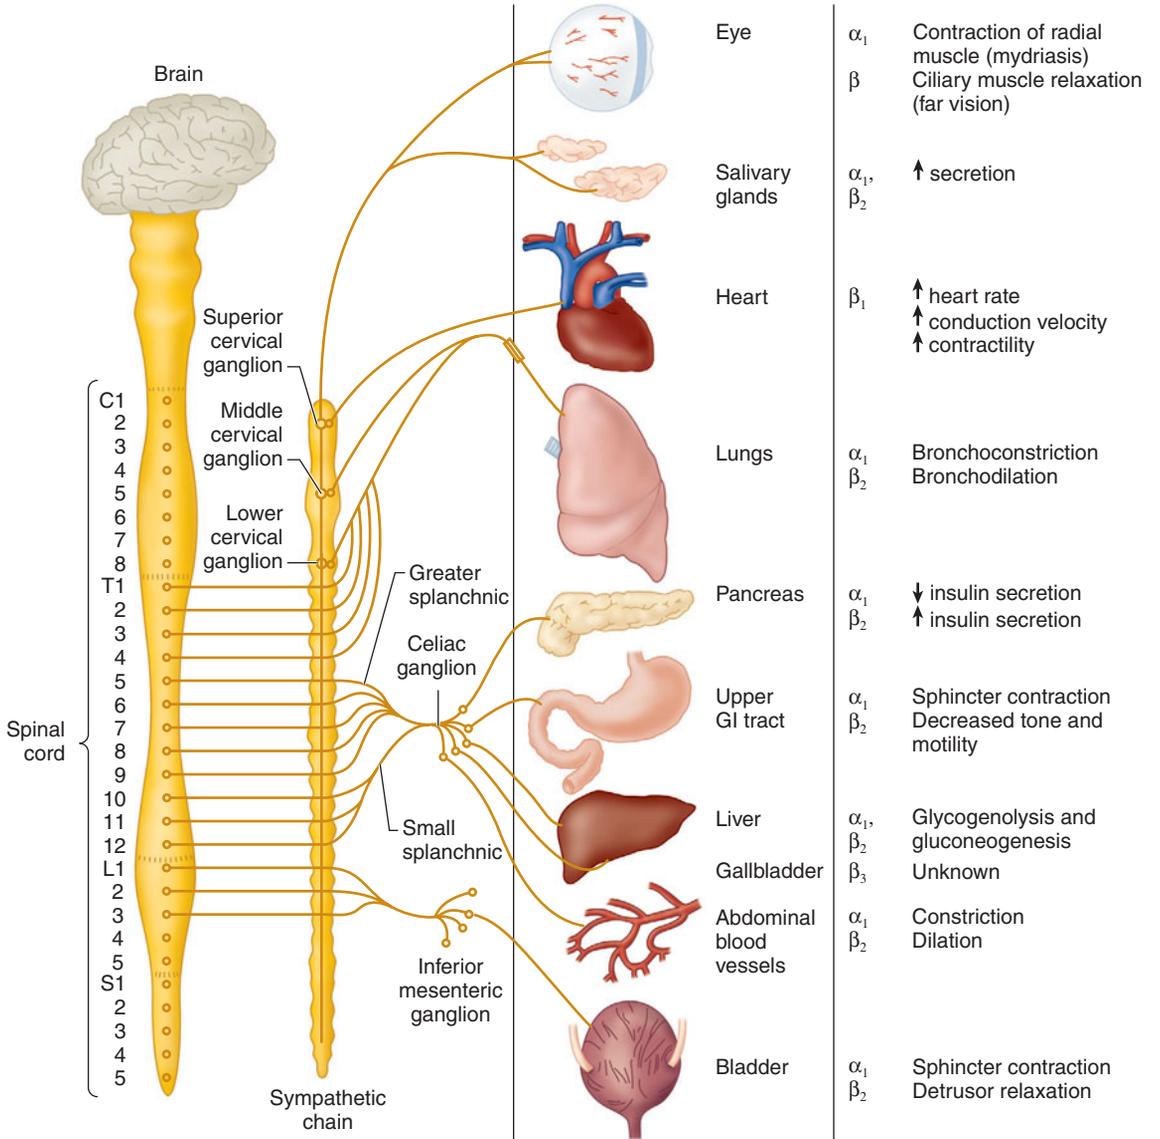

FIGURE 14-1 The sympathetic nervous system. Organ innervation, receptor type, and response to stimulation. The origin of the sympathetic chain is the thoracoabdominal (T1–L3) spinal cord, in contrast to the

craniosacral distribution of the parasympathetic nervous system. Another anatomic difference is the greater distance from the sympathetic ganglion to the visceral structures.

and epinephrine are equipotent on β_1 receptors, but epinephrine is significantly more potent than norepinephrine on β_2 receptors.

The most important β_1 -receptors are located on the postsynaptic membranes in the heart.

Stimulation of these receptors activates adenylate cyclase, which converts adenosine triphosphate to cyclic adenosine monophosphate and initiates a kinase phosphorylation cascade. Initiation of the cascade has positive chronotropic (increased heart

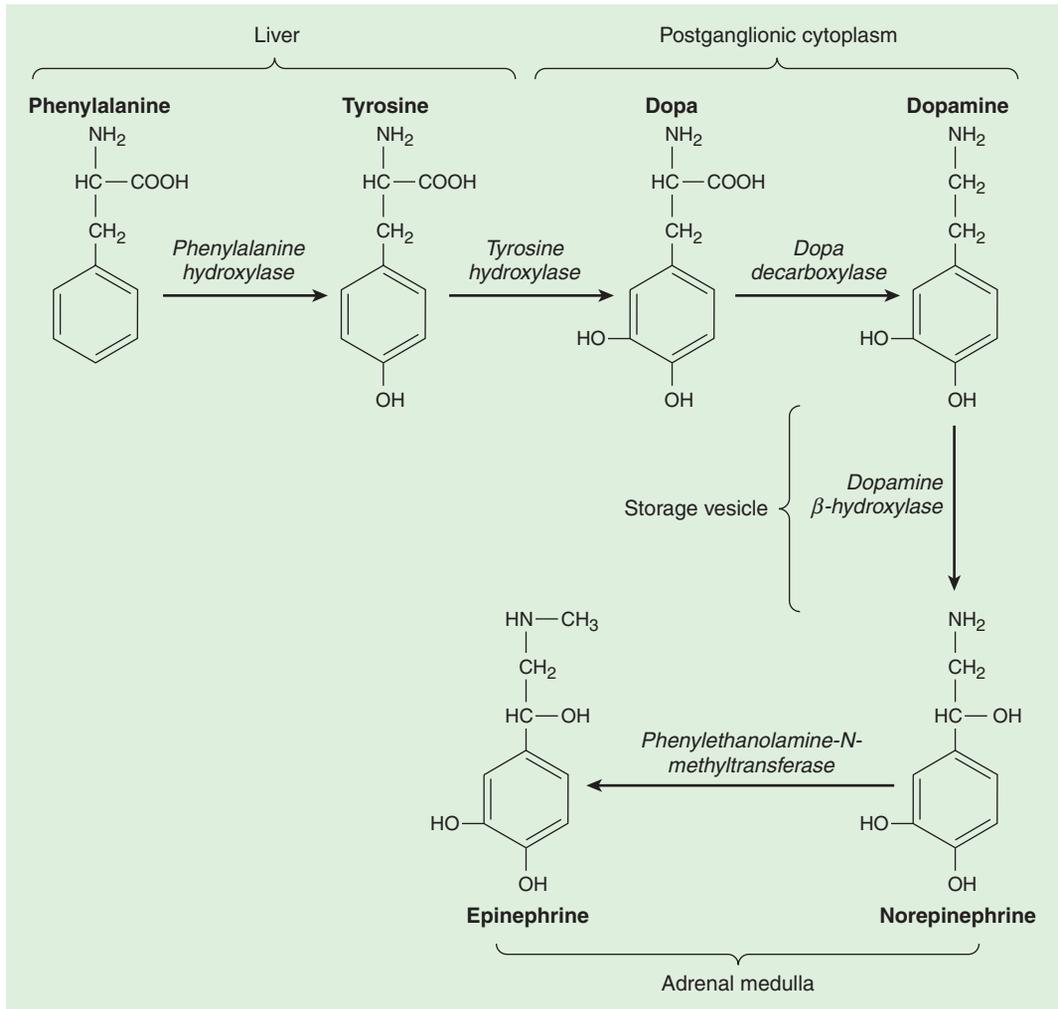

FIGURE 14-2 The synthesis of norepinephrine. Hydroxylation of tyrosine to dopa is the rate-limiting step. Dopamine is actively transported into storage vesicles. Norepinephrine can be converted to epinephrine in the adrenal medulla.

rate), dromotropic (increased conduction), and inotropic (increased contractility) effects.

β_2 -Receptors

β_2 -Receptors are primarily postsynaptic adrenoreceptors located in smooth muscle and gland cells. They share a common mechanism of action with β_1 -receptors: adenylate cyclase activation. Despite this commonality, β_2 stimulation relaxes smooth muscle, resulting in bronchodilation, vasodilation, and relaxation of the uterus (tocolysis), bladder, and

gut. Glycogenolysis, lipolysis, gluconeogenesis, and insulin release are stimulated by β_2 -receptor activation. β_2 -agonists also activate the sodium-potassium pump, which drives potassium intracellularly and can induce hypokalemia and dysrhythmias.

β_3 -Receptors

β_3 -Receptors are found in the gallbladder and brain adipose tissue. Their role in gallbladder physiology is unknown, but they are thought to play a role in lipolysis and thermogenesis in brown fat.

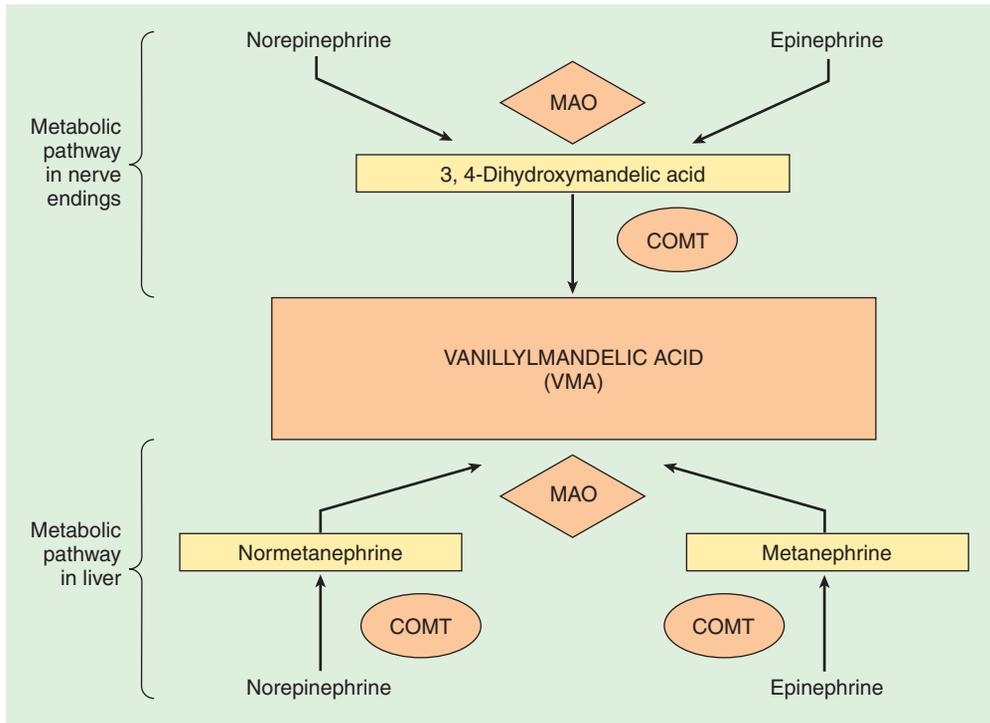

FIGURE 14-3 Sequential metabolism of norepinephrine and epinephrine. Monoamine oxidase (MAO) and catechol-O-methyltransferase (COMT) produce a common end product, vanillylmandelic acid (VMA).

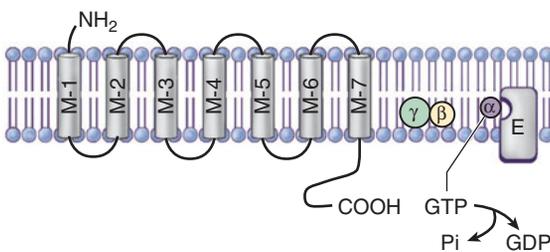

FIGURE 14-4 The adrenoceptor is a transmembrane-spanning receptor made up of seven subunits, which is linked to a G protein. G proteins are trimeric endoplasmic membrane proteins made of α , β , and γ units. With activation, GTP on the α -subunit is replaced by GDP, stimulating a conformational change, disassociating the α , β , and γ units. Either the G_α or $G_{\beta\gamma}$ subunits can activate (or inhibit) the enzyme effector for that adrenoceptor. M1–M7, membrane-spanning units; α , β , γ , subunits of G protein; GTP, guanosine triphosphate; P_i , inorganic phosphate—quickly assimilated; GDP, guanosine diphosphate; E, effector; cyclophosphatase for G_q , adenylate cyclase for G_r and G_s .

Dopaminergic Receptors

Dopamine (DA) receptors are a group of adrenergic receptors that are activated by dopamine; these receptors are classified as D_1 and D_2 receptors. Activation of D_1 receptors mediates vasodilation in the kidney, intestine, and heart. D_2 receptors are believed to play a role in the antiemetic action of droperidol.

Adrenergic Agonists

Adrenergic agonists interact with varying specificity (selectivity) at α - and β -adrenoceptors (Tables 14-1 and 14-2).

Overlapping of activity complicates the prediction of clinical effects. For example, epinephrine stimulates α_1 -, α_2 -, β_1 -, and β_2 -adrenoceptors. Its net effect on arterial blood pressure depends on the balance between α_1 -vasoconstriction, α_2 - and

²The α_1 -effects of epinephrine, norepinephrine, and dopamine become more prominent at high doses.

³The primary mode of action of ephedrine is indirect stimulation.

β_2 -vasodilation, and β_1 -inotropic influences. Moreover, this balance changes at different doses.

1 Adrenergic agonists can be categorized as direct or indirect. Direct agonists bind to the receptor, whereas indirect agonists increase

endogenous neurotransmitter activity. Mechanisms of indirect action include increased release or decreased reuptake of norepinephrine. The differentiation between direct and indirect mechanisms of action is particularly important in patients who

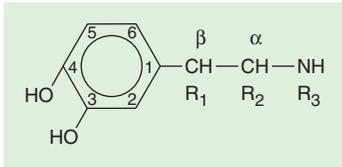

FIGURE 14-5 Adrenergic agonists that have a 3,4-dihydroxybenzene structure are known as catecholamines. Substitutions at the R_1 , R_2 , and R_3 sites affect activity and selectivity.

have abnormal endogenous norepinephrine stores, as may occur with use of some antihypertensive medications or monoamine oxidase inhibitors. Intraoperative hypotension in these patients should be treated with direct agonists, as their response to indirect agonists will be altered.

Another feature distinguishing adrenergic agonists from each other is their chemical structure. Adrenergic agonists that have a 3,4-dihydroxybenzene structure (Figure 14-5) are known as catecholamines. These drugs are typically short-acting because of their metabolism by monoamine oxidase and catechol-*O*-methyltransferase. Patients taking monoamine oxidase inhibitors or tricyclic antidepressants may therefore demonstrate an exaggerated response to catecholamines. The naturally occurring catecholamines are epinephrine, norepinephrine, and DA. Changing the side-chain structure (R_1 , R_2 , R_3) of naturally occurring catecholamines has led to the development of synthetic catecholamines (eg, isoproterenol and dobutamine), which tend to be more receptor specific.

Adrenergic agonists commonly used in anesthesiology are discussed individually below. Note that the recommended doses for continuous infusion are expressed as mcg/kg/min for some agents and mcg/min for others. In either case, these recommendations should be regarded only as guidelines, as individual responses are quite variable.

PHENYLEPHRINE

Clinical Considerations

Phenylephrine is a noncatecholamine with predominantly selective α_1 -agonist activity. The primary effect of phenylephrine is peripheral

vasoconstriction with a concomitant rise in systemic vascular resistance and arterial blood pressure. Reflex bradycardia mediated by the vagus nerve can reduce cardiac output. Phenylephrine is also used topically as a decongestant and a mydriatic agent.

Dosing & Packaging

Small intravenous boluses of 50–100 μg (0.5–1 mcg/kg) of phenylephrine rapidly reverse reductions in blood pressure caused by peripheral vasodilation (eg, spinal anesthesia). The duration of action is short, lasting approximately 15 min after administration of a single dose. A continuous infusion (100 mcg/mL at a rate of 0.25–1 mcg/kg/min) will maintain arterial blood pressure, but at the expense of renal blood flow. Tachyphylaxis occurs with phenylephrine infusions requiring upward titration of the infusion. Phenylephrine must be diluted from a 1% solution (10 mg/1-mL ampule), usually to a 100 mcg/mL solution.

α_2 -AGONISTS

Clinical Considerations

Clonidine is an α_2 -agonist that is commonly used for its antihypertensive and negative chronotropic effects. More recently, it and other α_2 -agonists are increasingly being used for their sedative properties. Various studies have examined the anesthetic effects of oral (3–5 mcg/kg), intramuscular (2 mcg/kg), intravenous (1–3 mcg/kg), transdermal (0.1–0.3 mg released per day), intrathecal (75–150 mcg), and epidural (1–2 mcg/kg) clonidine administration.

3 In general, clonidine seems to decrease anesthetic and analgesic requirements (decreases minimum alveolar concentration) and provides sedation and anxiolysis. During general anesthesia, clonidine reportedly enhances intraoperative circulatory stability by reducing catecholamine levels. During regional anesthesia, including peripheral nerve block, clonidine prolongs the duration of the block. Direct effects on the spinal cord may be mediated by α_2 -postsynaptic receptors within the dorsal horn. Other possible benefits include decreased postoperative shivering, inhibition of opioid-induced muscle rigidity, attenuation of opioid withdrawal symptoms, and the treatment of

some chronic pain syndromes. Side effects include bradycardia, hypotension, sedation, respiratory depression, and dry mouth.

4 Dexmedetomidine is a lipophilic α -methylol derivative with a higher affinity for α_2 -receptors than clonidine. Compared with clonidine, dexmedetomidine is more selective to α_2 -receptors (α_2 : α_1 specificity ratio is 200:1 for clonidine and 1600:1 for dexmedetomidine). Dexmedetomidine has a shorter half-life (2–3 h) than clonidine (12–24 h). It has sedative, analgesic, and sympatholytic effects that blunt many of the cardiovascular responses seen during the perioperative period. The sedative and analgesic effects are mediated by α_2 -adrenergic receptors in the brain (locus ceruleus) and spinal cord. When used intraoperatively, dexmedetomidine reduces intravenous and volatile anesthetic requirements; when used postoperatively, it reduces concurrent analgesic and sedative requirements. Dexmedetomidine is useful in sedating patients in preparation for awake fiberoptic intubation. It is also a useful agent for sedating patients postoperatively in postanesthesia and intensive care units, because it does so without significant ventilatory depression. Rapid administration may elevate blood pressure, but hypotension and bradycardia can occur during ongoing therapy. The recommended dosing of dexmedetomidine consists of a loading dose at 1 mcg/kg over 10 min followed by an infusion at 0.2–0.7 mcg/kg/hr.

Although these agents are adrenergic agonists, they are also considered to be sympatholytic because **5** sympathetic outflow is reduced. Long-term use of these agents, particularly clonidine and dexmedetomidine, leads to supersensitization and up-regulation of receptors; with abrupt discontinuation of either drug, an acute withdrawal syndrome manifested by a hypertensive crisis can occur. Because of the increased affinity of dexmedetomidine for the α_2 -receptor, compared with that of clonidine, this syndrome may manifest after only 48 hr of dexmedetomidine use when the drug is discontinued.

Dosing & Packaging

Clonidine is available as an oral, transdermal, or parenteral preparation. Dexmedetomidine is available as an injectable solution (100 mcg/mL), which

should be diluted to 5–10 mcg/mL for bolus administration and titrated to effect.

EPINEPHRINE

Clinical Considerations

Epinephrine is an endogenous catecholamine synthesized in the adrenal medulla. Direct stimulation of β_1 -receptors of the myocardium by epinephrine raises blood pressure, cardiac output, and myocardial oxygen demand by increasing contractility and heart rate (increased rate of spontaneous phase IV depolarization). α_1 -stimulation decreases splanchnic and renal blood flow but increases coronary perfusion pressure by increasing aortic diastolic pressure. Systolic blood pressure rises, although β_2 -mediated vasodilation in skeletal muscle may lower diastolic pressure. β_2 -stimulation also relaxes bronchial smooth muscle.

Administration of epinephrine is the principal pharmacological treatment for anaphylaxis and can be used to treat ventricular fibrillation. Complications include cerebral hemorrhage, coronary ischemia, and ventricular dysrhythmias. Volatile anesthetics, particularly halothane, potentiate the dysrhythmic effects of epinephrine.

Dosing & Packaging

In emergency situations (eg, cardiac arrest and shock), epinephrine is administered as an intravenous bolus of 0.05–1 mg, depending on the severity of cardiovascular compromise. In major anaphylactic reactions, epinephrine should be used at a dose of 100–500 mcg (repeated, if necessary) followed by infusion. To improve myocardial contractility or heart rate, a continuous infusion is prepared (1 mg in 250 mL [4 mcg/mL]) and run at a rate of 2–20 mcg/min. Epinephrine is also used to reduce bleeding from the operative sites. Some local anesthetic solutions containing epinephrine at a concentration of 1:200,000 (5 mcg/mL) or 1:400,000 (2.5 mcg/mL) are characterized by less systemic absorption and a longer duration of action. Epinephrine is available in vials at a concentration of 1:1000 (1 mg/mL) and prefilled syringes at a concentration of 1:10,000 (0.1 mg/mL [100 mcg/mL]). A 1:100,000 (10 mcg/mL) concentration is available for pediatric use.

EPHEDRINE

Clinical Considerations

The cardiovascular effects of ephedrine, a noncatecholamine sympathomimetic, are similar to those of epinephrine: increase in blood pressure, heart rate, contractility, and cardiac output. Likewise, ephedrine is also a bronchodilator. There are important differences, however: ephedrine has a longer duration of action, is much less potent, has indirect and direct actions, and stimulates the central nervous system (it raises minimum alveolar concentration). The indirect agonist properties of ephedrine may be due to peripheral postsynaptic norepinephrine release, or by inhibition of norepinephrine reuptake.

6 Ephedrine is commonly used as a vasopressor during anesthesia. As such, its administration should be viewed as a temporizing measure while the cause of hypotension is determined and remedied. Unlike direct-acting α_1 -agonists, ephedrine is believed not to decrease uterine blood flow, and thus was regarded as the preferred vasopressor for most obstetric uses. Recently, however, phenylephrine has been argued to be a better vasopressor in obstetric patients undergoing neuroaxial anesthesia due its faster onset, shorter duration of action, and better titratability and maintenance of fetal pH. Ephedrine has also been reported to possess antiemetic properties, particularly in association with hypotension following spinal anesthesia. Clonidine premedication augments the effects of ephedrine.

Dosing & Packaging

In adults, ephedrine is administered as a bolus of 2.5–10 mg; in children, it is given as a bolus of 0.1 mg/kg. Subsequent doses are increased to offset the development of tachyphylaxis, which is probably due to depletion of norepinephrine stores. Ephedrine is available in 1-mL ampules containing 25 or 50 mg of the agent.

NOREPINEPHRINE

Clinical Considerations

Direct α_1 -stimulation with little β_2 -activity induces intense vasoconstriction of arterial and venous vessels. Increased myocardial contractility from

β_1 -effects, along with peripheral vasoconstriction, contributes to a rise in arterial blood pressure. Both systolic and diastolic pressures usually rise, but increased afterload and reflex bradycardia prevent any elevation in cardiac output. Decreased renal and splanchnic blood flow and increased myocardial oxygen requirements limit the outcome benefits of norepinephrine in the management of refractory shock. Norepinephrine has been used with an α -blocker (eg, phentolamine) in an attempt to take advantage of its β -activity without the profound vasoconstriction caused by its α -stimulation. Extravasation of norepinephrine at the site of intravenous administration can cause tissue necrosis.

Dosing & Packaging

Norepinephrine is administered as a bolus (0.1 mcg/kg) or usually as a continuous infusion due to its short half-life at a rate of 2–20 mcg/min. Ampules contain 4 mg of norepinephrine in 4 mL of solution.

DOPAMINE

Clinical Considerations

The clinical effects of DA, an endogenous nonselective direct and indirect adrenergic and dopaminergic agonist, vary markedly with the dose. At low doses (0.5–3 mcg/kg/min), DA primarily activates dopaminergic receptors (specifically, DA_1 receptors); stimulation of these receptors vasodilates the renal vasculature and promotes diuresis and natriuresis. Although this action increases renal blood flow, use of this “renal dose” does not impart any beneficial effect on renal function. When used in moderate doses (3–10 mcg/kg/min), β_1 -stimulation increases myocardial contractility, heart rate, systolic blood pressure, and cardiac output. Myocardial oxygen demand typically increases more than supply. The α_1 -effects become prominent at higher doses (10–20 mcg/kg/min), causing an increase in peripheral vascular resistance and a fall in renal blood flow. The indirect effects of DA are due to release of norepinephrine from presynaptic sympathetic nerve ganglion.

DA is commonly used in the treatment of shock to improve cardiac output, support blood pressure, and maintain renal function. It is often used in combination with a vasodilator (eg, nitroglycerin

or nitroprusside), which reduces afterload and further improves cardiac output. The chronotropic and proarrhythmic effects of DA limit its usefulness in some patients.

Dosing & Packaging

DA is administered as a continuous infusion at a rate of 1–20 mcg/kg/min. It is most commonly supplied in 5–10 mL vials containing 200 or 400 mg of DA.

ISOPROTERENOL

Isoproterenol is of interest because it is a pure β_1 -agonist. β_1 -Effects increase heart rate, contractility, and cardiac output. Systolic blood pressure may increase or remain unchanged, but β_2 -stimulation decreases peripheral vascular resistance and diastolic blood pressure. Myocardial oxygen demand increases while oxygen supply falls, making isoproterenol or any pure β -agonist a poor inotropic choice in most situations.

DOBUTAMINE

Clinical Considerations

Dobutamine is a racemic mixture of two isomers with affinity for both β_1 and β_2 receptors, with relatively higher selectivity for β_1 receptors. Its primary cardiovascular effect is a rise in cardiac output as a result of increased myocardial contractility. A decline in peripheral vascular resistance caused by β_2 -activation usually prevents much of a rise in arterial blood pressure. Left ventricular filling pressure decreases, whereas coronary blood flow increases.

8 Favorable effects on myocardial oxygen balance are believed to make dobutamine a choice for patients with the combination of congestive heart failure and coronary artery disease, particularly if peripheral vascular resistance is elevated. However, because it has been shown to increase myocardial oxygen consumption, such as during stress testing (rationale for its use in perfusion imaging), some concern remains regarding its use in patients with myocardial ischemia. Moreover, dobutamine should not be routinely used without specific indications to facilitate separation from cardiopulmonary bypass.

Dosing & Packaging

Dobutamine is administered as an infusion at a rate of 2–20 mcg/kg/min. It is supplied in 20-mL vials containing 250 mg.

DOPEXAMINE

Clinical Considerations

Dopexamine, a structural analogue of DA, has potential advantages over DA because it has less β_1 -adrenergic (arrhythmogenic) and α -adrenergic effects. Because of the decreased β -adrenergic effects and its specific effect on renal perfusion, it may have advantages over dobutamine. The drug has been clinically available in many countries since 1990, but has not gained widespread acceptance in practice.

Dosing & Packaging

Dopexamine infusion should be started at a rate of 0.5 mcg/kg/min, increasing to 1 mcg/kg/min at intervals of 10–15 min to a maximum infusion rate of 6 mcg/kg/min.

FENOLDOPAM

Clinical Considerations

Fenoldopam is a selective D_1 -receptor agonist that has many of the benefits of DA but with little or no α - or β -adrenoceptor or D_2 -receptor agonist activity. Fenoldopam has been shown to exert hypotensive effects characterized by a decrease in peripheral vascular resistance, along with an increase in renal blood flow, diuresis, and natriuresis. It is indicated for patients undergoing cardiac surgery and aortic aneurysm repair with potential risk of perioperative renal impairment. Fenoldopam exerts an antihypertensive effect, but helps to maintain renal blood flow. It is also indicated for patients who have severe hypertension, particularly those with renal impairment. Along with its recommended use in hypertensive emergencies, fenoldopam is also indicated in the prevention of contrast media-induced nephropathy. Fenoldopam has a fairly rapid onset of action and is easily titratable because of its short elimination half-life. The ability of fenoldopam to “protect” the kidney perioperatively remains the subject of ongoing studies.

Dosing & Packaging

Fenoldopam is supplied in 1-, 2-, and 5-mL ampules, 10 mg/mL. It is started as a continuous infusion of 0.1 mcg/kg/min, increased by increments of 0.1 mcg/kg/min at 15- to 20-min intervals until target blood pressure is achieved. Lower doses have been associated with less reflex tachycardia.

Adrenergic Antagonists

Adrenergic antagonists bind but do not activate adrenoceptors. They act by preventing adrenergic agonist activity. Like the agonists, the antagonists differ in their spectrum of receptor interaction.

α -BLOCKERS—PHENTOLAMINE

Clinical Considerations

Phentolamine produces a competitive (reversible) blockade of both α_1 - and α_2 -receptors. α_1 -Antagonism and direct smooth muscle relaxation are responsible for peripheral vasodilation and a decline in arterial blood pressure. The drop in blood pressure provokes reflex tachycardia. This tachycardia is augmented by antagonism of presynaptic α_2 -receptors in the heart because α_2 -blockade promotes norepinephrine release by eliminating negative feedback. These cardiovascular effects are usually apparent within 2 min and last up to 15 min. As with all of the adrenergic antagonists, the extent of the response to receptor blockade depends on the degree of existing sympathetic tone. Reflex tachycardia and postural hypotension limit the usefulness of phentolamine to the treatment of hypertension caused by excessive α -stimulation (eg, pheochromocytoma, clonidine withdrawal). Prazosin and phenoxybenzamine are examples of other alpha antagonists.

Dosing & Packaging

Phentolamine is administered intravenously as intermittent boluses (1–5 mg in adults) or as a continuous infusion. To prevent tissue necrosis following extravasation of intravenous fluids containing an α -agonist (eg, norepinephrine), 5–10 mg of phentolamine in 10 mL of normal saline can be locally

infiltrated. Phentolamine is packaged as a lyophilized powder (5 mg).

MIXED ANTAGONISTS—LABETALOL

Clinical Considerations

Labetalol blocks α_1 -, β_1 -, and β_2 -receptors. The ratio of α -blockade to β -blockade has been estimated to be approximately 1:7 following intravenous administration. This mixed blockade reduces peripheral vascular resistance and arterial blood pressure. Heart rate and cardiac output are usually slightly depressed or unchanged. Thus, labetalol lowers blood pressure without reflex tachycardia because of its combination of α - and β -effects, which is beneficial to patients with coronary artery disease. Peak effect usually occurs within 5 min after an intravenous dose. Left ventricular failure, paradoxical hypertension, and bronchospasm have been reported.

Dosing & Packaging

The initial recommended dose of labetalol is 2.5–10 mg administered intravenously over 2 min. Twice this amount may be given at 10-min intervals until the desired blood pressure response is obtained. Labetalol can also be administered as a slow continuous infusion at a rate of 0.5–2 mg/min. However, due to its long elimination half-life (>5 h), prolonged infusions are not recommended.

β -BLOCKERS

β -Receptor blockers have variable degrees of selectivity for the β_1 -receptors. Those that are more β_1 selective have less influence on bronchopulmonary and vascular β_2 -receptors (Table 14–3). Theoretically, a selective β_1 -blocker would have less of an inhibitory effect on β_2 -receptors and, therefore, might be preferred in patients with chronic obstructive lung disease or peripheral vascular disease. Patients with peripheral vascular disease could potentially have a decrease in blood flow if β_2 -receptors, which dilate the arterioles, are blocked. β -Receptor blocking agents also reduce intraocular pressure in patients with glaucoma.

TABLE 14-3 Pharmacology of β -blockers.¹

	Selectivity for β_1 -Receptors	ISA	α -Blockade	Hepatic Metabolism	$t_{1/2}$
Atenolol	+	0	0	0	6–7
Esmolol	+	0	0	0	~¼
Labetalol		0	+	+	4
Metoprolol	+	0	0	+	3–4
Propranolol		0	0	+	4–6

¹ISA, intrinsic sympathomimetic activity; +, mild effect; 0, no effect.

β -Blockers are also classified by the amount of intrinsic sympathomimetic activity (ISA) they have. Many of the β -blockers have some agonist activity; although they would not produce effects similar to full agonists (such as epinephrine), β -blockers with ISA may not be as beneficial as β -blockers without ISA in treating patients with cardiovascular disease.

β -Blockers can be further classified as those that are eliminated by hepatic metabolism (such as metoprolol), those that are excreted by the kidneys unchanged (such as atenolol), or those that are hydrolyzed in the blood (such as esmolol).

ESMOLOL

Clinical Considerations

10 Esmolol is an ultrashort-acting selective β_1 -antagonist that reduces heart rate and, to a lesser extent, blood pressure. It has been successfully used to prevent tachycardia and hypertension in response to perioperative stimuli, such as intubation, surgical stimulation, and emergence. For example, esmolol (0.5–1 mg/kg) attenuates the rise in blood pressure and heart rate that usually accompanies electroconvulsive therapy, without significantly affecting seizure duration. Esmolol is as effective as propranolol in controlling the ventricular rate of patients with atrial fibrillation or flutter. Although esmolol is considered to be cardioselective, at higher doses it inhibits β_2 -receptors in bronchial and vascular smooth muscle.

The short duration of action of esmolol is due to rapid redistribution (distribution half-life is 2 min) and hydrolysis by red blood cell esterase

(elimination half-life is 9 min). Side effects can be reversed within minutes by discontinuing its infusion. As with all β_1 -antagonists, esmolol should be avoided in patients with sinus bradycardia, heart block greater than first degree, cardiogenic shock, or overt heart failure.

Dosing & Packaging

Esmolol is administered as a bolus (0.2–0.5 mg/kg) for short-term therapy, such as attenuating the cardiovascular response to laryngoscopy and intubation. Long-term treatment is typically initiated with a loading dose of 0.5 mg/kg administered over 1 min, followed by a continuous infusion of 50 mcg/kg/min to maintain therapeutic effect. If this fails to produce a sufficient response within 5 min, the loading dose may be repeated and the infusion increased by increments of 50 mcg/kg/min every 5 min to a maximum of 200 mcg/kg/min.

Esmolol is supplied as multidose vials for bolus administration containing 10 mL of drug (10 mg/mL). Ampules for continuous infusion (2.5 g in 10 mL) are also available but must be diluted prior to administration to a concentration of 10 mg/mL.

METOPROLOL

Clinical Considerations

Metoprolol is a selective β_1 -antagonist with no intrinsic sympathomimetic activity. It is available for both oral and intravenous use. It can be administered intravenously in 2–5 mg increments every 2 to 5 min, titrated to blood pressure and heart rate.

PROPRANOLOL

Clinical Considerations

Propranolol nonselectively blocks β_1 - and β_2 -receptors. Arterial blood pressure is lowered by several mechanisms, including decreased myocardial contractility, lowered heart rate, and diminished renin release. Cardiac output and myocardial oxygen demand are reduced. Propranolol is particularly useful during myocardial ischemia related to increased blood pressure and heart rate. Impedance of ventricular ejection is beneficial in patients with obstructive cardiomyopathy and aortic aneurysm. Propranolol slows atrioventricular conduction and stabilizes myocardial membranes, although the latter effect may not be significant at clinical doses. Propranolol is particularly effective in slowing the ventricular response to supraventricular tachycardia, and it occasionally controls recurrent ventricular tachycardia or fibrillation caused by myocardial ischemia. Propranolol blocks the β -adrenergic effects of thyrotoxicosis and pheochromocytoma.

Side effects of propranolol include bronchospasm (β_2 -antagonism), congestive heart failure, bradycardia, and atrioventricular heart block (β_1 -antagonism). Propranolol may worsen the myocardial depression of volatile anesthetics (eg, halothane) or unmask the negative inotropic characteristics of indirect cardiac stimulants (eg, isoflurane). Concomitant administration of propranolol and verapamil (a calcium channel blocker) can synergistically depress heart rate, contractility, and atrioventricular node conduction.

Propranolol is extensively protein bound and is cleared by hepatic metabolism. Its elimination half-life of 100 min is quite long compared with that of esmolol.

Dosing & Packaging

Individual dosage requirements of propranolol depend on baseline sympathetic tone. Generally, propranolol is titrated to the desired effect, beginning with 0.5 mg and progressing by 0.5-mg increments every 3–5 min. Total doses rarely exceed 0.15 mg/kg. Propranolol is supplied in 1-mL ampules containing 1 mg.

NEBIVOLOL

Clinical Considerations

Nebivolol is a newer generation β -blocker with high affinity for β_1 -receptors. The drug is unique in its ability to cause direct vasodilation via its stimulatory effect on endothelial nitric oxide synthase. It is presently available only in oral formulation; the recommended dose is 5–40 mg daily.

CARVEDILOL

Carvedilol is a mixed β - and α -blocker used in the management of chronic heart failure secondary to cardiomyopathy, left ventricular dysfunction following acute myocardial infarction, and hypertension. Carvedilol dosage is individualized and gradually increased up to 25 mg twice daily, as required and tolerated.

PERIOPERATIVE β -BLOCKER THERAPY

Management of β -blockers perioperatively is a key anesthesia performance indicator and is closely monitored by various “quality management” agencies. Although studies regarding the perioperative administration of β -blockers have yielded conflicting results as to benefit, maintenance of β -blockers in patients already being treated with them is essential, unless contraindicated by other clinical concerns.

β -Blocker therapy in the perioperative period has the potential to reduce the perioperative cardiovascular complications (myocardial ischemia, stroke, cardiac failure) due to counteraction of catecholamine-induced tachycardia and hypertension. However, these beneficial effects have not been widely demonstrated in recent clinical trials. Perioperative β -blocker therapy was associated with a reduced risk of in-hospital death in a small group of high-risk patients (ie, those with a Revised Cardiac Score Index of 3 or higher), but showed no improvement or even an increase in stroke and overall mortality in low-risk patients undergoing noncardiac surgery.

Current American Heart Association/American College of Cardiology guidelines recommend continuation of β -blocker therapy during the

perioperative period in patients who are receiving β -blockers for the treatment of angina, symptomatic arrhythmia, heart failure, and hypertension. In addition, β -blocker therapy should be initiated in patients undergoing vascular surgery who are at high risk of cardiac events because of findings of myocardial ischemia during perioperative testing. The guidelines also note that β -blockers titrated to heart rate and blood pressure are “reasonable” in patients undergoing vascular surgery who have more than one cardiac risk factor. Additionally, the guidelines suggest that perioperative β -blockers are likewise “reasonable” in patients undergoing intermediate-risk procedures who have more than one cardiac disease risk factor. The routine administration of high-dose β -blockers in the absence of dose titration may be harmful in patients not currently taking β -blockers who are undergoing noncardiac surgery.

11 Discontinuation of β -blocker therapy for 24–48 hr may trigger a withdrawal syndrome characterized by hypertension (rebound hypertension), tachycardia, and angina pectoris. This effect seems to be caused by an increase in the number of β -adrenergic receptors (up-regulation).

CASE DISCUSSION

Pheochromocytoma

A 45-year-old man with a history of paroxysmal attacks of headache, hypertension, sweating, and palpitations is scheduled for resection of an abdominal pheochromocytoma.

What is a pheochromocytoma?

A pheochromocytoma is a vascular tumor of chromaffin tissue (most commonly the adrenal medulla) that produces and secretes norepinephrine and epinephrine. The diagnosis and management of pheochromocytoma are based on the effects of abnormally high circulating levels of these endogenous adrenergic agonists.

How is the diagnosis of pheochromocytoma made in the laboratory?

Urinary excretion of vanillylmandelic acid (an end product of catecholamine metabolism), norepinephrine, and epinephrine is often markedly

increased. Elevated levels of urinary catecholamines and metanephrines (Figure 14–3) provide a highly accurate diagnosis. Fractionated plasma-free metanephrine levels may be superior to urinary studies in making the diagnosis. The location of the tumor can be determined by magnetic resonance imaging or computed tomographic scan with or without contrast.

What pathophysiology is associated with chronic elevations of norepinephrine and epinephrine?

α_1 -Stimulation increases peripheral vascular resistance and arterial blood pressure. Hypertension can lead to intravascular volume depletion (increasing hematocrit), renal failure, and cerebral hemorrhage. Elevated peripheral vascular resistance also increases myocardial work, which predisposes patients to myocardial ischemia, ventricular hypertrophy, and congestive heart failure. Prolonged exposure to epinephrine and norepinephrine may lead to a catecholamine-induced cardiomyopathy. Hyperglycemia results from decreased insulin secretion in the face of increased glycogenolysis and gluconeogenesis. β_1 -Stimulation increases automaticity and ventricular ectopy.

Which adrenergic antagonists might be helpful in controlling the effects of norepinephrine and epinephrine hypersecretion?

Phenoxybenzamine, an α_1 -antagonist, effectively reverses the vasoconstriction, resulting in a drop in arterial blood pressure and an increase in intravascular volume (hematocrit drops). Glucose intolerance is often corrected. Phenoxybenzamine can be administered orally and is longer acting than phentolamine, another α_1 -antagonist. For these reasons, phenoxybenzamine is often administered preoperatively to control symptoms.

Intravenous phentolamine is often used intraoperatively to control hypertensive episodes. Compared with some other hypotensive agents, however, phentolamine has a slow onset and long duration of action; furthermore, tachyphylaxis often develops.

β_1 -Blockade with an agent such as labetalol is recommended for patients with tachycardia or ventricular arrhythmias.

Why should α_1 -receptors be blocked with phenoxybenzamine before administration of a β -antagonist?

If β -receptors are blocked first, norepinephrine and epinephrine will produce unopposed α -stimulation. β_2 -Mediated vasodilation will not be able to offset α_1 -vasoconstriction, and peripheral vascular resistance would increase. This may explain the paradoxical hypertension that has been reported in a few patients with pheochromocytoma treated only with labetalol. Finally, the myocardium might not be able to handle its already elevated workload without the inotropic effects of β_1 -stimulation.

Which anesthetic agents should be specifically avoided?

Succinylcholine-induced fasciculations of the abdominal musculature will increase intraabdominal pressure, which theoretically might cause release of catecholamines from the tumor. Ketamine is a sympathomimetic and would exacerbate the effects of adrenergic agonists. Halothane sensitizes the myocardium to the arrhythmogenic effects of epinephrine. Vagolytic drugs (eg, anticholinergics and pancuronium) will worsen the imbalance of autonomic tone. Because histamine provokes catecholamine secretion by the tumor, drugs associated with histamine release (eg, atracurium) are best avoided. Vecuronium and rocuronium are probably the neuromuscular blocking agents of choice.

Would an epidural or spinal technique effectively block sympathetic hyperactivity?

A major regional block—such as an epidural or spinal anesthetic—could block sensory (afferent) nerves and sympathetic (efferent) discharge in

the area of the surgical field. The catecholamines released from a pheochromocytoma during surgical manipulation would still be able to bind and activate adrenergic receptors throughout the body, however.

GUIDELINES

Hypotensive Agents

KEY CONCEPTS

- 1 Clinical trials have shown that inhaled nitric oxide is a selective pulmonary vasodilator that is beneficial in the treatment of reversible pulmonary hypertension. By improving perfusion only in ventilated areas of the lung, inhaled nitric oxide may improve oxygenation in patients with acute respiratory distress syndrome or during one-lung ventilation.
- 2 Acute cyanide toxicity is characterized by metabolic acidosis, cardiac arrhythmias, and increased venous oxygen content (as a result of the inability to utilize oxygen). Another early sign of cyanide toxicity is the acute resistance to the hypotensive effects of increasing doses of sodium nitroprusside (tachyphylaxis).
- 3 By dilating pulmonary vessels, sodium nitroprusside may prevent the normal vasoconstrictive response of the pulmonary vasculature to hypoxia (hypoxic pulmonary vasoconstriction).
- 4 Preload reduction makes nitroglycerin an excellent drug for the relief of cardiogenic pulmonary edema.
- 5 Hydralazine relaxes arteriolar smooth muscle, causing dilatation of precapillary resistance vessels via increased cyclic guanosine 3',5'-monophosphate.
- 6 The body reacts to a hydralazine-induced fall in blood pressure by increasing heart rate, myocardial contractility, and cardiac output. These compensatory responses can be detrimental to patients with coronary artery disease and are minimized by the concurrent administration of a β -adrenergic antagonist.
- 7 Fenoldopam mesylate (infusion rates studied in clinical trials range from 0.01–1.6 mcg/kg/min) reduces systolic and diastolic blood pressure in patients with malignant hypertension to an extent comparable to nitroprusside.
- 8 Dihydropyridine calcium channel blockers preferentially dilate arterial vessels, often preserving or increasing cardiac output.

A multitude of drugs are capable of lowering blood pressure, including volatile anesthetics, sympathetic antagonists and agonists, calcium channel blockers, β -blockers, and angiotensin-converting enzyme inhibitors. This chapter examines agents that may be useful to the anesthesiologist for intraoperative control of arterial blood pressure.

Patients with an increasing “vascular age” routinely present for anesthesia and surgery. As patients chronologically age, so too does their vasculature. When a pulse wave is generated by ventricular contraction, it is propagated through the arterial system. At branch points of the aorta, the wave is reflected back toward the heart. In patients

of young vascular age, the reflected wave tends to augment diastole, improving diastolic pressure. In patients with “older” vasculature, the wave arrives sooner, being conducted back by the noncompliant vasculature during late systole, which causes an increase in cardiac workload and a decrease in diastolic pressure (Figure 15–1). Thus, older patients

develop increased systolic pressure and decreased diastolic pressure.

Widened pulse pressures (the difference between systolic and diastolic pressures) have been associated with both increased incidence of postoperative renal dysfunction and increased risk of cerebral events in patients undergoing coronary bypass

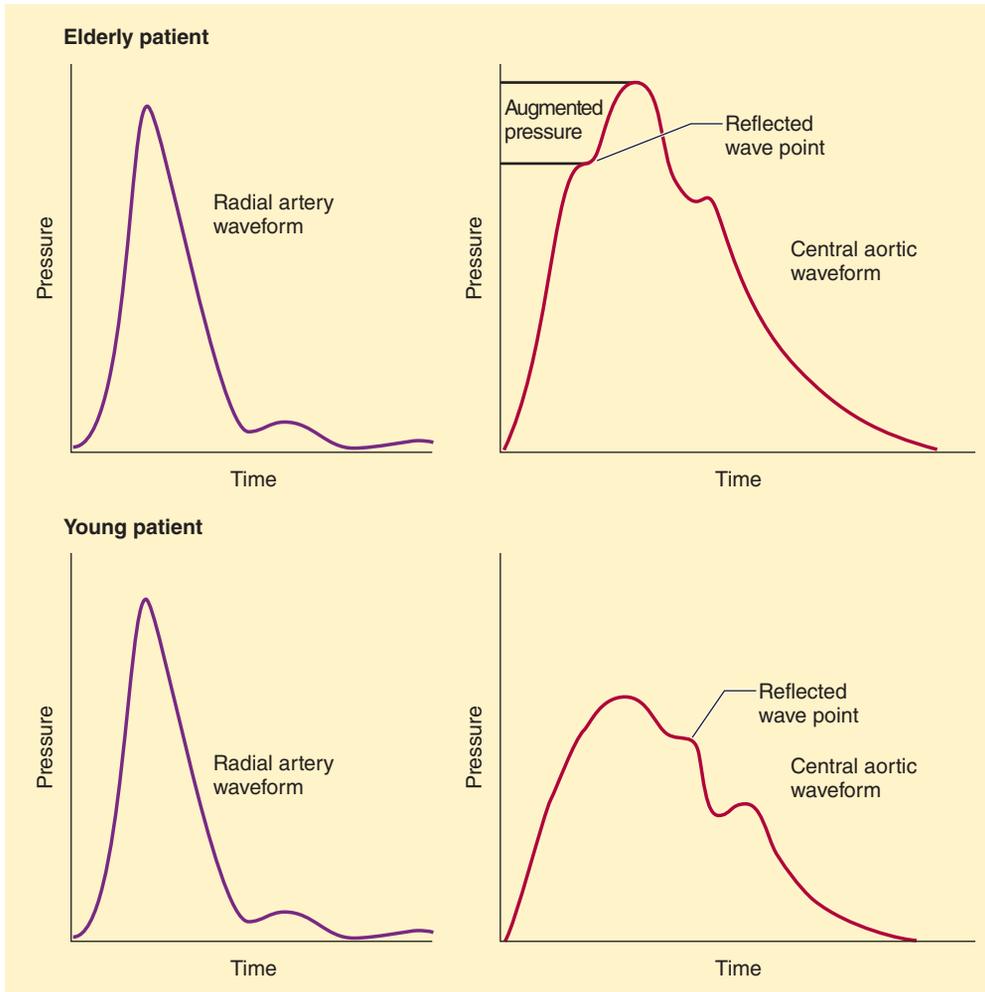

FIGURE 15–1 Illustration of the influence of increased vascular stiffness on peripheral (radial) and central (aortic) pressures. Note the similarity of peripheral radial pressures in individuals with normal (lower left panel) and increased (upper left panel) vascular stiffness. In young individuals with normal vascular stiffness, central aortic pressures are lower than radial pressures (lower panels). In contrast, in

older individuals with increased vascular stiffness, central aortic pressures are increased and can approach or equal peripheral pressures as a result of wave reflection and central wave augmentation during systole (top panels). (Reproduced, with permission, from Barodka V, Joshi B, Berkowitz D, Hogue CW Jr, Nyhan D: Implications of vascular aging. *Anesth Analg* 2011;112:1048.)

surgery. Consequently, control of blood pressure is essential to mitigate postoperative morbidity, especially as patients of advanced vascular age present for surgery.

β -Blocker therapy should be maintained perioperatively in patients who are being treated with β -blockers as a part of their routine medical regimen. Furthermore, according to the American College of Cardiology, β -blockers are also of potential benefit to patients with more than one cardiac risk factor, especially those who are undergoing vascular surgery. However, the routine administration of high-dose β -blocker therapy may, in the absence of dose titration, be harmful in patients not taking β -blockers. The American College of Cardiology/American Heart Association guidelines for β -blocker use perioperatively should be closely followed. Adherence to such guidelines is used by third parties as a “quality” performance indicator for anesthesia delivery. Thus, anesthesia providers should periodically review recommendations regarding β -blocker therapy, as guidelines evolve as new evidence becomes available and older evidence is refuted. β -Blockers (esmolol, metoprolol, and others) were previously discussed for the treatment of transient perioperative hypertension and are routinely used by anesthesia providers. This chapter discusses antihypertensive agents other than β -blockers that are used perioperatively.

Along with increased vascular age, diastolic dysfunction is often underestimated in patients, as it can present in individuals with preserved systolic function. Acute diastolic heart failure can develop in the perioperative period secondary to hypertensive crisis. Diastolic dysfunction occurs due to the inability of the heart to relax effectively. Failure to actively sequester calcium ion into the sarcoplasmic reticulum (an energy-dependent process) impedes relaxation. Acute hypertension can produce diastolic dysfunction perioperatively, leading to elevated left ventricular end-diastolic pressures, myocardial ischemia, and pulmonary edema. Consequently, as increasing numbers of patients have diastolic dysfunction, tight control of blood pressure perioperatively is essential for safe anesthetic practice.

Blood pressure is essentially the product of cardiac output and systemic vascular resistance. Agents

that lower blood pressure either reduce the force of myocardial contraction and/or produce vasodilation of the arterial and venous capacitance vessels. Agents used to lower blood pressure include nitrovasodilators, calcium antagonists, dopamine agonists, anesthetic agents, and angiotensin-converting enzyme inhibitors. β -Blockers have been previously discussed.

Nitrovasodilators

SODIUM NITROPRUSSIDE

Mechanism of Action

Sodium nitroprusside and other nitrovasodilators relax both arteriolar and venous smooth muscle. Its primary mechanism of action is shared with other nitrates (eg, hydralazine and nitroglycerin). As these drugs are metabolized, they release **nitric oxide**, which activates guanylyl cyclase. This enzyme is responsible for the synthesis of cyclic guanosine 3',5'-monophosphate (cGMP), which controls the phosphorylation of several proteins, including some involved in the control of free intracellular calcium and smooth muscle contraction.

Nitric oxide, a naturally occurring potent vasodilator released by endothelial cells (endothelium-derived relaxing factor), plays an important role in regulating vascular tone throughout the body. Its ultrashort half-life (<5 s) provides sensitive endogenous control of regional blood flow.

1 Inhaled nitric oxide is a selective pulmonary vasodilator that is beneficial and routinely used in the treatment of reversible pulmonary hypertension.

Clinical Uses

Sodium nitroprusside is a potent and reliable antihypertensive. It is usually diluted to a concentration of 100 mcg/mL and administered as a continuous intravenous infusion (0.5–10 mcg/kg/min). Its extremely rapid onset of action (1–2 min) and fleeting duration of action allow precise titration of arterial blood pressure. A bolus of 1–2 mcg/kg minimizes blood pressure elevation during laryngoscopy but can cause transient hypotension in some patients. The

potency of this drug requires frequent blood pressure measurements—or, preferably, intraarterial monitoring—and the use of mechanical infusion pumps. Solutions of sodium nitroprusside must be protected from light because of photodegradation.

Metabolism

After parenteral injection, sodium nitroprusside enters red blood cells, where it receives an electron from the iron (Fe^{2+}) of oxyhemoglobin. This nonenzymatic electron transfer results in an unstable nitroprusside radical and methemoglobin (Hgb Fe^{3+}). The former moiety spontaneously decomposes into five cyanide ions and the active nitroso ($\text{N}=\text{O}$) group.

The cyanide ions can be involved in one of three possible reactions: binding to methemoglobin to form **cyanmethemoglobin**; undergoing a reaction in the liver and kidney catalyzed by the enzyme rhodanase (thiosulfate + cyanide \rightarrow thiocyanate); or binding to tissue cytochrome oxidase, which interferes with normal oxygen utilization (Figure 15–2).

2 The last of these reactions is responsible for the development of **acute cyanide toxicity**, characterized by metabolic acidosis, cardiac arrhythmias, and increased venous oxygen content (as a result of the inability to utilize oxygen). Another early sign of cyanide toxicity is the acute resistance to the hypotensive effects of increasing doses of sodium nitroprusside (tachyphylaxis). It should be noted that tachyphylaxis implies acute tolerance to the drug following multiple rapid injections, as opposed to tolerance, which is caused by more chronic exposure. Cyanide toxicity is more likely

if the cumulative dose of sodium nitroprusside is greater than 500 mcg/kg administered at an infusion rate faster than 2 mcg/kg/min. Patients with cyanide toxicity should be mechanically ventilated with 100% oxygen to maximize oxygen availability. The pharmacological treatment of cyanide toxicity depends on increasing the kinetics of the two reactions by administering sodium thiosulfate (150 mg/kg over 15 min) or 3% sodium nitrate (5 mg/kg over 5 min), which oxidizes hemoglobin to methemoglobin. Hydroxocobalamin combines with cyanide to form cyanocobalamin (vitamin B_{12}).

Thiocyanate is slowly cleared by the kidney. Accumulation of large amounts of thiocyanate (eg, in patients with renal failure) may result in a milder toxic reaction that includes thyroid dysfunction, muscle weakness, nausea, hypoxia, and an acute toxic psychosis. The risk of cyanide toxicity is not increased by renal failure, however. Methemoglobinemia from excessive doses of sodium nitroprusside or sodium nitrate can be treated with methylene blue (1–2 mg/kg of a 1% solution over 5 min), which reduces methemoglobin to hemoglobin.

Effects on Organ Systems

The combined dilation of venous and arteriolar vascular beds by sodium nitroprusside results in reductions of preload and afterload. Arterial blood pressure falls due to the decrease in peripheral vascular resistance. Although cardiac output is usually unchanged in normal patients, the reduction in afterload may increase cardiac output in patients with congestive heart failure, mitral regurgitation, or aortic regurgitation. In opposition to any favorable changes in myocardial oxygen requirements are reflex-mediated responses to the fall in arterial blood pressure. These include tachycardia and increased myocardial contractility. In addition, dilation of coronary arterioles by sodium nitroprusside may result in an **intracoronary** steal of blood flow away from ischemic areas that are already maximally dilated.

Sodium nitroprusside dilates cerebral vessels and abolishes cerebral autoregulation. Cerebral blood flow is maintained or increases unless arterial blood pressure is markedly reduced. The resulting increase in cerebral blood volume tends to increase intracranial pressure, particularly in patients with

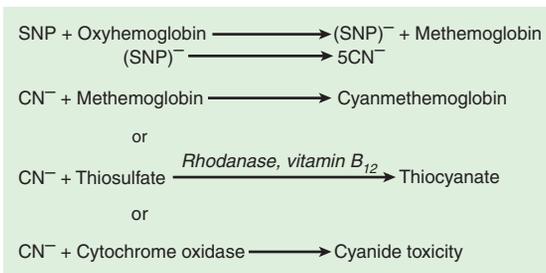

FIGURE 15–2 The metabolism of sodium nitroprusside.

reduced intracranial compliance (eg, brain tumors). This intracranial hypertension can be minimized by slow administration of sodium nitroprusside and institution of hypocapnia.

The pulmonary vasculature also dilates in response to sodium nitroprusside infusion. Reductions in pulmonary artery pressure may decrease the perfusion of some normally ventilated alveoli, increasing physiological dead space. By dilating pulmonary vessels, sodium nitroprusside may **3** prevent the normal vasoconstrictive response of the pulmonary vasculature to hypoxia (hypoxic pulmonary vasoconstriction). Both of these effects tend to mismatch pulmonary ventilation to perfusion and decrease arterial oxygenation.

In response to decreased arterial blood pressure, renin and catecholamines are released during administration of nitroprusside. Renal function is fairly well maintained during sodium nitroprusside infusion, despite moderate drops in arterial blood pressure and renal perfusion.

Sodium nitroprusside does not directly interact with neuromuscular blocking agents. Nonetheless, a decrease in muscle blood flow caused by arterial hypotension could indirectly delay the onset and prolong the duration of neuromuscular blockade.

NITROGLYCERIN

Mechanism of Action

Nitroglycerin relaxes vascular smooth muscle, with venous dilation predominating over arterial dilation. Its mechanism of action is presumably similar to that of sodium nitroprusside: metabolism to nitric oxide, which activates guanylyl cyclase, leading to increased cGMP, decreased intracellular calcium, and vascular smooth muscle relaxation.

Clinical Uses

Nitroglycerin relieves myocardial ischemia, hypertension, and ventricular failure. Like sodium nitroprusside, nitroglycerin is commonly diluted to a concentration of 100 mcg/mL and administered as a continuous intravenous infusion (0.5–10 mcg/kg/min). Glass containers and special intravenous tubing are recommended because of the adsorption of

nitroglycerin to polyvinylchloride. Nitroglycerin can also be administered by a sublingual (peak effect in 4 min) or transdermal (sustained release for 24 h) route. Some patients seem to require higher than expected doses of nitroglycerin to achieve a given drop in blood pressure, particularly after chronic administration (tolerance). Tolerance may be due to depletion of reactants necessary for nitric oxide formation, compensatory secretion of vasoconstrictive substances, or volume expansion. Dosing regimens that provide for intermittent periods of low or no drug exposure may minimize the development of tolerance.

Metabolism

Nitroglycerin undergoes rapid reductive hydrolysis in the liver and blood by glutathione-organic nitrate reductase. One metabolic product is nitrite, which can convert hemoglobin to methemoglobin. Significant methemoglobinemia is rare and can be treated with intravenous methylene blue (1–2 mg/kg over 5 min).

Nitroglycerin reduces myocardial oxygen demand and increases myocardial oxygen supply by several mechanisms:

- The pooling of blood in the large-capacitance vessels reduces venous return and preload. The accompanying decrease in ventricular end-diastolic pressure reduces myocardial oxygen demand and increases endocardial perfusion.
- Any afterload reduction from arteriolar dilation will decrease both end-systolic pressure and oxygen demand. Of course, a fall in diastolic pressure may lower coronary perfusion pressure and actually decrease myocardial oxygen supply.
- Nitroglycerin redistributes coronary blood flow to ischemic areas of the subendocardium.
- Coronary artery spasm may be relieved.

The beneficial effect of nitroglycerin in patients with coronary artery disease contrasts with the coronary steal phenomenon seen with sodium **4** nitroprusside. Preload reduction makes nitroglycerin an excellent drug for the relief of cardiogenic pulmonary edema. Heart rate is unchanged or minimally increased. Rebound hypertension is

less likely after discontinuation of nitroglycerin than following discontinuation of sodium nitroprusside. The prophylactic administration of low-dose nitroglycerin (0.5–2.0 mcg/kg/min) during anesthesia of patients at high risk for perioperative myocardial ischemia remains controversial.

The effects of nitroglycerin on cerebral blood flow and intracranial pressure are similar to those of sodium nitroprusside. Headache from dilation of cerebral vessels is a common side effect of nitroglycerin.

In addition to the dilating effects on the pulmonary vasculature (previously described for sodium nitroprusside), nitroglycerin relaxes bronchial smooth muscle.

Nitroglycerin (50–100 mcg boluses) has been demonstrated to be an effective (but transient) uterine relaxant that can be beneficial during certain obstetrical procedures if the placenta is still present in the uterus (eg, retained placenta, uterine inversion, uterine tetany, breech extraction, and external version of the second twin). Nitroglycerin therapy has been shown to diminish platelet aggregation, an effect enhanced by administration of *N*-acetylcysteine.

HYDRALAZINE

5 Hydralazine relaxes arteriolar smooth muscle, causing dilation of precapillary resistance vessels via increased cGMP.

Intraoperative hypertension is usually controlled with an intravenous dose of 5–20 mg of hydralazine. The onset of action is within 15 min, and the antihypertensive effect usually lasts 2–4 hr. Hydralazine can be used to control pregnancy-induced hypertension.

Hydralazine undergoes acetylation and hydroxylation in the liver.

Effects on Organ Systems

The lowering of peripheral vascular resistance causes

6 a drop in arterial blood pressure. The body reacts to a hydralazine-induced fall in blood pressure by increasing heart rate, myocardial contractility, and cardiac output. These compensatory responses can be detrimental to patients with coronary artery disease and are minimized by

the concurrent administration of a β -adrenergic antagonist. Conversely, the decline in afterload often proves beneficial to patients in congestive heart failure.

Hydralazine is a potent cerebral vasodilator and inhibitor of cerebral blood flow autoregulation. Unless blood pressure is markedly reduced, cerebral blood flow and intracranial pressure will rise.

Renal blood flow is usually maintained or increased by hydralazine.

Non-Nitrovasodilator Hypotensive Agents

FENOLDOPAM

Mechanism of Action

Fenoldopam mesylate causes rapid vasodilation by selectively activating D_1 -dopamine receptors. It has also demonstrated moderate affinity for α_2 -adrenoceptors. The R-isomer is responsible for the racemic mixture's biological activity due to its much greater receptor affinity, compared with the S-isomer.

Clinical Uses

7 Fenoldopam mesylate (infusion rates studied in clinical trials range from 0.01–1.6 mcg/kg/min) reduces systolic and diastolic blood pressure in patients with malignant hypertension to an extent comparable to nitroprusside. Side effects include headache, flushing, nausea, tachycardia, hypokalemia, and hypotension. The onset of the hypotensive effect occurs within 15 min, and discontinuation of an infusion quickly reverses this effect without rebound hypertension. Some degree of tolerance may develop 48 hr after the infusion. Studies are conflicted as to fenoldopam's ability to "protect" and "maintain" renal function in perioperative patients with hypertension at risk of perioperative kidney injury.

Metabolism

Fenoldopam undergoes conjugation without participation of the cytochrome P-450 enzymes, and its

metabolites are inactive. Clearance of fenoldopam remains unaltered despite the presence of renal or hepatic failure, and no dosage adjustments are necessary for these patients.

Effects on Organ Systems

Fenoldopam decreases systolic and diastolic blood pressure. Heart rate typically increases. Low initial doses (0.03–0.1 mcg/kg/min) titrated slowly have been associated with less reflex tachycardia than higher doses (>0.3 mcg/kg/min). Tachycardia decreases over time but remains substantial at higher doses.

Fenoldopam can lead to rises in intraocular pressure and should be administered with caution or avoided in patients with a history of glaucoma or intraocular hypertension.

As would be expected from a D_1 -dopamine receptor agonist, fenoldopam markedly increases renal blood flow. Despite a drop in arterial blood pressure, the glomerular filtration rate is well maintained. Fenoldopam increases urinary flow rate, urinary sodium extraction, and creatinine clearance compared with sodium nitroprusside.

CALCIUM ANTAGONISTS

8 Dihydropyridine calcium channel blockers (nicardipine, clevidipine) are arterial selective vasodilators routinely used for perioperative blood pressure control in patients undergoing cardiothoracic surgery. Clevidipine is a relatively new drug with a short half-life, which facilitates its rapid titration. Unlike verapamil and diltiazem, the dihydropyridine calcium channel blockers have minimal effects on cardiac conduction and ventricular contractility. Calcium channel blockers bind to L-type calcium channel and impair calcium entry into the vascular smooth muscle. These L-type receptors are more prevalent on arterial vessels than venous capacitance vessels. Consequently, cardiac filling and preload is less affected by these agents than nitrates, which might dilate both arterial and venous systems. With preload maintained, cardiac output often increases when vascular tone is reduced by use of dihydropyridine calcium

blockers. Nicardipine infusion is titrated to effect (5–15 mg/h).

Other intravenous agents that can produce hypotension perioperatively include the intravenous angiotensin-converting enzyme inhibitor enalaprilat (0.625–1.25 mg). The role of enalaprilat as a nondirect-acting agent in the acute treatment of a hypertensive crisis is limited.

CASE DISCUSSION

Controlled Hypotension

A 59-year-old man is scheduled for total hip arthroplasty under general anesthesia. The surgeon requests a controlled hypotensive technique.

What is controlled hypotension, and what are its advantages?

Controlled hypotension is the elective lowering of arterial blood pressure. The primary advantages of this technique are minimization of surgical blood loss and better surgical visualization.

How is controlled hypotension achieved?

The primary methods of electively lowering blood pressure are proper positioning, positive-pressure ventilation, and the administration of hypotensive drugs. Positioning involves elevation of the surgical site so that the blood pressure at the wound is selectively reduced. The increase in intrathoracic pressure that accompanies positive-pressure ventilation lowers venous return, cardiac output, and mean arterial pressure. Numerous pharmacological agents effectively lower blood pressure: volatile anesthetics, spinal and epidural anesthesia, sympathetic antagonists, calcium channel blockers, and the peripheral vasodilators discussed in this chapter.

What surgical procedures might benefit most from a controlled hypotensive technique?

Controlled hypotension has been successfully used during cerebral aneurysm repair, brain tumor resection, total hip arthroplasty, radical neck

dissection, radical cystectomy, and other operations associated with significant blood loss. Controlled hypotension may allow safer surgery of patients whose religious beliefs prohibit blood transfusions (eg, Jehovah's Witnesses). Decreasing extravasation of blood may improve the result of some plastic surgery procedures.

What are some relative contraindications to controlled hypotension?

Some patients have predisposing illnesses that decrease the margin of safety for adequate organ perfusion: severe anemia, hypovolemia, atherosclerotic cardiovascular disease, renal or hepatic insufficiency, cerebrovascular disease, or uncontrolled glaucoma.

What are the possible complications of controlled hypotension?

As the above list of contraindications suggests, the risks of low arterial blood pressure include cerebral thrombosis, hemiplegia (due to decreased spinal cord perfusion), acute tubular necrosis, massive hepatic necrosis, myocardial infarction, cardiac arrest, and blindness (from retinal artery thrombosis or ischemic optic neuropathy). These complications are more likely in patients with coexisting anemia. Consequently, the use of induced or controlled hypotension continues to decline.

What is a safe level of hypotension?

This depends on the patient. Healthy young individuals tolerate mean arterial pressures as low as 50–60 mm Hg without complications. On the other hand, chronically hypertensive patients have altered autoregulation of cerebral blood flow and may tolerate a mean arterial pressure of no more than 20% to 30% lower than baseline. Patients with a history of transient ischemic attacks may not tolerate any decline in cerebral perfusion.

What special monitoring is indicated during controlled hypotension?

Intraarterial blood pressure monitoring and electrocardiography with ST-segment analysis are strongly recommended. Central venous monitoring and measurement of urinary output by an indwelling catheter are indicated if extensive surgery is anticipated.

Local Anesthetics

KEY CONCEPTS

- 1 Sodium (Na) channels are membrane-bound proteins that are composed of one large α subunit, through which Na ions pass, and one or two smaller β subunits. Voltage-gated Na channels exist in (at least) three states—resting (nonconducting), open (conducting), and inactivated (nonconducting). Local anesthetics bind a specific region of the α subunit and inhibit voltage-gated Na channels, preventing channel activation and the Na influx associated with membrane depolarization.
- 2 Sensitivity of nerve fibers to inhibition by local anesthetics is determined by axonal diameter, myelination, and other anatomic and physiological factors.
- 3 Potency correlates with octanol solubility, which in turn reflects the ability of the local anesthetic molecule to permeate lipid membranes. Potency is increased by adding large alkyl groups to a parent molecule. There is no measurement of local anesthetic potency that is analogous to the minimum alveolar concentration of inhalation anesthetics.
- 4 Onset of action depends on many factors, including lipid solubility and the relative concentration of the nonionized lipid-soluble form (B) and the ionized water-soluble form (BH^+), expressed by the pK_a . The pK_a is the pH at which the fraction of ionized and nonionized drug is equal. Less potent, less lipid-soluble agents generally have a faster onset than more potent, more lipid-soluble agents.
- 5 Duration of action correlates with potency and lipid solubility. Highly lipid-soluble local anesthetics have a longer duration of action, presumably because they more slowly diffuse from a lipid-rich environment to the aqueous bloodstream.
- 6 In regional anesthesia local anesthetics are typically injected or applied very close to their intended site of action; thus their pharmacokinetic profiles are much more important determinants of elimination and toxicity than of their desired clinical effect.
- 7 The rate of systemic absorption is related to the vascularity of the site of injection: intravenous (or intraarterial) > tracheal > intercostal > paracervical > epidural > brachial plexus > sciatic > subcutaneous.
- 8 Ester local anesthetics are predominantly metabolized by pseudocholinesterase. Amide local anesthetics are metabolized (N-dealkylation and hydroxylation) by microsomal P-450 enzymes in the liver.
- 9 The central nervous system is vulnerable to local anesthetic toxicity and is the site of premonitory signs of rising blood concentrations in awake patients.

—Continued next page

Continued—

- 10 Major cardiovascular toxicity usually requires about three times the local anesthetic concentration in blood as that required to produce seizures.
- 11 Unintentional intravascular injection of bupivacaine during regional anesthesia may produce severe cardiovascular toxicity, including left ventricular depression, atrioventricular heart block, and life-threatening arrhythmias such as ventricular tachycardia and fibrillation.
- 12 True hypersensitivity reactions to local anesthetic agents—as distinct from systemic toxicity caused by excessive plasma concentration—are uncommon. Esters appear more likely to induce a true allergic reaction (due to IgG or IgE antibodies) especially if they are derivatives (eg, procaine or benzocaine) of *p*-aminobenzoic acid, a known allergen.

Local and regional anesthesia and analgesia techniques depend on a group of drugs—local anesthetics—that transiently inhibit sensory, motor, or autonomic nerve function, or a combination of these functions, when the drugs are injected or applied near neural tissue. This chapter presents the mechanism of action, structure–activity relationships, and clinical pharmacology of local anesthetic drugs. The more commonly used regional anesthetic techniques are presented in Section IV (see Chapters 45 and 46).

MECHANISMS OF LOCAL ANESTHETIC ACTION

Neurons (and all other living cells) maintain a resting membrane potential of -60 to -70 mV by active transport and passive diffusion of ions. The electrogenic, energy-consuming sodium–potassium pump ($\text{Na}^+\text{-K}^+\text{-ATPase}$) couples the transport of three sodium (Na) ions out of the cell for every two potassium (K) ions it moves into the cell. This creates an ionic disequilibrium (concentration gradient) that favors the movement of K ions from an intracellular to an extracellular location, and the movement of Na ions in the opposite direction. The cell membrane is normally much more “leaky” to K ions than to Na ions, so a relative excess of negatively charged ions (anions) accumulates intracellularly. This accounts

for the negative resting potential difference (-70 mV polarization).

Unlike most other types of tissue, excitable cells (eg, neurons or cardiac myocytes) have the capability of generating **action potentials**. Membrane-bound, voltage-gated Na channels in peripheral nerve axons can produce and transmit membrane depolarizations following chemical, mechanical, or electrical stimuli. When a stimulus is sufficient to depolarize a patch of membrane, the signal can be transmitted as a wave of depolarization along the nerve membrane (an impulse). Activation of voltage-gated Na channels causes a very brief (roughly 1 msec) change in the conformation of the channel, allowing an influx of Na ions and generating an action potential (**Figure 16–1**). The increase in Na permeability causes temporary depolarization of the membrane potential to $+35$ mV. The Na current is brief and is terminated by inactivation of voltage-gated Na channels, which do not conduct Na ions. Subsequently the membrane returns to its resting potential. Baseline concentration gradients are maintained by the sodium–potassium pump, and only a minuscule number of Na ions pass into the cell during an action potential.

1 Na channels are membrane-bound proteins that are composed of one large α subunit, through which Na ions pass, and one or two smaller β subunits. Voltage-gated Na channels exist in (at least) three states—resting (nonconducting), open

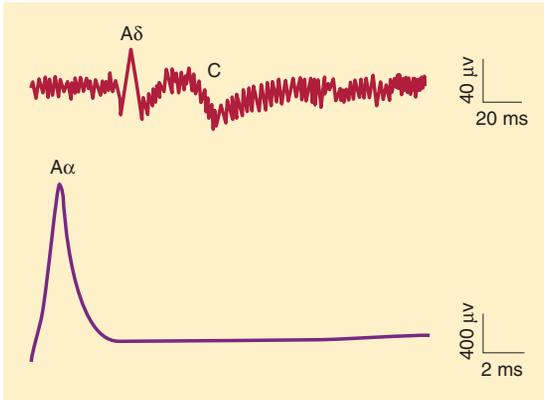

FIGURE 16-1 Compound $A\alpha$, $A\delta$, and C fiber action potentials recorded after supramaximal stimulation of a rat sciatic nerve. Note the differing time scale of the recordings. In peripheral nerves, $A\delta$ and C fibers have much slower conduction velocities, and their compound action potentials are longer and of less amplitude when compared with those from $A\alpha$ fibers. (Reproduced, with permission, from Butterworth JF 4th, Strichartz GR: The alpha 2-adrenergic agonists clonidine and guanfacine produce tonic and phasic block of conduction in rat sciatic nerve fibers. *Anesth Analg* 1993;76:295.)

(conducting), and inactivated (nonconducting) (Figure 16-2). Local anesthetics bind a specific region of the α subunit and inhibit voltage-gated Na channels, preventing channel activation and

inhibiting the Na influx associated with membrane depolarization. Local anesthetic binding to Na channels does not alter the resting membrane potential. With increasing local anesthetic concentrations, an increasing fraction of the Na channels in the membrane bind a local anesthetic molecule and cannot conduct Na ions. As a consequence, impulse conduction slows, the rate of rise and the magnitude of the action potential decrease, and the threshold for excitation and impulse conduction increases progressively. At high enough local anesthetic concentrations and with a sufficient fraction of local anesthetic-bound Na channels, an action potential can no longer be generated and impulse propagation is abolished. Local anesthetics have a greater affinity for the channel in the open or inactivated state than in the resting state. Local anesthetic binding to open or inactivated channels, or both, is facilitated by depolarization. The fraction of Na channels that have bound a local anesthetic increases with frequent depolarization (eg, during trains of impulses). This phenomenon is termed *use-dependent block*. Put another way, local anesthetic inhibition is both voltage and frequency dependent, and is greater when nerve fibers are firing rapidly than with infrequent depolarizations.

Local anesthetics may also bind and inhibit calcium (Ca), K, transient receptor potential

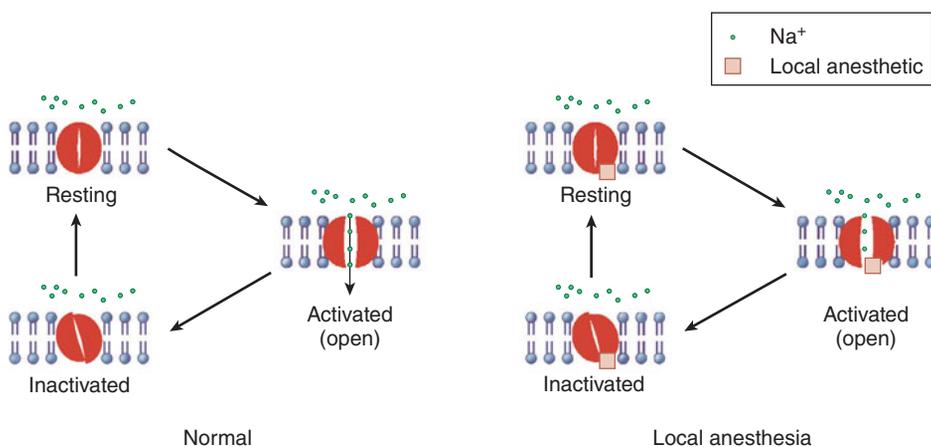

FIGURE 16-2 Voltage-gated sodium (Na) channels exist in (at least) three states—resting, activated (open), and inactivated. Note that local anesthetics bind and inhibit the voltage-gated Na channel from a site that is not

directly accessible from outside the cell, interfering with the large transient Na influx associated with membrane depolarization.

TABLE 16-1 Nerve fiber classification.¹

Fiber Type	Modality Served	Diameter (mm)	Conduction (m/s)	Myelinated?
A α	Motor efferent	12–20	70–120	Yes
A α	Proprioception	12–20	70–120	Yes
A β	Touch, pressure	5–12	30–70	Yes
A γ	Motor efferent (muscle spindle)	3–6	15–30	Yes
A δ	Pain Temperature Touch	2–5	12–30	Yes
B	Preganglionic autonomic fibers	<3	3–14	Some
C Dorsal root	Pain Temperature	0.4–1.2	0.5–2	No
C Sympathetic	Postganglionic sympathetic fibers	0.3–1.3	0.7–2.3	No

¹An alternative numerical system is sometimes used to classify sensory fibers.

vanilloid 1 (TRPV1), and many other channels and receptors. Conversely, other classes of drugs, most notably tricyclic antidepressants (amitriptyline), meperidine, volatile anesthetics, Ca channel blockers, and ketamine, also may inhibit Na channels. Tetrodotoxin is a poison that specifically binds Na channels but at a site on the exterior of the plasma membrane. Human studies are under way with similar toxins to determine whether they might provide effective, prolonged analgesia after local infiltration.

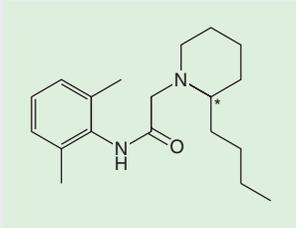

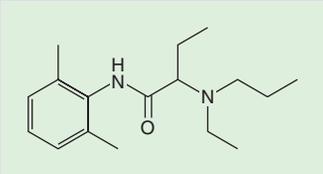

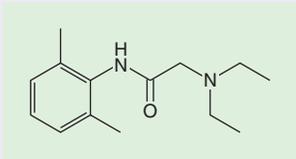

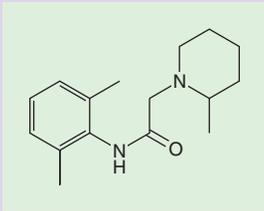

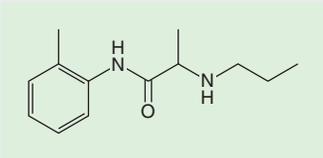

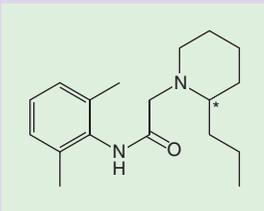

2 Sensitivity of nerve fibers to inhibition by local anesthetics is determined by axonal diameter, myelination, and other anatomic and physiological factors. **Table 16-1** lists the most commonly used classification for nerve fibers. In comparing nerve fibers of the same type, small diameter increases sensitivity to local anesthetics. Thus, larger, faster A α fibers are less sensitive to local anesthetics than smaller, slower-conducting A δ fibers, and larger unmyelinated fibers are less sensitive than smaller unmyelinated fibers. On the other hand, small unmyelinated C fibers are relatively resistant to inhibition by local anesthetics as compared with

larger myelinated fibers. In spinal nerves local anesthetic inhibition (and conduction failure) generally follows the sequence autonomic > sensory > motor, but at steady state if sensory anesthesia is present all fibers are inhibited.

STRUCTURE-ACTIVITY RELATIONSHIPS

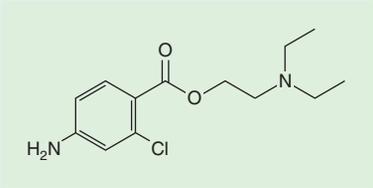

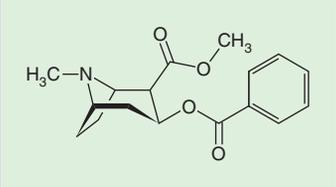

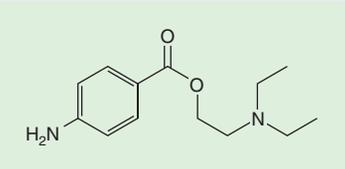

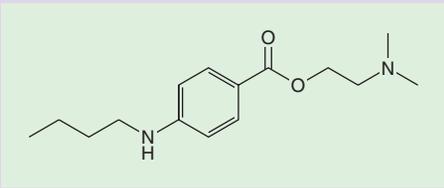

Local anesthetics consist of a lipophilic group (usually an aromatic benzene ring) separated from a hydrophilic group (usually a tertiary amine) by an intermediate chain that includes an ester or amide linkage. Articaine, the most popular local anesthetic for dentistry in several European countries, is an amide but it contains a thiophene ring rather than a benzene ring. Local anesthetics are weak bases that usually carry a positive charge at the tertiary amine group at physiological pH. The nature of the intermediate chain is the basis of the classification of local anesthetics as either esters or amides (**Table 16-2**). Physicochemical properties of local anesthetics depend on the substitutions in the aromatic ring, the type of linkage in the intermediate

TABLE 16-2 Physicochemical properties of local anesthetics.

Generic (Proprietary)	Structure	Relative Lipid Solubility of Unchanged Local Anesthetic	pK _a	Protein Binding (%)
Amides				
Bupivacaine (Marcaine, Sensorcaine)		8	8.2	96
Etidocaine (Duranest)		16	8.1	94
Lidocaine (Xylocaine)		1	8.2	64
Mepivacaine (Carbocaine)		0.3	7.9	78
Prilocaine (Citanest)		0.4	8.0	53
Ropivacaine (Naropin)		2.5	8.2	94

chain, and the alkyl groups attached to the amine nitrogen.

3 Potency correlates with octanol solubility, which in turn reflects the ability of the local anesthetic molecule to permeate lipid membranes. Potency is increased by adding large alkyl groups to a parent molecule (compare tetracaine to procaine or bupivacaine to mepivacaine). There is no measurement of local anesthetic potency that is analogous to the minimum alveolar concentration (MAC) of inhalation anesthetics. The minimum concentration of local anesthetic that will block nerve impulse

conduction is affected by several factors, including fiber size, type, and myelination; pH (acidic pH antagonizes block); frequency of nerve stimulation; and electrolyte concentrations (hypokalemia and hypercalcemia antagonize blockade).

4 Onset of local anesthetic action depends on many factors, including lipid solubility and the relative concentration of the nonionized lipid-soluble form (B) and the ionized water-soluble form (BH⁺), expressed by the pK_a. The pK_a is the pH at which the fraction of ionized and nonionized drug is equal. Less potent, less lipid-soluble agents generally

have a faster onset than more potent, more lipid-soluble agents.

Local anesthetics with a pK_a closest to physiological pH will have (at physiological pH) a greater fraction of nonionized base that more readily permeates the nerve cell membrane, generally facilitating a more rapid onset of action. It is the lipid-soluble form that more readily diffuses across the neural sheath (epineurium) and passes through the nerve membrane. Curiously, once the local anesthetic molecule gains access to the cytoplasmic side of the Na channel, it is the charged cation (rather than the nonionized base) that more avidly binds the Na channel. For instance, the pK_a of lidocaine exceeds physiological pH. Thus, at physiological pH (7.40) more than half the lidocaine will exist as the charged cation form (BH^+).

It is often stated that the onset of action of local anesthetics directly correlates with pK_a . This assertion is not supported by actual data; in fact, the agent of fastest onset (2-chloroprocaine) has the greatest pK_a of all clinically used agents. Other factors, such as ease of diffusion through connective tissue, can affect the onset of action in vivo. Moreover, not all local anesthetics exist in a charged form (eg, benzocaine).

The importance of the ionized and nonionized forms has many clinical implications, at least for those agents that exist in both forms. Local anesthetic solutions are prepared commercially as water-soluble hydrochloride salts (pH 6–7). Because epinephrine is unstable in alkaline environments, commercially formulated, epinephrine-containing, local anesthetic solutions are generally more acidic (pH 4–5) than the comparable “plain” solutions lacking epinephrine. As a direct consequence, these commercially formulated, epinephrine-containing preparations may have a lower concentration of free base and a slower onset than when the epinephrine is added by the clinician at the time of use. Similarly, the extracellular base-to-cation ratio is decreased and onset is delayed when local anesthetics are injected into acidic (eg, infected) tissues. Tachyphylaxis—the decreased efficacy of repeated doses—could be partly explained by the eventual consumption of the local extracellular buffering capacity by repeat injections

of the acidic local anesthetic solution, but data are lacking. Some researchers have found that alkalization of local anesthetic solutions (particularly commercially prepared, epinephrine-containing ones) by the addition of sodium bicarbonate (eg, 1 mL 8.4% sodium bicarbonate per 10 mL local anesthetic) speeds the onset and improves the quality of the block by increasing the amount of free base available. Interestingly, alkalization also decreases pain during subcutaneous infiltration.

5 Duration of action correlates with potency and lipid solubility. Highly lipid-soluble local anesthetics have a longer duration of action, presumably because they more slowly diffuse from a lipid-rich environment to the aqueous bloodstream. Lipid solubility of local anesthetics is correlated with plasma protein binding. Local anesthetics are mostly bound by α_1 -acid glycoprotein and to a lesser extent to albumin. Sustained-release systems using liposomal encapsulation or microspheres for delivery of local anesthetics can significantly prolong their duration of action, but these approaches are not yet being used for prolonged anesthesia in the way that extended-duration epidural morphine is being used for single-shot, prolonged epidural analgesia.

Differential block of sensory rather than motor function would be desirable. Unfortunately, only bupivacaine and ropivacaine display *some* selectivity (mostly during onset and offset of block) for sensory nerves; however, the concentrations required for surgical anesthesia almost always result in some motor blockade.

CLINICAL PHARMACOLOGY

Pharmacokinetics

6 In regional anesthesia local anesthetics are typically injected or applied very close to their intended site of action; thus their pharmacokinetic profiles are much more important determinants of elimination and toxicity than of their desired clinical effect.

A. Absorption

Most mucous membranes (eg, ocular conjunctiva, tracheal mucosa) provide a minimal barrier to local

anesthetic penetration, leading to a rapid onset of action. Intact skin, on the other hand, requires a high concentration of lipid-soluble local anesthetic base to ensure permeation and analgesia. EMLA cream consists of a 1:1 mixture of 5% lidocaine and 5% prilocaine bases in an oil-in-water emulsion. Dermal analgesia sufficient for beginning an intravenous line requires a contact time of at least 1 h under an occlusive dressing. Depth of penetration (usually 3–5 mm), duration of action (usually 1–2 h), and amount of drug absorbed depend on application time, dermal blood flow, keratin thickness, and total dose administered. Typically, 1–2 g of cream is applied per 10-cm² area of skin, with a maximum application area of 2000 cm² in an adult (100 cm² in children weighing less than 10 kg). Split-thickness skin-graft harvesting, laser removal of portwine stains, lithotripsy, and circumcision have been successfully performed with EMLA cream. Side effects include skin blanching, erythema, and edema. EMLA cream should not be used on mucous membranes, broken skin, infants younger than 1 month of age, or patients with a predisposition to methemoglobinemia (see Biotransformation and Excretion, below).

Systemic absorption of injected local anesthetics depends on blood flow, which is determined by the following factors.

7 1. Site of injection—The rate of systemic absorption is related to the vascularity of the site of injection: intravenous (or intraarterial) > tracheal > intercostal > paracervical > epidural > brachial plexus > sciatic > subcutaneous.

2. Presence of vasoconstrictors—Addition of epinephrine—or less commonly phenylephrine—causes vasoconstriction at the site of administration. The consequent decreased absorption reduces the peak local anesthetic concentration in blood, facilitates neuronal uptake, enhances the quality of analgesia, prolongs the duration of action, and limits toxic side effects. Vasoconstrictors have more pronounced effects on shorter-acting than longer-acting agents. For example, addition of epinephrine to lidocaine usually extends the duration of anesthesia by at least 50%, but epinephrine has little or no effect on the duration of bupivacaine peripheral nerve blocks. Epinephrine and clonidine

can also augment analgesia through activation of α_2 -adrenergic receptors.

3. Local anesthetic agent—More lipid-soluble local anesthetics that are highly tissue bound are also more slowly absorbed. The agents also vary in their intrinsic vasodilator properties.

B. Distribution

Distribution depends on organ uptake, which is determined by the following factors.

1. Tissue perfusion—The highly perfused organs (brain, lung, liver, kidney, and heart) are responsible for the initial rapid uptake (α phase), which is followed by a slower redistribution (β phase) to moderately perfused tissues (muscle and gut). In particular, the lung extracts significant amounts of local anesthetic; consequently, the threshold for systemic toxicity involves much lower doses following arterial injections than venous injections (and children with right-to-left shunts are more susceptible to toxic side effects of lidocaine injected as an antiarrhythmic agent).

2. Tissue/blood partition coefficient—Increasing lipid solubility is associated with greater plasma protein binding and also greater tissue uptake from an aqueous compartment.

3. Tissue mass—Muscle provides the greatest reservoir for distribution of local anesthetic agents in the bloodstream because of its large mass.

C. Biotransformation and Excretion

The biotransformation and excretion of local anesthetics is defined by their chemical structure.

8 1. Esters—Ester local anesthetics are predominantly metabolized by pseudocholinesterase (plasma cholinesterase or butyrylcholinesterase). Ester hydrolysis is very rapid, and the water-soluble metabolites are excreted in the urine. Procaine and benzocaine are metabolized to *p*-aminobenzoic acid (PABA), which has been associated with rare anaphylactic reactions. Patients with genetically abnormal pseudocholinesterase would theoretically be at increased risk for toxic side effects, as metabolism is slower, but clinical evidence for this is lacking. Cerebrospinal fluid lacks esterase enzymes, so the termination of action of intrathecally injected ester local anesthetics, eg, tetracaine, depends on

their redistribution into the bloodstream, as it does for all other nerve blocks. In contrast to other ester anesthetics, cocaine is partially metabolized (N-methylation and ester hydrolysis) in the liver and partially excreted unchanged in the urine.

2. Amides—Amide local anesthetics are metabolized (N-dealkylation and hydroxylation) by microsomal P-450 enzymes in the liver. The rate of amide metabolism depends on the specific agent (prilocaine > lidocaine > mepivacaine > ropivacaine > bupivacaine) but overall is consistently slower than ester hydrolysis of ester local anesthetics. Decreases in hepatic function (eg, cirrhosis of the liver) or liver blood flow (eg, congestive heart failure, β blockers, or H_2 -receptor blockers) will reduce the metabolic rate and potentially predispose patients to having greater blood concentrations and a greater risk of systemic toxicity. Very little unmetabolized local anesthetic is excreted by the kidneys, although water-soluble metabolites are dependent on renal clearance.

Prilocaine is the only local anesthetic that is metabolized to *o*-toluidine, which produces methemoglobinemia in a dose-dependent fashion. Classical teaching was that a defined minimal dose of prilocaine was needed to produce clinically important methemoglobinemia (in the range of 10 mg/kg); however, recent studies have shown that younger, healthier patients develop medically important methemoglobinemia after lower doses of prilocaine (and at lower doses than needed in older, sicker patients). Prilocaine is generally not used for epidural anesthesia during labor or in larger doses in patients with limited cardiopulmonary reserve. **Benzocaine, a common ingredient in topical local anesthetic sprays, can also cause dangerous levels of methemoglobinemia.** For this reason, many hospitals no longer permit benzocaine spray during endoscopic procedures. Treatment of medically important methemoglobinemia includes intravenous methylene blue (1–2 mg/kg of a 1% solution over 5 min). Methylene blue reduces methemoglobin (Fe^{3+}) to hemoglobin (Fe^{2+}).

Effects on Organ Systems

Because inhibition of voltage-gated Na channels from circulating local anesthetics might affect action

potentials in neurons throughout the body as well as impulse generation and conduction in the heart, it is not surprising that local anesthetics in high circulating concentrations could have the propensity for systemic toxicity. Although organ system effects are discussed for these drugs as a group, individual drugs differ.

Potency at most toxic side effects correlates with potency at nerve blocks. Maximum safe doses are listed in [Table 16–3](#), but it must be recognized that the maximum safe dose depends on the patient, the specific nerve block, the rate of injection, and a long list of other factors. In other words, tables of purported maximal safe doses are nearly nonsensical. Mixtures of local anesthetics should be considered to have additive toxic effects; therefore, a solution containing 50% of the toxic dose of lidocaine and 50% of the toxic dose of bupivacaine if injected by accident intravenously will produce toxic effects.

A. Neurological

9 The central nervous system is vulnerable to local anesthetic toxicity and is the site of premonitory signs of rising blood concentrations in awake patients. Early symptoms include circumoral numbness, tongue paresthesia, dizziness, tinnitus, and blurred vision. Excitatory signs include restlessness, agitation, nervousness, garrulousness, and a feeling of “impending doom.” Muscle twitching heralds the onset of tonic-clonic seizures. Still higher blood concentrations may produce central nervous system depression (eg, coma and respiratory arrest). The excitatory reactions are thought to be the result of selective blockade of inhibitory pathways. Potent, highly lipid-soluble local anesthetics produce seizures at lower blood concentrations than less potent agents. Benzodiazepines and hyperventilation raise the threshold of local anesthetic-induced seizures. Both respiratory and metabolic acidosis reduce the seizure threshold. Propofol (0.5–2 mg/kg) quickly and reliably terminates seizure activity (as do comparable doses of benzodiazepines or barbiturates). Maintaining a clear airway with adequate ventilation and oxygenation is of key importance.

Infused local anesthetics have a variety of actions. Systemically administered local anesthetics such as lidocaine (1.5 mg/kg) can decrease cerebral

TABLE 16-3 Clinical use of local anesthetic agents.

Agent	Techniques	Concentrations Available	Maximum Dose (mg/kg)	Typical Duration of Nerve Blocks ¹
Esters				
Benzocaine	Topical ²	20%	NA ³	NA
Chloroprocaine	Epidural, infiltration, peripheral nerve block, spinal ⁴	1%, 2%, 3%	12	Short
Cocaine	Topical	4%, 10%	3	NA
Procaine	Spinal, local infiltration	1%, 2%, 10%	12	Short
Tetracaine (amethocaine)	Spinal, topical (eye)	0.2%, 0.3%, 0.5%, 1%, 2%	3	Long
Amides				
Bupivacaine	Epidural, spinal, infiltration, peripheral nerve block	0.25%, 0.5%, 0.75%	3	Long
Lidocaine (lignocaine)	Epidural, spinal, infiltration, peripheral nerve block, intravenous regional, topical	0.5%, 1%, 1.5%, 2%, 4%, 5%	4.5 7 (with epinephrine)	Medium
Mepivacaine	Epidural, infiltration, peripheral nerve block, spinal	1%, 1.5%, 2%, 3%	4.5 7 (with epinephrine)	Medium
Prilocaine	EMLA (topical), epidural, intravenous regional (outside North America)	0.5%, 2%, 3%, 4%	8	Medium
Ropivacaine	Epidural, spinal, infiltration, peripheral nerve block	0.2%, 0.5%, 0.75%, 1%	3	Long

¹Wide variation depending on concentration, location, technique, and whether combined with a vasoconstrictor (epinephrine). Generally the shortest duration is with spinal anesthesia and the longest with peripheral nerve blocks.

²No longer recommended for topical anesthesia.

³NA, not applicable.

⁴Recent literature describes this agent for short-duration spinal anesthetics.

blood flow and attenuate the rise in intracranial pressure that may accompany intubation in patients with decreased intracranial compliance. Infusions of lidocaine and procaine have been used to supplement general anesthetic techniques, as they are capable of reducing the MAC of volatile anesthetics by up to 40%. Infusions of lidocaine inhibit inflammation and reduce postoperative pain. Infused lidocaine reduces postoperative opioid requirements sufficiently to reduce length of stay after colorectal or open prostate surgery.

Cocaine stimulates the central nervous system and at moderate doses usually causes a sense of euphoria. An overdose is heralded by restlessness, emesis, tremors, convulsions, arrhythmias, respiratory failure, and cardiac arrest.

Local anesthetics temporarily inhibit neuronal function. **In the past, unintentional injection of large volumes of chloroprocaine into the subarachnoid space (during attempts at epidural anesthesia), produced total spinal anesthesia and marked hypotension, and caused prolonged**

neurological deficits. The cause of this neural toxicity may be direct neurotoxicity or a combination of the low pH of chloroprocaine and a preservative, sodium bisulfite. The latter has been replaced in some formulations by an antioxidant, a derivative of disodium ethylenediaminetetraacetic acid (EDTA). Chloroprocaine has also been occasionally associated with severe back pain following epidural administration. The etiology is unclear. Chloroprocaine is available in a preservative-free formulation, which has been used in recent studies safely and successfully for short duration, outpatient spinal anesthetics.

Administration of 5% lidocaine has been associated with neurotoxicity (cauda equina syndrome) following infusion through small-bore catheters used in continuous spinal anesthesia. This may be due to pooling of drug around the cauda equina, resulting in high concentrations and permanent neuronal damage. Animal data suggest that the extent of histological evidence of neurotoxicity following repeat intrathecal injection is lidocaine = tetracaine > bupivacaine > ropivacaine.

Transient neurological symptoms, which consist of dysesthesia, burning pain, and aching in the lower extremities and buttocks, have been reported following spinal anesthesia with a variety of local anesthetic agents, most commonly after use of lidocaine for outpatient spinal anesthesia in men undergoing surgery in the lithotomy position. These symptoms have been attributed to radicular irritation and typically resolve within 1–4 weeks. Many clinicians have substituted 2-chloroprocaine, mepivacaine, or small doses of bupivacaine for lidocaine in spinal anesthesia in the hope of avoiding these transient symptoms.

B. Respiratory

Lidocaine depresses hypoxic drive (the ventilatory response to low PaO₂). Apnea can result from phrenic and intercostal nerve paralysis or depression of the medullary respiratory center following direct exposure to local anesthetic agents (as may occur after retrobulbar blocks; see Chapter 36). Apnea after administration of a “high” spinal or epidural anesthetic is nearly always the result of hypotension, rather than phrenic block. Local

anesthetics relax bronchial smooth muscle. Intravenous lidocaine (1.5 mg/kg) may be effective in blocking the reflex bronchoconstriction sometimes associated with intubation. Lidocaine (or any other inhaled agent) administered as an aerosol can lead to bronchospasm in some patients with reactive airway disease.

C. Cardiovascular

All local anesthetics depress myocardial automaticity (spontaneous phase IV depolarization). Myocardial contractility and conduction velocity are also depressed at higher concentrations. These effects result from direct cardiac muscle membrane changes (ie, cardiac Na channel blockade) and in intact organisms from inhibition of the autonomic nervous system. All local anesthetics except cocaine produce smooth muscle relaxation at higher concentrations, which may cause some degree of arteriolar vasodilation. At low concentrations all local anesthetics inhibit nitric oxide, causing vasoconstriction. At increased blood concentrations the combination of arrhythmias, heart block, depression of ventricular contractility, and hypotension **10** may culminate in cardiac arrest. Major cardiovascular toxicity usually requires about three times the local anesthetic concentration in blood as that required to produce seizures. Cardiac arrhythmias or circulatory collapse are the usual presenting signs of local anesthetic overdose during general anesthesia. Particularly in awake subjects, signs of transient cardiovascular stimulation (tachycardia and hypertension) may occur with central nervous system excitation at local anesthetic concentrations producing central nervous system toxic side effects.

Intravenous amiodarone provides effective treatment for some forms of ventricular arrhythmias. Myocardial contractility and arterial blood pressure are generally unaffected by the usual intravenous doses. The hypertension associated with laryngoscopy and intubation is attenuated in some patients by intravenous administration of lidocaine (1.5 mg/kg) 1–3 min prior to instrumentation. On the other hand, overdoses of lidocaine can lead to marked left ventricular contractile dysfunction.

11 Unintentional intravascular injection of bupivacaine during regional anesthesia may produce severe cardiovascular toxicity, including left ventricular depression, atrioventricular heart block, and life-threatening arrhythmias such as ventricular tachycardia and fibrillation. Pregnancy, hypoxemia, and respiratory acidosis are predisposing risk factors. Young children may also be at increased risk of toxicity. Multiple studies have demonstrated that bupivacaine is associated with more pronounced changes in conduction and a greater risk of terminal arrhythmias than comparable doses of lidocaine. Mepivacaine, ropivacaine, and bupivacaine have chiral carbons and therefore can exist in either of two optical isomers (enantiomers). The R(+) optical isomer of bupivacaine blocks more avidly and dissociates more slowly from cardiac Na channels than does the S(-) optical isomer. Resuscitation from bupivacaine-induced cardiac toxicity is often difficult and resistant to standard resuscitation drugs. Recent reports suggest that bolus administration of nutritional lipid solutions at 1.5 mL/kg can resuscitate bupivacaine-intoxicated patients who do not respond to standard therapy. Ropivacaine shares many physicochemical properties with bupivacaine. Onset time and duration of action are similar, but ropivacaine produces less motor block when injected at the same volume and concentration as bupivacaine (which may reflect an overall lower potency as compared with bupivacaine). Ropivacaine appears to have a greater therapeutic index than bupivacaine. This improved safety profile likely reflects its formulation as a pure S(-) isomer—that is, having no R(+) isomer—as opposed to racemic bupivacaine. Levobupivacaine, the S(-) isomer of bupivacaine, which is no longer available in the United States, was reported to have fewer cardiovascular and cerebral side effects than the racemic mixture; studies suggest its cardiovascular effects may approximate those of ropivacaine.

Cocaine's cardiovascular reactions are unlike those of any other local anesthetic. Adrenergic nerve terminals normally reabsorb norepinephrine after its release. Cocaine inhibits this reuptake, thereby potentiating the effects of adrenergic stimulation. Cardiovascular responses to cocaine

include hypertension and ventricular ectopy. The latter contraindicated its use in patients anesthetized with halothane. **Cocaine-induced arrhythmias** have been successfully treated with adrenergic and Ca channel antagonists. Cocaine produces vasoconstriction when applied topically and is a useful agent to reduce pain and epistaxis related to nasal intubation in awake patients.

D. Immunological

12 True hypersensitivity reactions to local anesthetic agents—as distinct from systemic toxicity caused by excessive plasma concentration—are uncommon. Esters appear more likely to induce a true allergic reaction (due to IgG or IgE antibodies) especially if they are derivatives (eg, procaine or benzocaine) of *p*-aminobenzoic acid, a known allergen. Commercial multidose preparations of amides often contain **methylparaben**, which has a chemical structure vaguely similar to that of PABA. As a consequence, generations of anesthesiologists have speculated whether this preservative may be responsible for most of the apparent allergic responses to amide agents. The signs and treatment of allergic drug reactions are discussed in Chapter 55.

E. Musculoskeletal

When directly injected into skeletal muscle (eg, trigger-point injection treatment of myofascial pain), local anesthetics are mildly myotoxic. Regeneration usually occurs 3–4 weeks after local anesthetic injection into muscle. Concomitant steroid or epinephrine injection worsens the myonecrosis.

F. Hematological

Lidocaine mildly depresses normal blood coagulation (reduced thrombosis and decreased platelet aggregation) and enhances fibrinolysis of whole blood as measured by thromboelastography. These effects may underlie the reduced efficacy of an epidural autologous blood patch shortly after local anesthetic administration and the lower incidence of embolic events in patients receiving epidural anesthetics (in older studies of patients not receiving prophylaxis against deep vein thrombosis).

Drug Interactions

Local anesthetics potentiate nondepolarizing muscle relaxant blockade in laboratory experiments, but the clinical importance of this observation is unknown (and probably nil).

Succinylcholine and ester local anesthetics depend on pseudocholinesterase for metabolism. Concurrent administration might conceivably increase the time that both drugs remain unmetabolized in the bloodstream. There is likely no actual clinical importance of this potential interaction.

Dibucaine, an amide local anesthetic, inhibits pseudochoolinesterase, and the extent of inhibition by dibucaine defines one family of genetically abnormal pseudochoolinesterases (see Chapter 11). Pseudochoolinesterase inhibitors (eg, organophosphate poisons) can prolong the metabolism of ester local anesthetics (see Table 11–3).

Histamine (H_2) receptor blockers and β blockers (eg, propranolol) decrease hepatic blood flow and lidocaine clearance. Opioids potentiate epidural and spinal analgesia produced by local anesthetics. Similarly α_2 -adrenergic agonists (eg, clonidine) potentiate local anesthetic analgesia produced after epidural or peripheral nerve block injections. Epidural chloroprocaine may interfere with the analgesic actions of neuraxial morphine, notably after cesarean delivery.

CASE DISCUSSION

Local Anesthetic Overdose

An 18-year-old woman in the active stage of labor requests an epidural anesthetic. Immediately following the epidural injection of 2 mL and 5 mL test doses of 2% lidocaine, the patient complains of lip numbness and becomes very apprehensive.

What is your presumptive diagnosis?

Circumoral numbness and apprehension immediately following administration of lidocaine suggest an intravascular injection. These signs will not always be followed by a seizure.

What prophylactic measures should be immediately taken?

The patient should already be receiving supplemental oxygen. She should be closely observed for a possible (but unlikely) seizure.

If symptoms progress to a generalized convulsion, what treatment should be initiated?

The laboring patient is always considered to be at risk for aspiration (see Chapter 41). Therefore, protecting the airway is an important concern. Immediate administration of succinylcholine should be followed by a rapid-sequence intubation (see Case Discussion, Chapter 17). Although the succinylcholine will eliminate tonic-clonic activity, it will not address the underlying cerebral excitability. An anticonvulsant such as midazolam (1–2 mg) or propofol (20–50 mg) should be administered with or before succinylcholine. It is clear from this sequence of events that wherever conduction anesthetics are administered, comparable resuscitation drugs and equipment must be available as for a general anesthetic.

What could have been expected if a large dose of bupivacaine (eg, 15 mL 0.5% bupivacaine)—instead of lidocaine—had been given intravascularly?

When administered at “comparably anesthetizing” doses bupivacaine is more cardiotoxic than lidocaine. Acute acidosis (nearly universal after a seizure) tends to potentiate local anesthetic toxicity. Ventricular arrhythmias and conduction disturbances may lead to cardiac arrest and death. Bupivacaine is considered a more potent cardiac Na channel inhibitor because Na channels unbind bupivacaine more slowly than lidocaine. Amiodarone should be considered the preferred alternative to lidocaine in the treatment of local anesthetic-induced ventricular tachyarrhythmias. Vasopressors may include epinephrine and vasopressin. The reason for the apparent greater susceptibility to local anesthetic cardiotoxicity during pregnancy is unclear. Although total dose (not concentration) of local anesthetic determines toxicity, the Food and

Drug Administration recommends against use of 0.75% bupivacaine in pregnant and elderly patients.

What could have prevented the toxic reaction described?

The risk from an accidental intravascular injection of local anesthetic during attempted epidural anesthesia is reduced by using test doses and administering the anesthetic dose in smaller, safer aliquots. Finally, one should administer only the minimum appropriate total dose of local anesthetic for a given regional anesthetic procedure.

This web site provides up-to-date information about the use of lipid for rescue from local anesthetic toxicity.

Adjuncts to Anesthesia

KEY CONCEPTS

- 1 Diphenhydramine is one of a diverse group of drugs that competitively blocks H_1 receptors. Many drugs with H_1 -receptor antagonist properties have considerable antimuscarinic, or atropine-like, activity (eg, dry mouth), or antiserotonergic activity (antiemetic).
- 2 H_2 blockers reduce the perioperative risk of aspiration pneumonia by decreasing gastric fluid volume and raising the pH of gastric contents.
- 3 Metoclopramide increases lower esophageal sphincter tone, speeds gastric emptying, and lowers gastric fluid volume by enhancing the stimulatory effects of acetylcholine on intestinal smooth muscle.
- 4 Ondansetron, granisetron, and dolasetron selectively block serotonin $5-HT_3$ receptors, with little or no effect on dopamine receptors. $5-HT_3$ receptors, which are located peripherally and centrally, appear to play an important role in the initiation of the vomiting reflex.
- 5 Ketorolac is a parenterally administered nonsteroidal antiinflammatory drug that provides analgesia by inhibiting prostaglandin synthesis.
- 6 Clonidine is a commonly used antihypertensive agent but in anesthesia it is used as an adjunct for epidural and peripheral nerve block anesthesia and analgesia. It is often used in the management of patients with chronic neuropathic pain to increase the efficacy of epidural opioid infusions.
- 7 Dexmedetomidine is a parenteral selective α_2 agonist with sedative properties. It appears to be more selective for the α_2 receptor than clonidine.
- 8 Selective activation of carotid chemoreceptors by low doses of doxapram stimulates hypoxic drive, producing an increase in tidal volume and a slight increase in respiratory rate. However, doxapram is not a specific reversal agent and should not replace standard supportive therapy (ie, mechanical ventilation).
- 9 Naloxone reverses the agonist activity associated with endogenous or exogenous opioid compounds.
- 10 Flumazenil is useful in the reversal of benzodiazepine sedation and the treatment of benzodiazepine overdose.
- 11 Aspiration does not necessarily result in aspiration pneumonia. The seriousness of the lung damage depends on the volume and composition of the aspirate. Patients are at risk if their gastric volume is greater than 25 mL (0.4 mL/kg) and their gastric pH is less than 2.5.

Many drugs are routinely administered by anesthesiologists perioperatively to protect against aspiration pneumonia, to prevent or reduce the incidence of perioperative nausea and vomiting, and to reverse respiratory depression secondary to narcotics or benzodiazepines. This chapter discusses these agents along with other unique classes of drugs that are often administered as adjuvants during anesthesia or analgesia.

Aspiration

Aspiration of gastric contents is a rare, potentially fatal, and often litigious event that can complicate anesthesia. Based on an animal study, it is often stated that aspiration of 25 mL of volume at a pH of less than 2.5 will be sufficient to produce aspiration pneumonia. Many factors place patients at risk for aspiration, including “full” stomach, intestinal obstruction, hiatal hernia, obesity, pregnancy, reflux disease, emergency surgery, and inadequate depth of anesthesia.

Many approaches are employed to reduce the potential for aspiration perioperatively. Many of these interventions, such as the holding of cricoid pressure (Sellick’s maneuver) and rapid sequence induction, may only offer limited protection. Cricoid pressure can be applied incorrectly and fail to occlude the esophagus. Whether it has *any* beneficial effect on outcomes even when it is applied correctly remains unproven. Anesthetic agents can decrease lower esophageal sphincter tone and decrease or obliterate the gag reflex, theoretically increasing the risk for passive aspiration. Additionally, inadequately anesthetized patients can vomit with an unprotected airway, likewise leading to aspiration. Different combinations of premedications have been advocated to reduce gastric volume, increase gastric pH, or augment lower esophageal sphincter tone. These agents include antihistamines, antacids, and metoclopramide.

HISTAMINE-RECEPTOR ANTAGONISTS

Histamine Physiology

Histamine is found in the central nervous system, in the gastric mucosa, and in other peripheral tissues. It is synthesized by decarboxylation of the amino

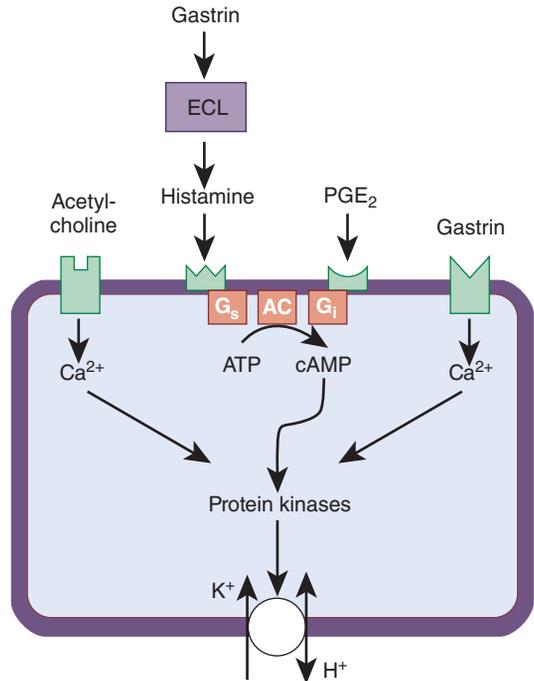

FIGURE 17-1 Secretion of hydrochloric acid is normally mediated by gastrin-induced histamine release from enterochromaffin-like cells (ECL) in the stomach. Note that acid secretion by gastric parietal cells can also be increased indirectly by acetylcholine (ACh) via stimulation of M₃ receptors and directly by gastrin through an increase in intracellular Ca²⁺ concentration. Prostaglandin E₂ (PGE₂) can inhibit acid secretion by decreasing cyclic adenosine monophosphate (cAMP) activity. ATP, adenosine triphosphate; G_i, G inhibitory protein; G_s, G stimulatory protein.

acid histidine. Histaminergic neurons are primarily located in the posterior hypothalamus but have wide projections in the brain. Histamine also normally plays a major role in the secretion of hydrochloric acid by parietal cells in the stomach (Figure 17-1). The highest concentrations of histamine are found in the storage granules of circulating basophils and mast cells throughout the body. Mast cells tend to be concentrated in connective tissue just beneath epithelial (mucosal) surfaces. Histamine release (degranulation) from these cells can be triggered by chemical, mechanical, or immunological stimulation

Multiple receptors mediate the effects of histamine. The H₁ receptor activates phospholipase C, whereas the H₂ receptor increases intracellular cyclic

adenosine monophosphate (cAMP). An H_3 receptor is primarily located on histamine-secreting cells and mediates negative feedback, inhibiting the synthesis and release of additional histamine. Histamine-*N*-methyltransferase metabolizes histamine to inactive metabolites that are excreted in the urine.

A. Cardiovascular

Histamine reduces arterial blood pressure but increases heart rate and myocardial contractility. H_1 -Receptor stimulation increases capillary permeability and enhances ventricular irritability, whereas H_2 -receptor stimulation increases heart rate and increases contractility. Both types of receptors mediate peripheral arteriolar dilation and some coronary vasodilation.

B. Respiratory

Histamine constricts bronchiolar smooth muscle via the H_1 receptor. H_2 -Receptor stimulation may produce mild bronchodilation. Histamine has variable effects on the pulmonary vasculature; the H_1 receptor appears to mediate some pulmonary vasodilation, whereas the H_2 receptor may be responsible for histamine-mediated pulmonary vasoconstriction.

C. Gastrointestinal

Activation of H_2 receptors in parietal cells increases gastric acid secretion. Stimulation of H_1 receptors leads to contraction of intestinal smooth muscle.

D. Dermal

The classic wheal-and-flare response of the skin to histamine results from increased capillary permeability and vasodilation, primarily via H_1 -receptor activation.

E. Immunological

Histamine is a major mediator of type 1 hypersensitivity reactions. H_1 -Receptor stimulation attracts leukocytes and induces synthesis of prostaglandin. In contrast, the H_2 receptor appears to activate suppressor T lymphocytes.

1. H_1 -Receptor Antagonists

Mechanism of Action

1 Diphenhydramine (an ethanolamine) is one of a diverse group of drugs that competitively blocks H_1 receptors (Table 17-1). Many drugs with

TABLE 17-1 Properties of commonly used H_1 -receptor antagonists.¹

Drug	Route	Dose (mg)	Duration (h)	Sedation	Antiemesis
Diphenhydramine (Benadryl)	PO, IM, IV	25–50	3–6	+++	++
Dimenhydrinate (Dramamine)	PO, IM, IV	50–100	3–6	+++	++
Chlorpheniramine (Chlor-Trimeton)	PO IM, IV	2–12 5–20	4–8	++	0
Hydroxyzine (Atarax, Vistaril)	PO, IM	25–100	4–12	+++	++
Promethazine (Phenergan)	PO, IM, IV	12.5–50	4–12	+++	+++
Cetirizine (Zyrtec)	PO	5–10	24	+	
Cyproheptadine (Periactin)	PO	4	6–8	++	
Dimenhydrinate (Dramamine)	PO	50	6–12	++	
Fexofenadine (Allegra)	PO	30–60	12	0	
Meclizine (Antivert)	PO	12.5–50	8–24	+	
Loratadine (Claritin)	PO	10	24	0	

¹0, no effect; ++, moderate activity; +++, marked activity.

H₁-receptor antagonist properties have considerable antimuscarinic, or atropine-like, activity (eg, dry mouth), or antiserotonergic activity (antiemetic). Promethazine is a phenothiazine derivative with H₁-receptor antagonist activity as well as antidopaminergic and α -adrenergic-blocking properties.

Clinical Uses

Like other H₁-receptor antagonists, diphenhydramine has a multitude of therapeutic uses: suppression of allergic reactions and symptoms of upper respiratory tract infections (eg, urticaria, rhinitis, conjunctivitis); vertigo, nausea, and vomiting (eg, motion sickness, Ménière's disease); sedation; suppression of cough; and dyskinesia (eg, parkinsonism, drug-induced extrapyramidal side effects). Some of these actions are predictable from an understanding of histamine physiology, whereas others are the result of the drugs' antimuscarinic and antiserotonergic effects (Table 17-1). Although H₁ blockers prevent the bronchoconstrictive response to histamine, they are ineffective in treating bronchial asthma, which is primarily due to other mediators. Likewise, H₁ blockers will not completely prevent the hypotensive effect of histamine unless an H₂ blocker is administered concomitantly.

The antiemetic and mild hypnotic effects of antihistaminic drugs (particularly diphenhydramine, promethazine, and hydroxyzine) have led to their use for premedication. Although many H₁ blockers cause significant sedation, ventilatory drive is usually unaffected in the absence of other sedative medications. Promethazine and hydroxyzine were often combined with opioids to potentiate analgesia. Newer (second-generation) antihistamines tend to produce little or no sedation because of limited penetration across the blood-brain barrier. This group of drugs is used primarily for allergic rhinitis and urticaria. They include loratadine, fexofenadine, and cetirizine. Many preparations for allergic rhinitis often also contain vasoconstrictors such as pseudoephedrine. Meclizine and dimenhydrinate are used primarily as an antiemetic, particularly for motion sickness, and in the management of vertigo. Cyproheptadine, which also has significant serotonin antagonist activity, has been used in the

management of Cushing's Disease, carcinoid syndrome, and vascular (cluster) headaches.

Dosage

The usual adult dose of diphenhydramine is 25–50 mg (0.5–1.5 mg/kg) orally, intramuscularly, or intravenously every 4–6 h. The doses of other H₁-receptor antagonists are listed in Table 17-1.

Drug Interactions

The sedative effects of H₁-receptor antagonists can potentiate other central nervous system depressants such as barbiturates, benzodiazepines, and opioids.

2. H₂-Receptor Antagonists

Mechanism of Action

H₂-Receptor antagonists include cimetidine, famotidine, nizatidine, and ranitidine (Table 17-2). These agents competitively inhibit histamine binding to H₂ receptors, thereby reducing gastric acid output and raising gastric pH.

Clinical Uses

All H₂-receptor antagonists are equally effective in the treatment of peptic duodenal and gastric ulcers, hypersecretory states (Zollinger–Ellison syndrome), and gastroesophageal reflux disease (GERD). Intravenous preparations are also used to prevent stress ulceration in critically ill patients. Duodenal and gastric ulcers are usually associated with *Helicobacter pylori* infection, which is treated with combinations of bismuth, tetracycline, and metronidazole. By decreasing gastric fluid volume and hydrogen ion content, H₂ blockers reduce the perioperative risk of aspiration pneumonia. These drugs affect the pH of only those gastric secretions that occur after their administration.

The combination of H₁- and H₂-receptor antagonists provides some protection against drug-induced allergic reactions (eg, intravenous radiocontrast, chymopapain injection for lumbar disk disease, protamine, vital blue dyes used for sentinel node biopsy). Although pretreatment with these agents does not reduce histamine release, it may decrease subsequent hypotension.

TABLE 17-2 Pharmacology of aspiration pneumonia prophylaxis.¹

Drug	Route	Dose	Onset	Duration	Acidity	Volume	LES Tone
Cimetidine (Tagamet)	PO IV	300–800 mg 300 mg	1–2 h	4–8 h	↓↓↓	↓↓	0
Ranitidine (Zantac)	PO IV	150–300 mg 50 mg	1–2 h	10–12 h	↓↓↓	↓↓	0
Famotidine (Pepcid)	PO IV	20–40 mg 20 mg	1–2 h	10–12 h	↓↓↓	↓↓	0
Nizatidine (Axid)	PO	150–300 mg	0.5–1 h	10–12 h	↓↓↓	↓↓	0
Nonparticulate antacids (Bicitra, Polycitra)	PO	15–30 mL	5–10 min	30–60 min	↓↓↓	↑	0
Metoclopramide (Reglan)	IV PO	10 mg 10–15 mg	1–3 min	1–2 h 30–60 min ²	0	↓↓	↑↑

¹0, no effect; ↓↓, moderate decrease; ↓↓↓, marked decrease; ↑, slight increase; ↑↑, moderate increase; LES, lower esophageal sphincter.

²Oral metoclopramide has a quite variable onset of action and duration of action.

Side Effects

Rapid intravenous injection of cimetidine or ranitidine has been rarely associated with hypotension, bradycardia, arrhythmias, and cardiac arrest. These adverse cardiovascular effects have been reported following the administration of cimetidine to critically ill patients. In contrast, famotidine can be safely injected intravenously over a 2-min period. H₂-Receptor antagonists change the gastric flora by virtue of their pH effects. Complications of long-term cimetidine therapy include hepatotoxicity (elevated serum transaminases), interstitial nephritis (elevated serum creatinine), granulocytopenia, and thrombocytopenia. Cimetidine also binds to androgen receptors, occasionally causing gynecomastia and impotence. Finally, cimetidine has been associated with changes in mental status ranging from lethargy and hallucinations to seizures, particularly in elderly patients. In contrast, ranitidine, nizatidine, and famotidine do not affect androgen receptors and penetrate the blood–brain barrier poorly.

Dosage

As a premedication to reduce the risk of aspiration pneumonia, H₂-receptor antagonists should be administered at bedtime and again at least 2 h before surgery (Table 17-2). Because all four drugs

are eliminated primarily by the kidneys, the dose should be reduced in patients with significant renal dysfunction.

Drug Interactions

Cimetidine may reduce hepatic blood flow and binds to the cytochrome P-450 mixed-function oxidases. These effects slow the metabolism of a multitude of drugs, including lidocaine, propranolol, diazepam, theophylline, phenobarbital, warfarin, and phenytoin. Ranitidine is a weak inhibitor of the cytochrome P-450 system, and no significant drug interactions have been demonstrated. Famotidine and nizatidine do not appear to affect the cytochrome P-450 system.

ANTACIDS

Mechanism of Action

Antacids neutralize the acidity of gastric fluid by providing a base (usually hydroxide, carbonate, bicarbonate, citrate, or trisilicate) that reacts with hydrogen ions to form water.

Clinical Uses

Common uses of antacids include the treatment of gastric and duodenal ulcers, GERD, and Zollinger–Ellison syndrome. In anesthesiology, antacids

provide protection against the harmful effects of aspiration pneumonia by raising the pH of gastric contents. Unlike H_2 -receptor antagonists, antacids have an immediate effect. Unfortunately, they increase intragastric volume. Aspiration of particulate antacids (aluminum or magnesium hydroxide) produces abnormalities in lung function comparable to those that occur following acid aspiration. Nonparticulate antacids (sodium citrate or sodium bicarbonate) are much less damaging to lung alveoli if aspirated. Furthermore, nonparticulate antacids mix with gastric contents better than particulate solutions. Timing is critical, as nonparticulate antacids lose their effectiveness 30–60 min after ingestion.

Dosage

The usual adult dose of a 0.3 M solution of sodium citrate—Bicitra (sodium citrate and citric acid) or Polycitra (sodium citrate, potassium citrate, and citric acid)—is 15–30 mL orally, 15–30 min prior to induction.

Drug Interactions

Because antacids alter gastric and urinary pH, they change the absorption and elimination of many drugs. The rate of absorption of digoxin, cimetidine, and ranitidine is slowed, whereas the rate of phenobarbital elimination is quickened.

METOCLOPRAMIDE

Mechanism of Action

Metoclopramide acts peripherally as a cholinomimetic (ie, facilitates acetylcholine transmission at selective muscarinic receptors) and centrally as a dopamine receptor antagonist. Its action as a prokinetic agent in the upper gastrointestinal (GI) tract is not dependent on vagal innervation but is abolished by anticholinergic agents. It does not stimulate secretions.

Clinical Uses

3 By enhancing the stimulatory effects of acetylcholine on intestinal smooth muscle, metoclopramide increases lower esophageal sphincter tone, speeds gastric emptying, and lowers gastric fluid

volume. These properties account for its efficacy in the treatment of patients with diabetic gastroparesis and GERD, as well as prophylaxis for those at risk for aspiration pneumonia. Metoclopramide does not affect the secretion of gastric acid or the pH of gastric fluid.

Metoclopramide produces an antiemetic effect by blocking dopamine receptors in the chemoreceptor trigger zone of the central nervous system. However, at doses used clinically during the perioperative period, the drug's ability to reduce postoperative nausea and vomiting is negligible.

Side Effects

Rapid intravenous injection may cause abdominal cramping, and metoclopramide is contraindicated in patients with complete intestinal obstruction. It can induce a hypertensive crisis in patients with pheochromocytoma by releasing catecholamines from the tumor. Sedation, nervousness, and extrapyramidal signs from dopamine antagonism (eg, akathisia) are uncommon and reversible. Nonetheless, metoclopramide is best avoided in patients with Parkinson's disease. Metoclopramide-induced increases in aldosterone and prolactin secretion are probably inconsequential during short-term therapy. Metoclopramide may rarely result in hypotension and arrhythmias.

Dosage

An adult dose of 10–20 mg of metoclopramide (0.25 mg/kg) is effective orally, intramuscularly, or intravenously (injected over 5 min). Larger doses (1–2 mg/kg) have been used to prevent emesis during chemotherapy. The onset of action is much more rapid following parenteral (3–5 min) than oral (30–60 min) administration. Because metoclopramide is excreted in the urine, its dose should be decreased in patients with renal dysfunction.

Drug Interactions

Antimuscarinic drugs (eg, atropine, glycopyrrolate) block the GI effects of metoclopramide. Metoclopramide decreases the absorption of orally administered cimetidine. Concurrent use of phenothiazines or butyrophenones (droperidol) increases the likelihood of extrapyramidal side effects.

PROTON PUMP INHIBITORS

Mechanism of Action

These agents, including omeprazole (Prilosec), lansoprazole (Prevacid), rabeprazole (Aciphex), esomeprazole (Nexium), and pantoprazole (Protonix), bind to the proton pump of parietal cells in the gastric mucosa and inhibit secretion of hydrogen ions.

Clinical Uses

Proton pump inhibitors (PPIs) are indicated for the treatment of duodenal ulcer, GERD, and Zollinger–Ellison syndrome. They may promote healing of peptic ulcers and erosive GERD more quickly than H₂-receptor blockers. There are ongoing questions regarding the safety of PPIs in patients taking clopidogrel (Plavix) because of concerns of inadequate antiplatelet therapy when these drugs are combined.

Side Effects

PPIs are generally well tolerated, causing few side effects. Adverse side effects primarily involve the GI system (nausea, abdominal pain, constipation, diarrhea). On rare occasions, these drugs have been associated with myalgias, anaphylaxis, angioedema, and severe dermatological reactions. Long-term use of PPIs has also been associated with gastric enterochromaffin-like cell hyperplasia and an increased risk of pneumonia secondary to bacterial colonization in the higher-pH environment.

Dosage

Recommended oral doses for adults are omeprazole, 20 mg; lansoprazole, 15 mg; rabeprazole, 20 mg; and pantoprazole, 40 mg. Because these drugs are primarily eliminated by the liver, repeat doses should be decreased in patients with severe liver impairment.

Drug Interactions

PPIs can interfere with hepatic P-450 enzymes, potentially decreasing the clearance of diazepam, warfarin, and phenytoin. Concurrent administration can decrease clopidogrel (Plavix) effectiveness, as the latter medication is dependent on hepatic enzymes for activation.

Postoperative Nausea & Vomiting (PONV)

Without any prophylaxis, PONV occurs in approximately 20–30% of the general surgical population and up to 70–80% in patients with predisposing risk factors (Table 17–3). As anesthetic duration increases, so, too, does PONV risk. When the risk is sufficiently great, prophylactic antiemetic medications are administered and strategies to reduce its incidence are initiated. The Society of Ambulatory Anesthesia (SAMBA) provides simplified risk scoring systems, which assign points for specific risk factors, as well as guidelines that assist in the management of at-risk patients (Table 17–4). Obesity, anxiety, and reversal of neuromuscular blockade are not independent risk factors for PONV.

Drugs used in the prophylaxis and treatment of PONV include 5-HT₃ antagonists, butyrophenones, dexamethasone, neurokinin-1 receptor antagonists (aprepitant, Emend); antihistamines and transdermal scopolamine may also be used. At-risk patients often benefit from one or more prophylactic measures.

TABLE 17–3 Risk factors for postoperative nausea and vomiting (PONV).^{1,2}

Patient-specific risk factors:
Female gender
Nonsmoking status
History of PONV/motion sickness
Anesthetic risk factors:
Use of volatile anesthetics
Use of nitrous oxide
Use of intraoperative and postoperative opioids
Surgical risk factors:
Duration of surgery (each 30-min increase in duration increases PONV risk by 60%, so that a baseline risk of 10% is increased by 16% after 30 min)
Type of surgery

²Risk factors are assigned points and an increasing number of points increases the likelihood of PONV. Refer to the Society of Ambulatory Anesthesia (SAMBA) guidelines.

TABLE 17-4 SAMBA guidelines to reduce the risk of postoperative nausea and vomiting (PONV).¹

1. Identify patients at risk for PONV.
2. Employ management strategies to reduce PONV risk.
3. Employ one to two prophylactic measures in adults at moderate PONV risk.
4. Use multiple interventions in patients at high PONV risk.
5. Administer prophylactic antiemetic therapy to children at high risk using combination therapy.
6. Provide antiemetic therapy to patients with PONV who did not receive prophylactic therapy or in whom prophylaxis failed. Therapy should be with a drug from a different class than that which failed to provide prophylaxis.

¹Data based on guidelines from the Society of Ambulatory Anesthesia (SAMBA). Refer to Gan TJ, Meyer TA, Apfel CC, et al: Society for ambulatory anesthesia guidelines for management of postoperative nausea and vomiting. *Anesth Analg* 2007;105:1615.

5-HT₃ RECEPTOR ANTAGONISTS

Serotonin Physiology

Serotonin, 5-hydroxytryptamine (5-HT), is present in large quantities in platelets and the GI tract (enterochromaffin cells and the myenteric plexus). It is also an important neurotransmitter in multiple areas of the central nervous system. Serotonin is formed by hydroxylation and decarboxylation of tryptophan. Monoamine oxidase inactivates serotonin into 5-hydroxyindoleacetic acid (5-HIAA). The physiology of serotonin is very complex because there are at least seven receptor types, most with multiple subtypes. The 5-HT₃ receptor mediates vomiting and is found in the GI tract and the brain (area postrema). The 5-HT_{2A} receptors are responsible for smooth muscle contraction and platelet aggregation, the 5-HT₄ receptors in the GI tract mediate secretion and peristalsis, and the 5-HT₆ and 5-HT₇ receptors are located primarily in the limbic system where they appear to play a role in depression. All except the 5-HT₃ receptor are coupled to G proteins and affect either adenylyl cyclase or phospholipase C; effects of the 5-HT₃ receptor are mediated via an ion channel.

A. Cardiovascular

Except in the heart and skeletal muscle, serotonin is a powerful vasoconstrictor of arterioles and veins. Its vasodilator effect in the heart is endothelium

dependent. When the myocardial endothelium is damaged following injury, serotonin produces vasoconstriction. The pulmonary and renal vasculatures are very sensitive to the arterial vasoconstrictive effects of serotonin. Modest and transient increases in cardiac contractility and heart rate may occur immediately following serotonin release; reflex bradycardia often follows. Vasodilation in skeletal muscle can subsequently cause hypotension.

B. Respiratory

Contraction of smooth muscle increases airway resistance. Bronchoconstriction from released serotonin is often a prominent feature of carcinoid syndrome

C. Gastrointestinal

Direct smooth muscle contraction (via 5-HT₂ receptors) and serotonin-induced release of acetylcholine in the myenteric plexus (via 5-HT₃ receptors) greatly augment peristalsis. Secretions are unaffected.

D. Hematological

Activation of 5-HT₂ receptors causes platelet aggregation.

Mechanism of Action

4 Ondansetron (Zofran), granisetron (Kytril), and dolasetron (Anzemet) selectively block serotonin 5-HT₃ receptors, with little or no effect on dopamine receptors (**Figure 17-2**). 5-HT₃

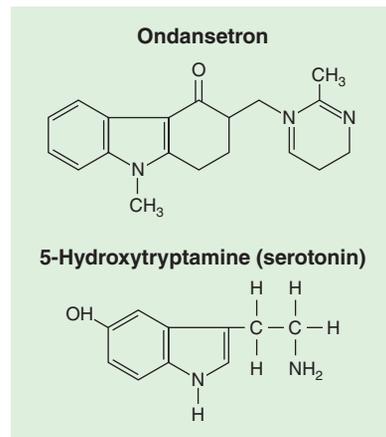

FIGURE 17-2 Ondansetron is structurally related to serotonin.

receptors, which are located peripherally (abdominal vagal afferents) and centrally (chemoreceptor trigger zone of the area postrema and the nucleus tractus solitarius), appear to play an important role in the initiation of the vomiting reflex. The 5-HT₃ receptors of the chemoreceptor trigger zone in the area postrema reside outside the blood–brain barrier. The trigger zone is activated by substances such as anesthetics and opioids and signals the nucleus tractus solitarius, resulting in PONV. Emetogenic stimuli from the GI tract similarly stimulate the development of PONV.

Clinical Uses

5-HT₃-receptor antagonists are generally administered at the end of surgery. All these agents are effective antiemetics in the postoperative period. In comparison with other antiemetic agents such as droperidol (1.25 mg) and dexamethasone (4 mg), ondansetron appears equally effective. A new agent, palonosetron (Aloxi), has an extended duration of action and may reduce the incidence of postdischarge nausea and vomiting (PDNV).

Side Effects

5-HT₃ receptor antagonists are essentially devoid of serious side effects, even in amounts several times the recommended dose. They do not appear to cause sedation, extrapyramidal signs, or respiratory depression. The most commonly reported side effect is headache. All three drugs can slightly prolong the QT interval on the electrocardiogram. This effect may be more frequent with dolasetron, although it has not been associated with any adverse arrhythmias. Nonetheless, these drugs, particularly dolasetron, should be used cautiously in patients who are taking antiarrhythmic drugs or who have a prolonged QT interval.

Ondansetron undergoes extensive metabolism in the liver via hydroxylation and conjugation by cytochrome P-450 enzymes. Liver failure impairs clearance several-fold, and the dose should be reduced accordingly. The recommended intravenous dose is 12.5 mg for dolasetron and 1 mg for granisetron. All three drugs are available in oral formulations for PONV prophylaxis.

BUTYROPHENONES

Droperidol (0.625–1.25 mg) was previously used routinely for PONV prophylaxis. Given at the end of the procedure it blocks dopamine receptors that contribute to the development of PONV. Despite its effectiveness, many practitioners no longer routinely administer this medication because of a U.S. Food and Drug Administration (FDA) black box warning related to concerns that doses described in the product labeling (“package insert”) may lead to QT prolongation and development of torsades des pointes dysrhythmia. However, the doses relevant to the FDA warning, as acknowledged by the FDA, were those used for neurolept anesthesia (5–15 mg), not the much smaller doses employed for PONV. Cardiac monitoring is warranted when large doses of the drug are used. There is no evidence that use of droperidol at the doses routinely employed for PONV management increases the risk of sudden cardiac death in the perioperative population.

As with other drugs that antagonize dopamine, droperidol use in patients with Parkinson’s disease and in patients manifesting extrapyramidal signs should be carefully considered.

The phenothiazine, prochlorperazine (Compazine), which affects multiple receptors (histaminergic, dopaminergic, muscarinic), may be used for PONV management. It may cause extrapyramidal and anticholinergic side effects. Promethazine (Phenergan) works primarily as an anticholinergic agent and antihistamine and likewise can be used to treat PONV. As with other agents of this class, anticholinergic effects (sedation, delirium, confusion, vision changes) can complicate the postoperative period.

DEXAMETHASONE

Dexamethasone (Decadron) in doses as small as 4 mg has been shown to be as effective as ondansetron in reducing the incidence of PONV. Dexamethasone should be given at induction as opposed to the end of surgery, and its mechanism of action is unclear. There appear to be no significant or long-lasting systemic effects from this dose of glucocorticoid.

NEUROKININ-1 RECEPTOR ANTAGONIST

Substance P is a neuropeptide that interacts at neurokinin-1 (NK₁) receptors. NK₁ antagonists inhibit substance P at central and peripheral receptors. Aprepitant (Emend), an NK₁ antagonist, has been found to reduce PONV perioperatively and is additive with ondansetron for this indication.

OTHER PONV STRATEGIES

Several other agents and techniques have been employed to reduce the incidence of PONV. Transdermal scopolamine has been used effectively, although it may produce central anticholinergic effects (confusion, blurred vision, and dry mouth). Acupuncture, acupressure, and transcutaneous electrical stimulation of the P6 acupuncture point can reduce PONV incidence and medication requirements.

As no single agent will both treat and prevent PONV, perioperative management centers on identifying patients at greatest risk so that prophylaxis, often with multiple agents, may be initiated.

Other Drugs Used as Adjuvants to Anesthesia

KETOROLAC

Mechanism of Action

5 Ketorolac is a parenteral nonsteroidal antiinflammatory drug (NSAID) that provides analgesia by inhibiting prostaglandin synthesis.

Clinical Uses

Ketorolac is indicated for the short-term (<5 days) management of pain, and appears to be particularly useful in the immediate postoperative period. A standard dose of ketorolac provides analgesia equivalent to 6–12 mg of morphine administered by the same route. Its time to onset is also similar to morphine, but ketorolac has a longer duration of action (6–8 h).

Ketorolac, a peripherally acting drug, has become a popular alternative to opioids for postoperative analgesia because of its minimal central nervous system side effects. Specifically, ketorolac does not cause respiratory depression, sedation, or nausea and vomiting. In fact, ketorolac does not cross the blood–brain barrier to any significant degree. Numerous studies have shown that oral and parenteral NSAIDs have an opioid-sparing effect. They may be most beneficial in patients at increased risk for postoperative respiratory depression or emesis.

Side Effects

As with other NSAIDs, ketorolac inhibits platelet aggregation and prolongs bleeding time. It and other NSAIDs should therefore be used with caution in patients at risk for postoperative hemorrhage. Long-term administration may lead to renal toxicity (eg, papillary necrosis) or GI tract ulceration with bleeding and perforation. Because ketorolac depends on elimination, it should not be given to patients with kidney failure. Ketorolac is contraindicated in patients allergic to aspirin or NSAIDs. Patients with asthma have an increased incidence of aspirin sensitivity (approximately 10%), particularly if they also have a history of nasal polyps (approximately 20%).

Dosage

Ketorolac has been approved for administration as either a 60 mg intramuscular or 30 mg intravenous loading dose; a maintenance dose of 15–30 mg every 6 h is recommended. Elderly patients clear ketorolac more slowly and should receive reduced doses.

Drug Interactions

Aspirin decreases the protein binding of ketorolac, increasing the amount of active unbound drug. Ketorolac does not affect minimum alveolar concentration of inhalation anesthetic agents, and its administration does not alter the hemodynamics of anesthetized patients. It decreases the postoperative requirement for opioid analgesics.

Other NSAID Adjuvant Drugs

Other NSAID agents are used perioperatively. Ketorolac and other NSAIDs inhibit cyclooxygenase

(COX) isoenzymes. COX-1 maintains gastric mucosa and stimulates platelet aggregation. COX-2 is expressed during inflammation. Whereas ketorolac is a nonselective COX inhibitor, other agents such as parecoxib (Dynastat), celecoxib (Celebrex), and rofecoxib (Vioxx) are specific for COX-2. COX-2 inhibitors spare both the gastric mucosa and platelet function. However, their use is associated with an increased risk of cardiovascular thromboembolic events. Because nonspecific NSAIDs such as ketorolac also inhibit COX-2, their use following cardiac bypass surgery is contraindicated.

Intravenous acetaminophen (Ofirmev) has recently become available for perioperative use in the United States. Acetaminophen is a centrally acting analgesic with likely central COX inhibition and with weak peripheral COX effects resulting in a lack of gastric irritation and clotting abnormalities. A maximal adult (>50 kg weight) dose of 1 g is infused to a maximum total dose of 4 g/d. Patients weighing 50 kg or less should receive a maximal dose of 15 mg/kg and a maximal total dose of 75 mg/kg/d. Hepatotoxicity is a known risk of overdose, and the drug should be used with caution in patients with hepatic disease or undergoing hepatic surgery.

CLONIDINE

Mechanism of Action

Clonidine (Catapres, Duraclon) is an imidazoline derivative with predominantly α_2 -adrenergic agonist activity. It is highly lipid soluble and readily penetrates the blood–brain barrier and the placenta. Studies indicate that binding of clonidine to receptors is highest in the rostral ventrolateral medulla in the brainstem (the final common pathway for sympathetic outflow) where it activates inhibitory neurons. The overall effect is to decrease sympathetic activity, enhance parasympathetic tone, and reduce circulating catecholamines. There is also evidence that much of clonidine's antihypertensive action occurs via binding to a nonadrenergic (imidazoline) receptor. In contrast, its analgesic effects, particularly in the spinal cord, are mediated entirely via pre- and possibly postsynaptic α_2 -adrenergic receptors that block nociceptive transmission. Clonidine also has local anesthetic effects when applied to

peripheral nerves and is frequently added to local anesthetic solutions.

Clinical Uses

6 Clonidine is a commonly used antihypertensive agent that reduces sympathetic tone, decreasing systemic vascular resistance, heart rate, and blood pressure. In anesthesia, clonidine is used as an adjunct for epidural, caudal, and peripheral nerve block anesthesia and analgesia. It is often used in the management of patients with chronic neuropathic pain to increase the efficacy of epidural opioid infusions. When given epidurally, the analgesic effect of clonidine is segmental, being localized to the level at which it is injected or infused. When added to local anesthetics of intermediate duration (eg, mepivacaine or lidocaine) administered for epidural or peripheral nerve block, clonidine will markedly prolong both the anesthetic and analgesic effects.

Unlabeled/investigational uses of clonidine include serving as an adjunct in premedication, control of withdrawal syndromes (nicotine, opioids, alcohol, and vasomotor symptoms of menopause), and treatment of glaucoma as well as various psychiatric disorders.

Side Effects

Sedation, dizziness, bradycardia, and dry mouth are common side effects. Less commonly, bradycardia, orthostatic hypotension, nausea, and diarrhea may be observed. Abrupt discontinuation of clonidine following long-term administration (>1 mo) can produce a withdrawal phenomenon characterized by rebound hypertension, agitation, and sympathetic overactivity.

Dosage

Epidural clonidine is usually started at 30 mcg/h in a mixture with an opioid or a local anesthetic. Oral clonidine is readily absorbed, has a 30–60 min onset, and lasts 6–12 h. In the treatment of acute hypertension, 0.1 mg can be given orally every hour until the blood pressure is controlled, or up to a maximum of 0.6 mg; the maintenance dose is 0.1–0.3 mg twice daily. Transdermal preparations of clonidine can also be used for maintenance therapy. They are available as 0.1, 0.2, and 0.3 mg/d patches that are replaced

every 7 days. Clonidine is metabolized by the liver and excreted renally. Dosages should be reduced for patients with renal insufficiency.

Drug Interactions

Clonidine enhances and prolongs sensory and motor blockade from local anesthetics. Additive effects with hypnotic agents, general anesthetics, and sedatives can potentiate sedation, hypotension, and bradycardia. The drug should be used cautiously, if at all, in patients who take β -adrenergic blockers and in those with significant cardiac conduction system abnormalities. Lastly, clonidine can mask the symptoms of hypoglycemia in diabetic patients.

DEXMEDETOMIDINE

Mechanism of Action

7 Dexmedetomidine (Precedex) is a parenteral selective α_2 agonist with sedative properties. It appears to be more selective for the α_2 receptor than clonidine. At higher doses it loses its selectivity and also stimulates α_1 -adrenergic receptors.

Clinical Uses

Dexmedetomidine causes dose-dependent sedation, anxiolysis, and some analgesia and blunts the sympathetic response to surgery and other stress. Most importantly, it has an opioid-sparing effect and does not significantly depress respiratory drive; excessive sedation, however, may cause airway obstruction. The drug is used for short-term (<24 h), intravenous sedation of mechanically ventilated patients. Discontinuation after more prolonged use can potentially cause a withdrawal phenomenon similar to that of clonidine. It has also been used for intraoperative sedation and as an adjunct to general anesthetics.

Side Effects

The principal side effects are bradycardia, heart block, and hypotension. It may also cause nausea.

Dosage

The recommended initial loading dose is 1 mcg/kg intravenously over 10 min with a maintenance

infusion rate of 0.2–0.7 mcg/kg/h. Dexmedetomidine has a rapid onset and terminal half-life of 2 h. The drug is metabolized in the liver and its metabolites are eliminated in the urine. Dosage should be reduced in patients with renal insufficiency or hepatic impairment.

Drug Interactions

Caution should be used when dexmedetomidine is administered with vasodilators, cardiac depressants, and drugs that decrease heart rate. Reduced requirements of hypnotics/anesthetic agents should prevent excessive hypotension.

DOXAPRAM

Mechanism of Action

Doxapram (Dopram) is a peripheral and central nervous system stimulant. Selective activation **8** of carotid chemoreceptors by low doses of doxapram stimulates hypoxic drive, producing an increase in tidal volume and a slight increase in respiratory rate. At larger doses, the central respiratory centers in the medulla are stimulated.

Clinical Uses

Because doxapram mimics a low PaO_2 , it may be useful in patients with chronic obstructive pulmonary disease who are dependent on hypoxic drive yet require supplemental oxygen. Drug-induced respiratory and central nervous system depression, including that seen immediately postoperatively, can be *temporarily* overcome. Doxapram is not a specific reversal agent, however, and should not replace standard supportive therapy (mechanical ventilation). For example, doxapram will not reverse paralysis caused by muscle relaxants, although it may transiently mask respiratory failure. The most common cause of postoperative hypoventilation—airway obstruction—will not be alleviated by doxapram. For these reasons, many anesthesiologists believe that the usefulness of doxapram is very limited.

Side Effects

Stimulation of the central nervous system leads to a variety of possible side effects: changes in mental

status (confusion, dizziness, seizures), cardiac abnormalities (tachycardia, dysrhythmias, hypertension), and pulmonary dysfunction (wheezing, tachypnea). Vomiting and laryngospasm are of particular concern to the anesthesiologist in the postoperative period. Doxapram should not be used in patients with a history of epilepsy, cerebrovascular disease, acute head injury, coronary artery disease, hypertension, or bronchial asthma.

Dosage

Bolus intravenous administration (0.5–1 mg/kg) results in transient increases in minute ventilation (the onset of action is 1 min; the duration of action is 5–12 min). Continuous intravenous infusions (1–3 mg/min) provide longer-lasting effects (the maximum dose is 4 mg/kg).

Drug Interactions

The sympathetic stimulation produced by doxapram may exaggerate the cardiovascular effects of monoamine oxidase inhibitors or adrenergic agents. Doxapram should probably not be used in patients awakening from halothane anesthesia, as halothane sensitizes the myocardium to catecholamines.

NALOXONE

Mechanism of Action

Naloxone (Narcan) is a competitive opioid receptor antagonist. Its affinity for opioid μ receptors appears to be much greater than for opioid κ or δ receptors. Naloxone has no significant agonist activity.

Clinical Uses

9 Naloxone reverses the agonist activity associated with endogenous (enkephalins, endorphins) or exogenous opioid compounds. A dramatic example is the reversal of unconsciousness that occurs in a patient with opioid overdose who has received naloxone. Perioperative respiratory depression caused by excessive opioid administration is rapidly antagonized (1–2 min). Some degree of opioid analgesia can often be spared if the dose

of naloxone is limited to the minimum required to maintain adequate ventilation. Low doses of intravenous naloxone reverse the side effects of epidural opioids without necessarily reversing the analgesia.

Side Effects

Abrupt reversal of opioid analgesia can result in sympathetic stimulation (tachycardia, ventricular irritability, hypertension, pulmonary edema) caused by severe, acute pain, and an acute withdrawal syndrome in patients who are opioid-dependent. The extent of these side effects is proportional to the amount of opioid being reversed and the speed of the reversal.

Dosage

In postoperative patients experiencing respiratory depression from excessive opioid administration, intravenous naloxone (0.4 mg/mL vial diluted in 9 mL saline to 0.04 mg/mL) can be titrated in increments of 0.5–1 mcg/kg every 3–5 min until adequate ventilation and alertness are achieved. Doses in excess of 0.2 mg are rarely indicated. The brief duration of action of intravenous naloxone (30–45 min) is due to rapid redistribution from the central nervous system. A more prolonged effect is almost always necessary to prevent the recurrence of respiratory depression from longer-acting opioids. Therefore, intramuscular naloxone (twice the required intravenous dose) or a continuous infusion (4–5 mcg/kg/h) is recommended. Neonatal respiratory depression resulting from maternal opioid administration is treated with 10 mcg/kg, repeated in 2 min if necessary. Neonates of opioid-dependent mothers will exhibit withdrawal symptoms if given naloxone. The primary treatment of respiratory depression is always establishment of an adequate airway to permit spontaneous, assisted, or controlled ventilation.

Drug Interactions

The effect of naloxone on nonopioid anesthetic agents such as nitrous oxide is insignificant. Naloxone may antagonize the antihypertensive effect of clonidine.

NALTREXONE

Naltrexone is also a pure opioid antagonist with a high affinity for the μ receptor, but with a significantly longer half-life than naloxone. Naltrexone is used orally for maintenance treatment of opioid addicts and for ethanol abuse. In the latter instance, it appears to block some of the pleasant effects of alcohol in some individuals.

FLUMAZENIL

Mechanism of Action

Flumazenil (Romazicon), an imidazobenzodiazepine, is a specific and competitive antagonist of benzodiazepines at benzodiazepine receptors.

Clinical Uses

10 Flumazenil is useful in the reversal of benzodiazepine sedation and the treatment of benzodiazepine overdose. Although it promptly (onset <1 min) reverses the hypnotic effects of benzodiazepines, amnesia has proved to be less reliably prevented. Some evidence of respiratory depression may linger despite an alert and awake appearance. Specifically, tidal volume and minute ventilation return to normal, but the slope of the carbon dioxide response curve remains depressed. Effects in elderly patients appear to be particularly difficult to reverse fully, and these patients are more prone to re sedation.

Side Effects & Drug Interactions

Rapid administration of flumazenil may cause anxiety reactions in previously sedated patients and symptoms of withdrawal in those on long-term benzodiazepine therapy. Flumazenil reversal has been associated with increases in intracranial pressure in patients with head injuries and abnormal intracranial compliance. Flumazenil may induce seizure activity if benzodiazepines have been given as anticonvulsants or in conjunction with an overdose of tricyclic antidepressants. Flumazenil reversal following a midazolam–ketamine anesthetic technique may increase the incidence of emergence dysphoria and hallucinations. Nausea and vomiting are not uncommon following administration of

flumazenil. The reversal effect of flumazenil is based on its strong antagonist affinity for benzodiazepine receptors. Flumazenil does not affect the minimum alveolar concentration of inhalation anesthetics.

Dosage

Gradual titration of flumazenil is usually accomplished by intravenous administration of 0.2 mg/min until reaching the desired degree of reversal. The usual total dose is 0.6–1.0 mg. Because of flumazenil's rapid hepatic clearance, repeat doses may be required after 1–2 h to avoid re sedation and premature recovery room or outpatient discharge. A continuous infusion (0.5 mg/h) may be helpful in the case of an overdose of a longer-acting benzodiazepine. Liver failure prolongs the clearance of flumazenil and benzodiazepines.

CASE DISCUSSION

Management of Patients at Risk for Aspiration Pneumonia

A 58-year-old man is scheduled for elective inguinal hernia repair. His past history reveals a persistent problem with heartburn and passive regurgitation of gastric contents into the pharynx. He has been told by his internist that these symptoms are due to a hiatal hernia.

Why would a history of hiatal hernia concern the anesthesiologist?

Perioperative aspiration of gastric contents (Mendelson's syndrome) is a potentially fatal complication of anesthesia. Hiatal hernia is commonly associated with symptomatic GERD, which is considered a predisposing factor for aspiration. Mild or occasional heartburn may not significantly increase the risk of aspiration. In contrast, symptoms related to passive reflux of gastric fluid, such as acid taste or sensation of refluxing liquid into the mouth, should alert the clinician to a high risk of pulmonary aspiration. Paroxysms of coughing or wheezing, particularly at night or when the patient is flat, may be indicative of chronic aspiration. Aspiration can occur on induction, during maintenance, or upon emergence from anesthesia.

Which patients are predisposed to aspiration?

Patients with altered airway reflexes (eg, drug intoxication, general anesthesia, encephalopathy, neuromuscular disease) or abnormal pharyngeal or esophageal anatomy (eg, large hiatal hernia, Zenker's diverticulum, scleroderma, pregnancy, obesity) are prone to pulmonary aspiration.

11 Does aspiration consistently result in aspiration pneumonia?

Not necessarily. The seriousness of the lung damage depends on the volume and composition of the aspirate. Traditionally, patients are considered to be at risk if their gastric volume is greater than 25 mL (0.4 mL/kg) and their gastric pH is less than 2.5. Some investigators believe that controlling acidity is more important than volume and that the criteria should be revised to a pH less than 3.5 with a volume greater than 50 mL.

Patients who have eaten immediately prior to emergency surgery are obviously at risk. Traditionally, "NPO after midnight" implied a preoperative fast of at least 6 h. Current opinion allows clear liquids until 2–4 h before induction of anesthesia, although solids are still taboo for 6 h in adult patients. Some patients who have fasted for 8 h or more before elective surgery also meet the at-risk criteria, however. Certain patient populations are particularly likely to have large volumes of acidic gastric fluid: patients with an acute abdomen or peptic ulcer disease, children, the elderly, diabetic patients, pregnant women, and obese patients. Furthermore, pain, anxiety, or opioid-agonists may delay gastric emptying. Note that pregnancy and obesity place patients in double jeopardy by increasing the chance of aspiration (increased intraabdominal pressure and distortion of the lower esophageal sphincter) and the risk of aspiration pneumonia (increased acidity and volume of gastric contents). Aspiration is more common in patients undergoing esophageal, upper abdominal, or emergency laparoscopic surgery.

Which drugs lower the risk of aspiration pneumonia?

H₂-Receptor antagonists decrease gastric acid secretion. Although they will not affect gastric

contents already in the stomach, they will inhibit further acid production. Both gastric pH and volume are affected. In addition, the long duration of action of ranitidine and famotidine may provide protection in the recovery room.

Metoclopramide shortens gastric emptying time and increases lower esophageal sphincter tone. It does not affect gastric pH, and it cannot clear large volumes of food in a few hours. Nonetheless, metoclopramide with ranitidine is a good combination for most at-risk patients. Antacids usually raise gastric fluid pH, but, at the same time, they increase gastric volume. Although antacid administration technically removes a patient from the at-risk category, aspiration of a substantial volume of particulate matter will lead to serious physiological damage. For this reason, clear antacids (eg, sodium citrate) are strongly preferred. In contrast to H₂ antagonists, antacids are immediately effective and alter the acidity of existing gastric contents. Thus, they are useful in emergency situations and in patients who have recently eaten.

Anticholinergic drugs, particularly glycopyrrolate, decrease gastric secretions if large doses are administered; however, lower esophageal sphincter tone is reduced. Overall, anticholinergic drugs do not reliably reduce the risk of aspiration pneumonia and can reverse the protective effects of metoclopramide. Proton pump inhibitors are generally as effective as H₂ antagonists.

What anesthetic techniques are used in full-stomach patients?

If the full stomach is due to recent food intake and the surgical procedure is elective, the operation should be postponed. If the risk factor is not reversible (eg, large hiatal hernia) or the case is emergent, proper anesthetic technique can minimize the risk of aspiration pneumonia. Regional anesthesia with minimal sedation should be considered in patients at increased risk for aspiration pneumonia. If local anesthetic techniques are impractical, the patient's airway must be protected. Delivering anesthesia by mask or laryngeal mask airway is contraindicated. As in every

anesthetic case, the availability of suction must be confirmed before induction. If there are signs suggesting a difficult airway, intubation should precede induction. Otherwise, a rapid-sequence induction is indicated.

How does a rapid-sequence induction differ from a routine induction?

- The patient is always preoxygenated prior to induction. Patients with lung disease require 3–5 min of preoxygenation.
- Prior curarization with a nondepolarizing muscle relaxant may prevent the increase in intraabdominal pressure that accompanies the fasciculations caused by succinylcholine. This step is often omitted, however, as it can decrease lower esophageal sphincter tone. If rocuronium has been selected for relaxation, a small priming dose (0.1 mg/kg) given 2–3 min prior to induction may speed its onset of action.
- A wide assortment of blades, video laryngoscopes, and endotracheal tubes are prepared in advance.
- An assistant may apply firm pressure over the cricoid cartilage prior to induction (Sellick's maneuver). Because the cricoid cartilage forms an uninterrupted and incompressible ring, pressure over it is transmitted to underlying tissue. The esophagus is collapsed, and passively regurgitated gastric fluid cannot reach the hypopharynx. Excessive cricoid pressure (beyond what can be tolerated by a conscious person) applied during active regurgitation has been associated with rupture of the posterior wall of the esophagus. The effectiveness of Sellick's maneuver has been questioned.
- A propofol induction dose is given as a bolus. Obviously, this dose must be modified if there is any indication that the patient's cardiovascular system is unstable. Other rapid-acting induction agents can be substituted (eg, etomidate, ketamine).
- Succinylcholine (1.5 mg/kg) or rocuronium (0.9–1.2 mg/kg) is administered immediately following the induction dose, even if the patient has not yet lost consciousness.

- The patient is not artificially ventilated, to avoid filling the stomach with gas and thereby increasing the risk of emesis. Once spontaneous efforts have ceased or muscle response to nerve stimulation has disappeared, the patient is rapidly intubated. Cricoid pressure is maintained until the endotracheal tube cuff is inflated and tube position is confirmed. A modification of the classic rapid-sequence induction allows gentle ventilation as long as cricoid pressure is maintained.
- If the intubation proves difficult, cricoid pressure is maintained and the patient is gently ventilated with oxygen until another intubation attempt can be performed. If intubation is still unsuccessful, spontaneous ventilation should be allowed to return and an awake intubation performed.
- After surgery, the patient should remain intubated until airway reflexes have returned and consciousness has been regained.

What are the relative contraindications to rapid-sequence inductions?

Rapid-sequence inductions are usually associated with increases in intracranial pressure, arterial blood pressure, and heart rate. Contraindications to succinylcholine also apply (eg, thermal burns).

Describe the pathophysiology and clinical findings associated with aspiration pneumonia.

The pathophysiological changes depend on the composition of the aspirate. Acid solutions cause atelectasis, alveolar edema, and loss of surfactant. Particulate aspirate will also result in small-airway obstruction and alveolar necrosis. Granulomas may form around food or antacid particles. The earliest physiological change following aspiration is intrapulmonary shunting, resulting in hypoxia. Other changes may include pulmonary edema, pulmonary hypertension, and hypercapnia.

Wheezing, rhonchi, tachycardia, and tachypnea are common physical findings. Decreased lung compliance can make ventilation difficult. Hypotension signals significant fluid shifts into the alveoli and is associated with massive lung injury.

Chest roentgenography may not demonstrate diffuse bilateral infiltrates for several hours after the event. Arterial blood gases reveal hypoxemia, hypercapnia, and respiratory acidosis.

What is the treatment for aspiration pneumonia?

As soon as regurgitation is suspected, the patient should be placed in a head-down position so that gastric contents drain out of the mouth instead of into the trachea. The pharynx and, if possible, the trachea should be thoroughly suctioned. The mainstay of therapy in patients who subsequently become hypoxic is positive-pressure ventilation. Intubation and the institution of positive end-expiratory pressure or continuous positive airway pressure are often required. Bronchoscopy and pulmonary lavage are usually indicated when particulate aspiration has occurred. Use of corticosteroids is generally not recommended and antibiotics are administered depending upon culture results.

Preoperative Assessment, Premedication, & Perioperative Documentation

KEY CONCEPTS

- 1 The cornerstones of an effective preoperative evaluation are the history and physical examination, which should include a complete account of all medications taken by the patient in the recent past, all pertinent drug and contact allergies, and responses and reactions to previous anesthetics.
- 2 The anesthesiologist should not be expected to provide the risk-versus-benefit discussion for the proposed procedure; this is the responsibility and purview of the responsible surgeon or “proceduralist.”
- 3 By convention physicians in many countries use the American Society of Anesthesiologists’ classification to identify relative risk prior to conscious sedation and surgical anesthesia.
- 4 In general, the indications for cardiovascular investigations are the same in surgical patients as in any other patient.
- 5 Adequacy of long-term blood glucose control can be easily and rapidly assessed by measurement of hemoglobin A_{1c}.
- 6 In patients deemed at high risk for thrombosis (eg, those with certain mechanical heart valve implants or with atrial fibrillation and a prior thromboembolic stroke), warfarin should be replaced by intravenous heparin or, more commonly, by intramuscular heparinoids to minimize the risk.
- 7 Current guidelines recommend postponing all but mandatory emergency surgery until at least 1 month after any coronary intervention and suggest that treatment options *other* than a drug-eluting stent (which requires prolonged dual antiplatelet therapy) be used in patients expected to undergo a surgical procedure within 12 months after the intervention.
- 8 There are no good outcomes data to support restricting fluid intake (of any kind or any amount) more than 2 h before induction of general anesthesia in healthy patients undergoing elective procedures; indeed, there is evidence that nondiabetic patients should be encouraged to drink glucose-containing fluids up to 2 h before induction of anesthesia.
- 9 To be valuable, preoperative testing must discriminate: an increased perioperative risk exists when the results are abnormal (and unknown); a reduced risk exists when the abnormality is absent or detected (and perhaps corrected).

—Continued next page

Continued—

- 10 The utility of a test depends on its sensitivity and specificity. Sensitive tests have a low rate of false-negative results and rarely fail to identify an abnormality when one is present, whereas specific tests have a low rate of false-positive results and rarely identify an abnormality when one is not present.
- 11 Premedication should be given purposefully, not as a mindless routine.
- 12 Incomplete, inaccurate, or illegible records unnecessarily complicate defending a physician against otherwise unjustified allegations of malpractice.

PREOPERATIVE EVALUATION

1 The cornerstones of an effective preoperative evaluation are the medical history and physical examination, which should include a complete account of all medications taken by the patient in the recent past, all pertinent drug and contact allergies, and responses and reactions to previous anesthetics. Additionally, this evaluation should include any indicated diagnostic tests, imaging procedures, or consultations from other physicians. The preoperative evaluation guides the anesthetic plan: inadequate preoperative planning and incomplete patient preparation are commonly associated with anesthetic complications.

The preoperative evaluation serves multiple purposes. One purpose is to identify those few patients whose outcomes likely will be improved by implementation of a specific medical treatment (which in rare circumstances may require that the planned surgery be rescheduled). For example, a 60-year-old patient scheduled for elective total hip arthroplasty who also has unstable angina from left main coronary artery disease would more likely survive if coronary artery bypass grafting is performed before the elective procedure. Another purpose is to identify patients whose condition is so poor that the proposed surgery might only hasten death without improving the quality of life. For example, a patient with severe chronic lung disease, end-stage kidney failure, liver failure, and heart failure likely would not survive to derive benefit from an 8-hour, complex, multilevel spinal fusion with instrumentation.

The preoperative evaluation can identify patients with specific characteristics that likely will influence the proposed anesthetic plan (Table 18-1). For example, the anesthetic plan may need to be reassessed for a patient whose trachea appears difficult to intubate, one with a family history of malignant hyperthermia, or one with an infection near where a proposed regional anesthetic would be

TABLE 18-1 The anesthetic plan.

Will sedative-hypnotic premedication be useful?
What type(s) of anesthesia will be employed?
General ¹
Airway management
Induction drugs

Technique(s)
Agent(s)
Sedation and monitored anesthesia care
Supplemental oxygen
Specific sedative drugs
Are there special intraoperative management issues?
Nonstandard monitors
Positions other than supine
Relative or absolute contraindications to specific anesthetic drugs
Fluid management
Special techniques
Site (anesthetizing location) concerns
How will the patient be managed postoperatively?
Management of acute pain
Intensive care
Postoperative ventilation
Hemodynamic monitoring

¹Including need for (or need for avoidance of) muscle relaxation.

administered. Another purpose of the evaluation is to provide the patient with an estimate of anesthetic risk. However, the anesthesiologist should not be expected to provide the risk-versus-benefit discussion for the proposed procedure; this is the responsibility and purview of the responsible surgeon or “proceduralist.” For example, a discussion of the risks and benefits of robotic prostatectomy versus radiation therapy versus “watchful waiting” requires knowledge of both the medical literature and the morbidity–mortality statistics of an individual surgeon, and it would be most unusual for an anesthesiologist to have access to the necessary data for this discussion. Finally, the preoperative evaluation is an opportunity for the anesthesiologist to describe the proposed anesthetic plan in the context of the overall surgical and postoperative plan, provide the patient with psychological support, and obtain informed consent for the proposed anesthetic plan from the surgical patient.

By convention, physicians in many countries use the American Society of Anesthesiologists’ (ASA) classification to define relative risk prior to conscious sedation and surgical anesthesia (Table 18–2). The ASA physical status classification has many advantages over all other risk classification tools: it is time honored, simple, reproducible, and, most importantly, it has been shown to be strongly associated with perioperative risk. But, many other risk assessment tools are available.

Elements of the Preoperative History

Patients presenting for elective surgery and anesthesia typically require a focused preoperative medical history emphasizing cardiac and pulmonary function, kidney disease, endocrine and metabolic diseases, musculoskeletal and anatomic issues relevant to airway management and regional anesthesia, and responses and reactions to previous anesthetics. The ASA publishes and periodically updates general guidelines for preoperative assessment (see Guidelines at end of Chapter).

A. Cardiovascular Issues

Guidelines for preoperative cardiac assessment are available from the American College of Cardiology/

TABLE 18–2 American Society of Anesthesiologists’ physical status classification of patients.¹

Class	Definition
1	Normal healthy patient
2	Patient with mild systemic disease (no functional limitations)
3	Patient with severe systemic disease (some functional limitations)
4	Patient with severe systemic disease that is a constant threat to life (functionality incapacitated)
5	Moribund patient who is not expected to survive without the operation
6	Brain-dead patient whose organs are being removed for donor purposes
E	If the procedure is an emergency, the physical status is followed by “E” (for example, “2E”)

¹Data from Committee on Standards and Practice Parameters, Apfelbaum JL, Connis RT, et al: Practice advisory for preanesthesia evaluation: An updated report by the American Society of Anesthesiologists Task Force on Preanesthesia Evaluation. *Anesthesiology* 2012;116:522.

American Heart Association and from the European Society of Cardiology (see Guidelines). A more complete discussion of cardiovascular assessment is provided in Chapter 21. The focus of preoperative cardiac assessment should be on determining whether the patient’s condition can and must be improved prior to the scheduled procedure, and whether the patient meets criteria for further cardiac evaluation prior to the scheduled surgery. Clearly the criteria for what must be done before elective arthroplasty will differ from what must be done before an operation for resectable pancreatic cancer, given the benign results of a delay in the former procedure and the potential life-shortening effects of a delay in the latter procedure. In general, the indications for cardiovascular investigations are the same in surgical patients as in any other patient. Put another way, the fact that a patient is scheduled to undergo surgery does not change the indications for such measures as noninvasive stress testing to diagnose coronary artery disease.

B. Pulmonary Issues

Perioperative pulmonary complications, most notably postoperative respiratory depression and respiratory failure, are vexing problems that have become seemingly more common as severe obesity and obstructive sleep apnea have increased in incidence. A recent guideline developed by the American College of Physicians takes an aggressive stance; it identifies patients 60 years of age or older, those with chronic obstructive lung disease, those with markedly reduced exercise tolerance and functional dependence, and those with heart failure as potentially requiring preoperative and postoperative interventions to avoid complications. The risk of postoperative pulmonary complications is closely associated with these factors, and with the following: ASA class (class 3 and 4 patients have a markedly increased risk of pulmonary complications relative to class 1 patients), cigarette smoking, longer surgeries (>4 h), certain types of surgery (abdominal, thoracic, aortic aneurysm, head and neck, and emergency surgery), and general anesthesia (compared with cases in which general anesthesia was not used).

Efforts at prevention of pulmonary complications should focus on cessation of cigarette smoking prior to surgery and on lung expansion techniques (eg, incentive spirometry) after surgery in patients at risk. Patients with asthma, particularly those receiving suboptimal medical management, have a greater risk for bronchospasm during airway manipulation. Appropriate use of analgesia and monitoring are key strategies for avoiding postoperative respiratory depression in patients with obstructive sleep apnea. Further discussion of this topic appears in Chapter 44.

C. Endocrine and Metabolic Issues

Appropriate targets for control of diabetes mellitus and of blood glucose in critically ill patients have been subjects of great debate over the past decade. “Tight” control of blood glucose, with a target level in the normal range, was shown in the Diabetes Control and Complications Trial to improve outcomes in ambulatory patients with type 1 diabetes mellitus. It has become the usual practice to obtain a blood glucose measurement on the morning of elective surgery. Unfortunately, many diabetic patients

presenting for elective surgery do not maintain blood glucose within the desired range. Other patients, who may be unaware that they have type 2 diabetes, present with blood glucose measurements **5** above the normal range. Adequacy of long-term blood glucose control can be easily and rapidly assessed by measurement of hemoglobin A_{1c}. In patients with abnormally elevated hemoglobin A_{1c}, referral to a diabetology service for education about the disease and adjustment of diet and medications to improve metabolic control may be beneficial. Elective surgery should be delayed in patients presenting with marked hyperglycemia; this delay might consist only of rearranging the order of scheduled cases to allow insulin infusion to bring the blood glucose concentration closer to the normal range before surgery begins. A more complete discussion of diabetes mellitus and other perioperative endocrine concerns is provided in Chapter 34.

D. Coagulation Issues

Three important coagulation issues that must be addressed during the preoperative evaluation are (1) how to manage patients who are taking warfarin on a long-term basis; (2) how to manage patients who are taking clopidogrel and related agents; and (3) how to safely provide regional anesthesia to patients who either are receiving long-term anticoagulation therapy or who will receive anticoagulation perioperatively. In the first circumstance, most patients who undergoing anything more involved than minor surgery will require discontinuation of warfarin 5 days in advance of surgery to avoid excessive blood loss. The key question to be answered is whether the patient will require “bridging” therapy with another agent while warfarin is discontinued.

6 In patients deemed at high risk for thrombosis (eg, those with certain mechanical heart valve implants or with atrial fibrillation and a prior thromboembolic stroke), warfarin should be replaced by intravenous heparin or, more commonly, by intramuscular heparinoids to minimize the risk. In patients receiving bridging therapy for a high risk of thrombosis, the risk of death from excessive bleeding is an order of magnitude lower than the risk of death or disability from stroke if the bridging therapy is omitted. Patients at lower risk for thrombosis may have warfarin discontinued and then reinitiated

after successful surgery. Decisions regarding bridging therapy often require consultation with the physician who initiated the warfarin therapy.

Clopidogrel and related agents are most often administered with aspirin (so-called dual antiplatelet therapy) to patients with coronary artery disease who have received intracoronary stenting. Immediately after stenting, such patients are at increased risk of acute myocardial infarction if clopidogrel (or related agents) and aspirin are abruptly discontinued for a surgical procedure.

7 Therefore, current guidelines recommend postponing all but mandatory emergency surgery until at least 1 month after any coronary intervention and suggest that treatment options *other* than a drug-eluting stent (which will require prolonged dual antiplatelet therapy) be used in patients expected to undergo a surgical procedure within 12 months after the intervention (eg, in a patient with colon cancer who requires treatment for coronary disease). As the available drugs, treatment options, and consensus guidelines are updated relatively frequently, we recommend consultation with a cardiologist regarding safe management of patients receiving these agents who require a surgical procedure.

The third circumstance—when it may be safe to perform regional (particularly neuraxial) anesthesia in patients who are or will be receiving anticoagulation therapy—has also been the subject of debate among hematologists and regional anesthesiologists. The American Society of Regional Anesthesia publishes a periodically updated consensus guideline on this topic, and other prominent societies (eg, the European Society of Anaesthesiologists) also provide guidance on this topic. This topic is considered in greater detail in Chapter 45.

E. Gastrointestinal Issues

Since Mendelson's 1946 report, aspiration of gastric contents has been recognized as a potentially disastrous pulmonary complication of surgical anesthesia. It has also been long recognized that the risk of aspiration is increased in certain groups of patients: pregnant women in the second and third trimesters, those whose stomachs have not emptied after a recent meal, and those with serious gastroesophageal reflux disease (GERD).

Although there is a consensus that pregnant women and those who have recently (within 6 h) consumed a full meal should be treated as if they have “full” stomachs, there is less consensus as to the necessary period of time in which patients must fast before elective surgery. Proof of the lack of consensus is the fact that the ASA's guideline on this topic was voted down by the ASA House of Delegates several years in a row before it was presented in a form that received majority approval. The guideline as approved is more permissive of fluid intake than many anesthesiologists would prefer, and many medical centers have policies that are more restrictive than the ASA guideline on this topic. **8** The truth is that there are no good outcomes data to support restricting fluid intake (of any kind or any amount) more than 2 h before induction of general anesthesia in healthy patients undergoing elective procedures; indeed, there is evidence that nondiabetic patients should be encouraged to drink glucose-containing fluids up to 2 h before induction of anesthesia.

Patients with a history of GERD present vexing problems. Some of these patients will clearly be at increased risk for aspiration; others may carry this “self-diagnosis” based on television advertisements or conversations with friends and family, or may have been given this diagnosis by a physician who did not follow the standard diagnostic criteria. Our approach is to treat patients who have only occasional symptoms like any other patient without GERD, and to treat patients with consistent symptoms (multiple times per week) with medications (eg, nonparticulate antacids such as sodium citrate) and techniques (eg, tracheal intubation rather than laryngeal mask airway) as if they were at increased risk for aspiration.

Elements of the Preoperative Physical Examination

The preoperative history and physical examination complement one another: The physical examination may detect abnormalities not apparent from the history, and the history helps focus the physical examination. Examination of healthy asymptomatic patients should include measurement of vital signs (blood pressure, heart rate, respiratory rate, and

temperature) and examination of the airway, heart, lungs, and musculoskeletal system using standard techniques of inspection, auscultation, palpation, and percussion. Before procedures such as a nerve block, regional anesthesia, or invasive monitoring the relevant anatomy should be examined; evidence of infection near the site or of anatomic abnormalities may contraindicate the planned procedure (see Chapters 5, 45, and 46). An abbreviated neurological examination is important when regional anesthesia will likely be used. The preoperative neurological examination serves to document whether any neurological deficits may be present *before* the block is performed.

The anesthesiologist must examine the patient's airway before every anesthetic procedure. The patient's dentition should be inspected for loose or chipped teeth, caps, bridges, or dentures. Poor fit of the anesthesia mask should be expected in edentulous patients and those with significant facial abnormalities. Micrognathia (a short distance between the chin and the hyoid bone), prominent upper incisors, a large tongue, limited range of motion of the temporomandibular joint or cervical spine, or a short or thick neck suggest that difficulty may be encountered in direct laryngoscopy for tracheal intubation (see Chapter 19).

Preoperative Laboratory Testing

Routine laboratory testing when patients are fit and asymptomatic is not recommended. Testing should be guided by the history and physical examination. "Routine" testing is expensive and rarely alters perioperative management; moreover, abnormal values often are overlooked or if recognized may result in unnecessary delays. Nonetheless, despite the lack of evidence of benefit, many physicians order a hematocrit or hemoglobin concentration, urinalysis, serum electrolyte measurements, coagulation studies, an electrocardiogram, and a chest radiograph for all patients, perhaps in the misplaced hope of reducing their exposure to litigation.

9 To be valuable, preoperative testing must discriminate: there must be an increased perioperative risk when the results are abnormal (and unknown when the test is not performed), and there must be a reduced risk when the abnormality is not

detected (or it has been corrected). This requires that the test have a very low rate of false-positive and **10** false-negative results. **The utility of a test depends on its sensitivity and specificity. Sensitive tests have a low rate of false-negative results and rarely fail to identify an abnormality when one is present, whereas specific tests have a low rate of false-positive results and rarely identify an abnormality when one is not present.** The prevalence of a disease or of an abnormal test result varies with the population tested. Testing is therefore most effective when sensitive and specific tests are used in patients in whom the abnormality will be detected frequently enough to justify the expense and inconvenience of the test procedure. Accordingly, laboratory testing should be based on the presence or absence of underlying diseases and drug therapy as detected by the history and physical examination. The nature of the proposed surgery or procedure should also be taken into consideration. Thus, a baseline hemoglobin or hematocrit measurement is desirable in any patient about to undergo a procedure that may result in extensive blood loss and require transfusion, particularly when there is sufficient time to correct anemia preoperatively (eg, with iron supplements).

Testing fertile women for an undiagnosed early pregnancy is controversial and should not be done without the permission of the patient; pregnancy testing involves detection of chorionic gonadotropin in urine or serum. Routine testing for HIV antibody is not indicated. Routine coagulation studies and urinalysis are not cost-effective in asymptomatic healthy patients; nevertheless, a preoperative urinalysis is required by state law in at least one U.S. jurisdiction.

PREMEDICATION

A classic study showed that a preoperative visit from an anesthesiologist resulted in a greater reduction in patient anxiety than preoperative sedative drugs. Yet, there was a time when virtually every patient received premedication before arriving in the preoperative area in anticipation of surgery. Despite the evidence, the belief was that all patients benefitted from sedation and anticholinergics, and most patients would benefit from a preoperative opioid. After such premedication, some patients arrived

in a nearly anesthetized state. With the move to outpatient surgery and “same-day” hospital admission, the practice has shifted. Today, preoperative sedative-hypnotics or opioids are almost never administered before patients arrive in the preoperative holding area (other than for intubated patients who have been previously sedated in the intensive care unit). Children, especially those aged 2–10 years who will experience separation anxiety on being removed from their parent, may benefit from premedication administered in the preoperative holding area. This topic is discussed in Chapter 42. Midazolam, administered either intravenously or orally, is a common method. Adults often receive intravenous midazolam (2–5 mg) once an intravenous line has been established, and if a painful procedure (eg, regional block or a central venous line) will be performed while the patient remains awake, small doses of opioid (typically fentanyl) will often be given. Patients who will undergo airway surgery or extensive airway manipulations benefit from preoperative administration of an anticholinergic agent (glycopyrrolate or atropine) to reduce airway secretions **11** before and during surgery. The fundamental message here is that premedication should be given purposefully, not as a mindless routine.

DOCUMENTATION

Physicians should first and foremost provide high-quality and efficient medical care. Secondly, they must document the care that has been provided. Adequate documentation provides guidance to those who may encounter the patient in the future. It permits others to assess the quality of the care that was given and to provide risk adjustment of outcomes. Adequate documentation is required for a physician to submit a bill for his or her services. Finally, adequate and well-organized documentation (as opposed to inadequate and sloppy documentation) supports a potential defense case should a claim for medical malpractice be filed.

Preoperative Assessment Note

The preoperative assessment note should appear in the patient’s permanent medical record and should describe pertinent findings, including the medical

history, anesthetic history, current medications (and whether they were taken on the day of surgery), physical examination, ASA physical status class, laboratory results, interpretation of imaging, electrocardiograms, and recommendations of any consultants. A comment is particularly important when the consultant’s recommendation will not be followed. As most North American hospitals are transitioning to electronic medical records, the preanesthetic note will often appear as a standardized form.

The preoperative note should briefly describe the anesthetic plan and include a statement regarding informed consent from the patient (or guardian). The plan should indicate whether regional or general anesthesia (or sedation) will be used, and whether invasive monitoring or other advanced techniques will be employed. Documentation of the informed consent discussion sometimes takes the form of a narrative indicating that the plan, alternative plans, and their advantages and disadvantages (including their relative risks) were presented, understood, and accepted by the patient. Alternatively, the patient may be asked to sign a special anesthesia consent form that contains the same information. A sample preanesthetic report form is illustrated in [Figure 18–1](#).

In the United States, The Joint Commission (TJC) requires an immediate preanesthetic reevaluation to determine whether the patient’s status has changed in the time since the preoperative evaluation was performed. Even when the elapsed time is less than a minute, the bureaucracy will not be denied: the “box” must be checked to indicate that there has been no interval change.

Intraoperative Anesthesia Record

The intraoperative anesthesia record ([Figure 18–2](#)) serves many purposes. It functions as documentation of intraoperative monitoring, a reference for future anesthetics for that patient, and a source of data for quality assurance. This record should be terse, pertinent, and accurate. Increasingly, parts of the anesthesia record are generated automatically and recorded electronically. Such anesthesia information management systems (commonly abbreviated AIMS) have many theoretical and practical advantages over the traditional paper record but also introduce all the common pitfalls of

computerization, including the potential for unrecognized recording of artifactual data, the possibility that practitioners will find attending to the computer more interesting than attending to the patient, and the inevitable occurrence of device and software shutdowns. Regardless of whether the record is on paper or electronic it should document the anesthetic care in the operating room by including the following elements:

- Whether there has been a preoperative check of the anesthesia machine and other relevant equipment.
- Whether there has been a reevaluation of the patient immediately prior to induction of anesthesia (a TJC requirement); this generally includes a review of the medical record to search for any new laboratory results or consultation reports.
- Time of administration, dosage, and route of drugs given intraoperatively.
- Intraoperative estimates of blood loss and urinary output.
- Results of laboratory tests obtained during the operation.
- Intravenous fluids and any blood products administered.
- Pertinent procedure notes (such as for tracheal intubation or insertion of invasive monitors).
- A notation regarding specialized intraoperative techniques such as the mode of ventilation, or special techniques such as the use of hypotensive anesthesia, one-lung ventilation, high-frequency jet ventilation, or cardiopulmonary bypass.
- Timing and conduct of intraoperative events such as induction, positioning, surgical incision, and extubation.
- Unusual events or complications (eg, arrhythmias).
- Condition of the patient at the time of release to the postanesthesia or intensive care unit nurse.

By tradition and convention (and, in the United States, according to practice guidelines) arterial

blood pressure and heart rate are recorded graphically no less frequently than at 5-min intervals. Data from other monitors are also usually entered graphically, whereas descriptions of techniques or complications are described in text. In some anesthetizing locations of most hospitals the computerized AIMS will be unavailable. Unfortunately, the conventional, handwritten intraoperative anesthetic record often proves inadequate for documenting critical incidents, such as a cardiac arrest. In such cases, a separate text note inserted in the patient's medical record may be necessary. Careful recording of the timing of events is needed to avoid discrepancies between multiple simultaneous records (anesthesia record, nurses' notes, cardiopulmonary resuscitation record, and other physicians' entries in the medical record). Such discrepancies are frequently targeted by malpractice attorneys as evidence of incompetence, **12** inaccuracy, or deceit. Incomplete, inaccurate, or illegible records unnecessarily complicate defending a physician against otherwise unjustified allegations of malpractice.

Postoperative Notes

The anesthesiologist's immediate responsibility to the patient does not end until the patient has recovered from the effects of the anesthetic. After accompanying the patient to the postanesthesia care unit (PACU), the anesthesiologist should remain with the patient until normal vital signs have been measured and the patient's condition is deemed stable. Before discharge from the PACU, a note should be written by the anesthesiologist to document the patient's recovery from anesthesia, any apparent anesthesia-related complications, the immediate postoperative condition of the patient, and the patient's disposition (discharge to an outpatient area, an inpatient ward, an intensive care unit, or home). In the United States, as of 2009, the Centers for Medicare and Medicaid Services require that certain elements be included in all postoperative notes ([Table 18-3](#)). Recovery from anesthesia should be assessed at least once within 48 h after discharge from the PACU in all inpatients. Postoperative notes should document the general condition of the patient, the presence or absence of any anesthesia-related complications, and any measures undertaken to treat such complications.

CASE DISCUSSION

Medical Malpractice (also see Chapter 54)

A healthy 45-year-old man has a cardiac arrest during an elective laparoscopic inguinal hernia repair. Although cardiopulmonary resuscitation is successful, the patient is left with permanent changes in mental status that preclude his return to work. One year later, the patient files a complaint against the anesthesiologist, surgeon, and hospital.

What four elements must be proved by the plaintiff (patient) to establish negligence on the part of the defendant (physician or hospital)?

1. *Duty*: Once a physician establishes a professional relationship with a patient, the physician owes that patient certain obligations, such as adhering to the “standard of care.”
2. *Breach of Duty*: If these obligations are not fulfilled, the physician has breached his duties to the patient.
3. *Injury*: An injury must result. The injury may result in general damages (eg, pain and suffering) or special damages (eg, loss of income).
4. *Causation*: The plaintiff must demonstrate that the breach of duty was causally related to the injury. But for the breach of duty, the injury

should not have occurred. This proximate cause does not have to be the most important or immediate cause of the injury.

How is the standard of care defined and established?

Individual physicians are expected to perform as any prudent and reasonable physician would in similar circumstances. This does *not* require “best” care or optimal care, only that the care meet the minimum standard of a prudent and reasonable physician. As a specialist, the anesthesiologist is held to a higher standard of knowledge and skill with respect to the subject matter of that specialty than would a general practitioner or a physician in another specialty. Expert witnesses usually provide testimony to define the standard of care in legal proceedings. Although most jurisdictions have extended the “locality rule” to encompass a national standard of care, medical malpractice cases are governed by the laws of the jurisdiction in which the event took place and these may differ from state to state. The specific circumstances pertaining to each individual case are taken into account. The law recognizes that there are differences of opinion and varying schools of thought within the medical profession.

How is causation determined?

It is usually the plaintiff who bears the burden of proving that the injury would not have occurred “but for” the negligence of the physician, or that the physician’s action was a “substantial factor” in causing the injury. An exception is the doctrine of *res ipsa loquitur* (“the thing speaks for itself”), which permits a finding of negligence based solely on the evidence. For example, if a set of car keys were visualized inside a patient on a chest radiograph after a thoracotomy, the doctrine of *res ipsa loquitur* would apply. *Res ipsa loquitur* could not be used in the case under discussion because the plaintiff would have to establish that cardiac arrest could not occur in the absence of negligence and that cardiac arrest could not have been due to something outside the control of the anesthesiologist. An important concept is that causation in civil cases need only be established

by a preponderance of the evidence (“more likely than not”)—as opposed to criminal cases, in which all elements of a charged offense must be proved “beyond a reasonable doubt.”

What factors influence the likelihood of a malpractice suit?

1. *The Physician–Patient Relationship:* This is particularly important for the anesthesiologist, who usually does not meet the patient until immediately before the operation. Another problem is that the patient is unconscious while under the anesthesiologist’s care. Thus, the preoperative and postoperative visits with the patient are often the only opportunities to establish a good relationship with the patient. Family members should also be included during these meetings with patients (provided the patient does not object), particularly during the postoperative visit if there has been an intraoperative complication.
2. *Adequacy of Informed Consent:* Rendering care to a competent patient who does not consent constitutes assault and battery. Consent is not enough, however. The patient should be informed of the contemplated procedure, including its reasonably anticipated risks, its possible benefits, and the therapeutic alternatives. The physician may be liable for a complication—even if it is not due to the negligent performance of a procedure—if a jury is convinced that a reasonable person would have refused treatment if properly informed of the possibility of the complication. This does not mean, of course, that a documented consent relieves from liability physicians who violate the standard of care.
3. *Quality of Documentation:* Careful documentation of the perioperative visits, informed consent, consultations with other specialists, intraoperative events, and postoperative care is essential. The viewpoint of many courts and juries, reinforced by plaintiff’s attorneys, is that “if it isn’t written, it wasn’t done.” It goes without saying that medical records should never be intentionally destroyed or altered.

Airway Management

KEY CONCEPTS

- 1 Improper face mask technique can result in continued deflation of the anesthesia reservoir bag when the adjustable pressure-limiting valve is closed, usually indicating a substantial leak around the mask. In contrast, the generation of high breathing circuit pressures with minimal chest movement and breath sounds implies an obstructed airway or obstructed tubing.
- 2 The laryngeal mask airway partially protects the larynx from pharyngeal secretions, but not gastric regurgitation.
- 3 After insertion of a tracheal tube (TT), the cuff is inflated with the least amount of air necessary to create a seal during positive-pressure ventilation to minimize the pressure transmitted to the tracheal mucosa.
- 4 Although the persistent detection of CO₂ by a capnograph is the best confirmation of tracheal placement of a TT, it cannot exclude bronchial intubation. The earliest evidence of bronchial intubation often is an increase in peak inspiratory pressure.
- 5 After intubation, the cuff of a TT should not be felt above the level of the cricoid cartilage, because a prolonged intralaryngeal location may result in postoperative hoarseness and increases the risk of accidental extubation.
- 6 Unrecognized esophageal intubation can produce catastrophic results. Prevention of this complication depends on direct visualization of the tip of the TT passing through the vocal cords, careful auscultation for the presence of bilateral breath sounds and the absence of gastric gurgling while ventilating through the TT, analysis of exhaled gas for the presence of CO₂ (the most reliable automated method), chest radiography, or use of fiberoptic bronchoscopy.
- 7 Clues to the diagnosis of bronchial intubation include unilateral breath sounds, unexpected hypoxia with pulse oximetry (unreliable with high inspired oxygen concentrations), inability to palpate the TT cuff in the sternal notch during cuff inflation, and decreased breathing bag compliance (high peak inspiratory pressures).
- 8 The large negative intrathoracic pressures generated by a struggling patient in laryngospasm can result in the development of negative-pressure pulmonary edema even in healthy patients.

Expert airway management is an essential skill in anesthetic practice. This chapter reviews the anatomy of the upper respiratory tract; describes the necessary equipment for successful management,

presents various management techniques; and discusses complications of laryngoscopy, intubation, and extubation. Patient safety depends on a thorough understanding of each of these topics.

ANATOMY

The upper airway consists of the pharynx, nose, mouth, larynx, trachea, and main-stem bronchi. The mouth and pharynx are also a part of the upper gastrointestinal tract. The laryngeal structures in part serve to prevent aspiration into the trachea.

There are two openings to the human airway: the nose, which leads to the nasopharynx, and the mouth, which leads to the oropharynx. These passages are separated anteriorly by the palate, but they join posteriorly in the pharynx (Figure 19-1). The pharynx is a U-shaped fibromuscular structure that extends from the base of the skull to the cricoid cartilage at the entrance to the esophagus. It opens anteriorly into the nasal cavity, the mouth, the larynx, and the nasopharynx, oropharynx, and laryngopharynx, respectively. The nasopharynx is separated from the oropharynx by an imaginary plane that extends posteriorly. At the base of the tongue, the epiglottis functionally separates the oropharynx from the laryngopharynx (or hypopharynx).

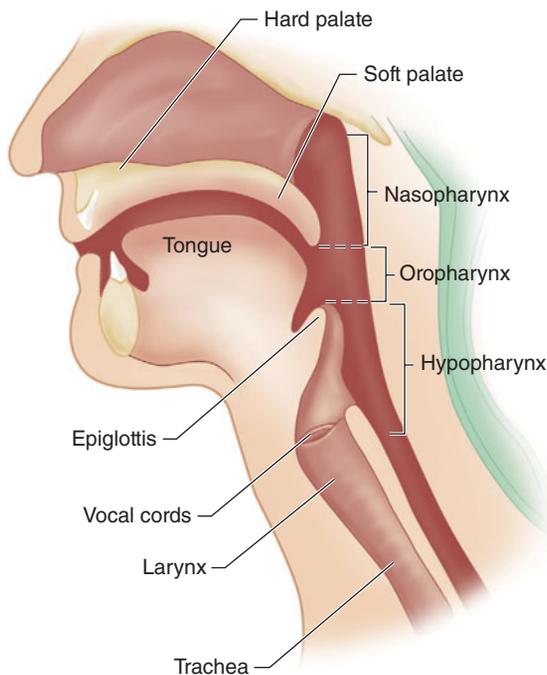

FIGURE 19-1 Anatomy of the airway.

The epiglottis prevents aspiration by covering the glottis—the opening of the larynx—during swallowing. The larynx is a cartilaginous skeleton held together by ligaments and muscle. The larynx is composed of nine cartilages (Figure 19-2): thyroid, cricoid, epiglottic, and (in pairs) arytenoid, corniculate, and cuneiform. The thyroid cartilage shields the conus elasticus, which forms the vocal cords.

The sensory supply to the upper airway is derived from the cranial nerves (Figure 19-3). The mucous membranes of the nose are innervated by the ophthalmic division (V_1) of the trigeminal nerve anteriorly (anterior ethmoidal nerve) and by the maxillary division (V_2) posteriorly (sphenopalatine nerves). The palatine nerves provide sensory fibers from the trigeminal nerve (V) to the superior and inferior surfaces of the hard and soft palate. The **olfactory nerve** (cranial nerve I) innervates the nasal mucosa to provide the sense of smell. The lingual nerve (a branch of the mandibular division [V_3] of the trigeminal nerve) and the glossopharyngeal nerve (the ninth cranial nerve) provide general sensation to the anterior two-thirds and posterior one-third of the tongue, respectively. Branches of the facial nerve (VII) and glossopharyngeal nerve provide the sensation of taste to those areas, respectively. The **glossopharyngeal nerve** also innervates the roof of the pharynx, the tonsils, and the under-surface of the soft palate. The **vagus nerve** (the tenth cranial nerve) provides sensation to the airway below the epiglottis. The superior laryngeal branch of the vagus divides into an external (motor) nerve and an internal (sensory) laryngeal nerve that provide sensory supply to the larynx between the epiglottis and the vocal cords. Another branch of the vagus, the **recurrent laryngeal nerve**, innervates the larynx below the vocal cords and the trachea.

The muscles of the larynx are innervated by the recurrent laryngeal nerve, with the exception of the cricothyroid muscle, which is innervated by the external (motor) laryngeal nerve, a branch of the superior laryngeal nerve. The posterior cricoarytenoid muscles abduct the vocal cords, whereas the lateral cricoarytenoid muscles are the principal adductors.

Phonation involves complex simultaneous actions by several laryngeal muscles. Damage to the motor nerves innervating the larynx leads

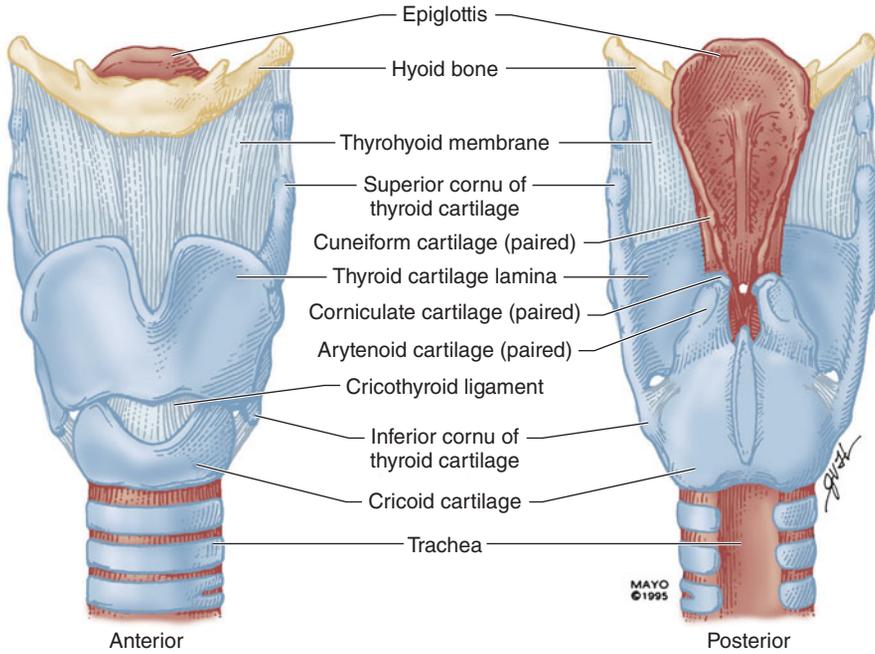

FIGURE 19-2 Cartilaginous structures comprising the larynx. (With permission, from The Mayo Foundation.)

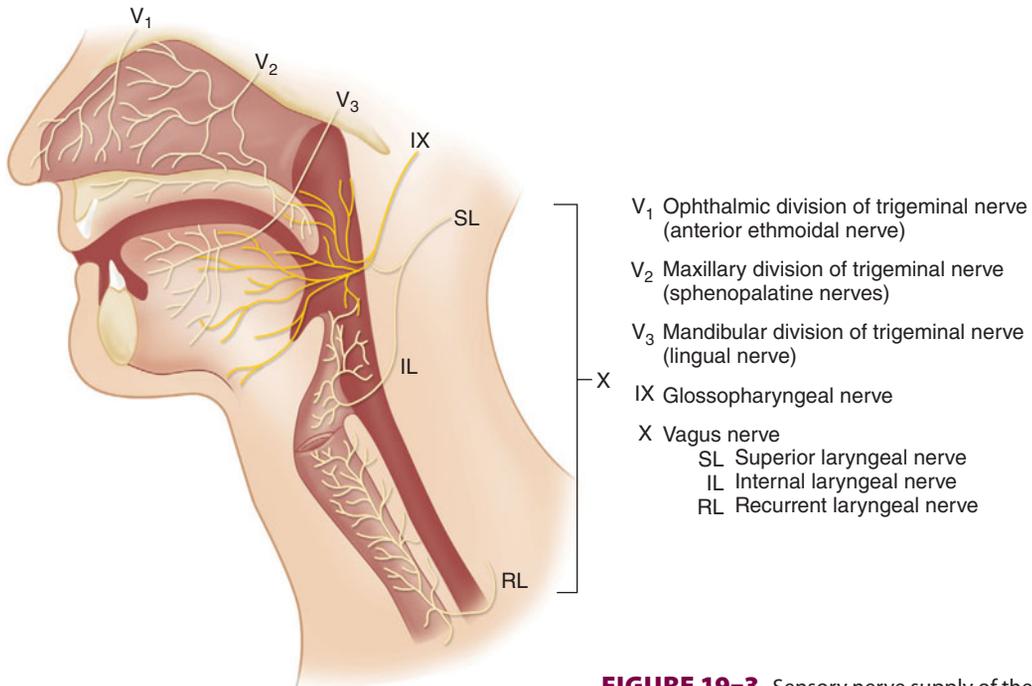

FIGURE 19-3 Sensory nerve supply of the airway.

TABLE 19-1 The effects of laryngeal nerve injury on the voice.

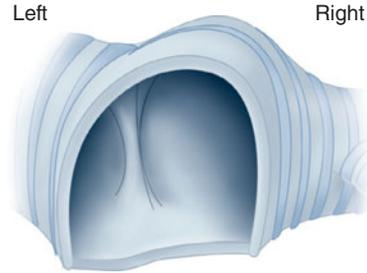

Nerve	Effect of Nerve Injury
Superior laryngeal nerve	
Unilateral	Minimal effects
Bilateral	Hoarseness, tiring of voice
Recurrent laryngeal nerve	
Unilateral	Hoarseness
Bilateral	
Acute	Stridor, respiratory distress
Chronic	Aphonia
Vagus nerve	
Unilateral	Hoarseness
Bilateral	Aphonia

to a spectrum of speech disorders (Table 19-1). Unilateral denervation of a cricothyroid muscle causes very subtle clinical findings. Bilateral palsy of the superior laryngeal nerve may result in hoarseness or easy tiring of the voice, but airway control is not jeopardized.

Unilateral paralysis of a recurrent laryngeal nerve results in paralysis of the ipsilateral vocal cord, causing deterioration in voice quality. Assuming intact superior laryngeal nerves, *acute* bilateral recurrent laryngeal nerve palsy can result in stridor and respiratory distress because of the remaining unopposed tension of the cricothyroid muscles. Airway problems are less frequent in *chronic* bilateral recurrent laryngeal nerve loss because of the development of various compensatory mechanisms (eg, atrophy of the laryngeal musculature).

Bilateral injury to the vagus nerve affects both the superior and the recurrent laryngeal nerves. Thus, bilateral vagal denervation produces flaccid, midpositioned vocal cords similar to those seen after administration of succinylcholine. Although phonation is severely impaired in these patients, airway control is rarely a problem.

The blood supply of the larynx is derived from branches of the thyroid arteries. The cricothyroid artery arises from the superior thyroid artery itself, the first branch given off from the external carotid artery, and crosses the upper cricothyroid membrane (CTM), which extends from the cricoid cartilage to

**FIGURE 19-4** Carina.

the thyroid cartilage. The superior thyroid artery is found along the lateral edge of the CTM.

The trachea begins beneath the cricoid cartilage and extends to the carina, the point at which the right and left main-stem bronchi divide (Figure 19-4). Anteriorly, the trachea consists of cartilaginous rings; posteriorly, the trachea is membranous.

ROUTINE AIRWAY MANAGEMENT

Routine airway management associated with general anesthesia consists of:

- Airway assessment
- Preparation and equipment check
- Patient positioning
- Preoxygenation
- Bag and mask ventilation (BMV)
- Intubation (if indicated)
- Confirmation of endotracheal tube placement
- Intraoperative management and troubleshooting
- Extubation

AIRWAY ASSESSMENT

Airway assessment is the first step in successful airway management. Several anatomical and functional maneuvers can be performed to estimate the difficulty of endotracheal intubation; however, it is important to note that successful ventilation (with or without intubation) must be achieved by

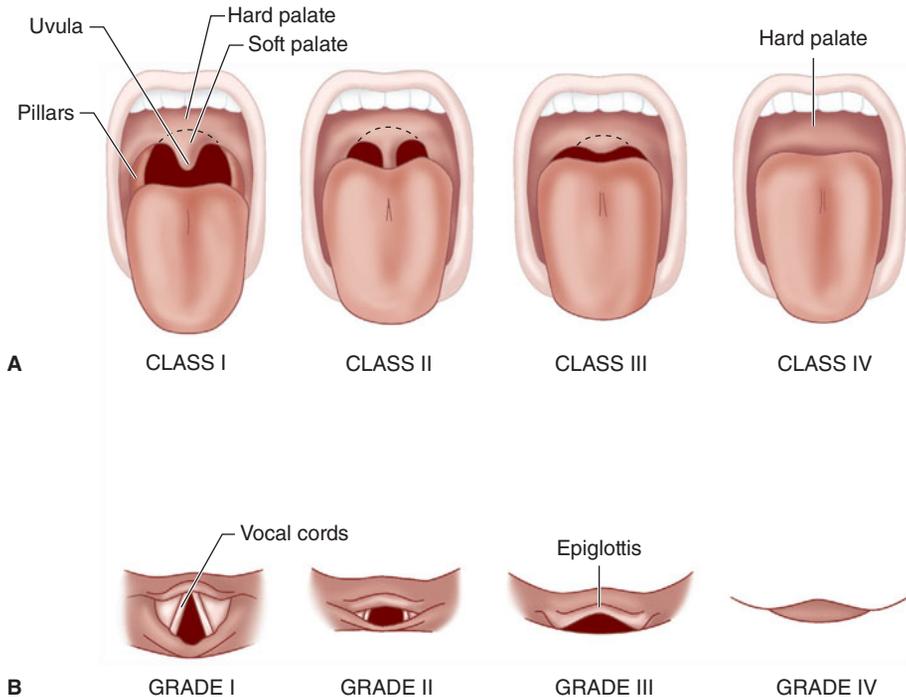

FIGURE 19-5 **A:** Mallampati classification of oral opening. **B:** Grading of the laryngeal view. A difficult orotracheal intubation (grade III or IV) may be predicted by the inability to visualize certain pharyngeal structures

(class III or IV) during the preoperative examination of a seated patient. (Reproduced, with permission, from Mallampati SR: Clinical signs to predict difficult tracheal intubation [hypothesis]. *Can Anaesth Soc J* 1983;30:316.)

the anesthetist if mortality and morbidity are to be avoided. Assessments include:

- Mouth opening: an incisor distance of 3 cm or greater is desirable in an adult.
- Upper lip bite test: the lower teeth are brought in front of the upper teeth. The degree to which this can be done estimates the range of motion of the temporomandibular joints.
- Mallampati classification: a frequently performed test that examines the size of the tongue in relation to the oral cavity. The greater the tongue obstructs the view of the pharyngeal structures, the more difficult intubation may be ([Figure 19-5](#)).
 - Class I: the entire palatal arch, including the bilateral faucial pillars, are visible down to their bases.

- Class II: the upper part of the faucial pillars and most of the uvula are visible.
- Class III: only the soft and hard palates are visible.
- Class IV: only the hard palate is visible.
- Thyromental distance: the distance between the mentum and the superior thyroid notch. A distance greater than 3 fingerbreadths is desirable.
- Neck circumference: a neck circumference of greater than 27 in is suggestive of difficulties in visualization of the glottic opening.

Although the presence of these findings may not be particularly sensitive for detecting a difficult intubation, the absence of these findings is predictive for relative ease of intubation.

Increasingly, patients present with morbid obesity and body mass indices of 30 kg/m² or greater. Although some morbidly obese patients have relatively normal head and neck anatomy, others have much redundant pharyngeal tissue and increased neck circumference. Not only may these patients prove to be difficult to intubate, but routine ventilation with bag and mask also may be problematic.

EQUIPMENT

Preparation is mandatory for all airway management scenarios. The following equipment is routinely needed in airway management situations:

- An oxygen source
- BMV capability
- Laryngoscopes (direct and video)
- Several endotracheal tubes of different sizes
- Other (not endotracheal tube) airway devices (eg, oral, nasal airways)
- Suction
- Oximetry and CO₂ detection
- Stethoscope
- Tape
- Blood pressure and electrocardiography (ECG) monitors
- Intravenous access

Oral & Nasal Airways

Loss of upper airway muscle tone (eg, weakness of the genioglossus muscle) in anesthetized patients allows the tongue and epiglottis to fall back against the posterior wall of the pharynx. Repositioning the head or a jaw thrust is the preferred technique for opening the airway. To maintain the opening, an artificial airway can be inserted through the mouth or nose to maintain an air passage between the tongue and the posterior pharyngeal wall (**Figure 19–6**). Awake or lightly anesthetized patients with intact laryngeal reflexes may cough or even develop laryngospasm during airway insertion. Placement of an oral airway is sometimes facilitated by suppressing airway reflexes, and, in addition, sometimes by depressing the tongue with a tongue blade. Adult oral airways typically come in small (80 mm [Guedel No. 3]), medium (90 mm [Guedel No. 4]), and large (100 mm [Guedel No. 5]) sizes.

The length of a nasal airway can be estimated as the distance from the nares to the meatus of the ear and should be approximately 2–4 cm longer than oral airways. Because of the risk of epistaxis, nasal airways are less desirable in anticoagulated or thrombocytopenic patients. Also, nasal airways (and nasogastric tubes) should be used with caution in patients with basilar skull fractures, where there has been a case report of a nasogastric tube entering the cranial vault. All tubes inserted through the nose (eg, nasal airways, nasogastric

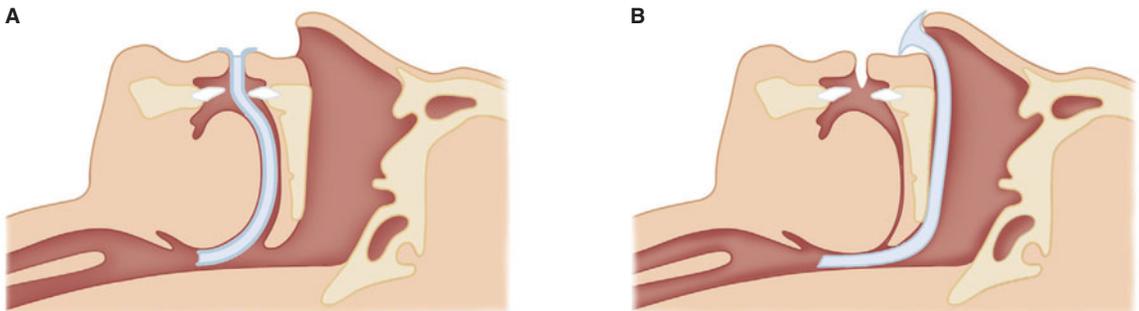

FIGURE 19–6 **A:** The oropharyngeal airway in place. The airway follows the curvature of the tongue, pulling it and the epiglottis away from the posterior pharyngeal wall and providing a channel for air passage. **B:** The nasopharyngeal airway in place. The airway passes

through the nose and extends to just above the epiglottis. (Modified and reproduced, with permission, from Face masks and airways. In: *Understanding Anesthesia Equipment*, 4th ed. Dorsch JA, Dorsch SE, eds. Williams & Wilkins, 1999.)

catheters, nasotracheal tubes) should be lubricated before being advanced along the floor of the nasal passage.

Face Mask Design & Technique

The use of a face mask can facilitate the delivery of oxygen or an anesthetic gas from a breathing system to a patient by creating an airtight seal with the patient's face (Figure 19-7). The rim of the mask is contoured and conforms to a variety of facial features. The mask's 22-mm orifice attaches to the breathing circuit of the anesthesia machine through a right-angle connector. Several mask designs are available. Transparent masks allow observation of exhaled humidified gas and immediate recognition of vomitus. Retaining hooks surrounding the orifice can be attached to a head strap so that the mask does not have to be continually held in place. Some pediatric masks are specially designed to minimize apparatus dead space (Figure 19-8).

Effective mask ventilation requires both a gas-tight mask fit and a patent airway. Improper face mask technique can result in continued deflation of the anesthesia reservoir bag when the adjustable pressure-limiting valve is closed, usually indicating a substantial leak around the mask. In contrast, the generation of high breathing circuit pressures with minimal chest movement and breath sounds implies an obstructed airway or obstructed tubing.

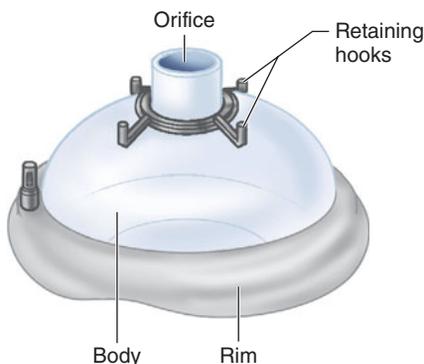

FIGURE 19-7 Clear adult face mask.

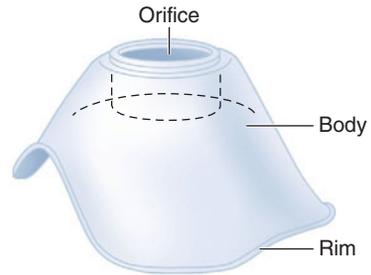

FIGURE 19-8 The Rendell-Baker-Soucek pediatric face mask has a shallow body and minimal dead space.

If the mask is held with the left hand, the right hand can be used to generate positive-pressure ventilation by squeezing the breathing bag. The mask is held against the face by downward pressure on the mask body exerted by the left thumb and index finger (Figure 19-9). The middle and ring finger grasp the mandible to facilitate extension of the atlanto-occipital joint. This is a maneuver that is easier to teach than to describe. Finger pressure should be placed on the bony mandible and not on the soft tissues supporting the base of the tongue, which may obstruct the airway. The little finger is placed under the angle of the jaw and used to thrust the jaw anteriorly, the most important maneuver to allow ventilation to the patient.

FIGURE 19-9 One-handed face mask technique.

FIGURE 19-10 A difficult airway can often be managed with a two-handed technique.

In difficult situations, two hands may be needed to provide adequate jaw thrust and to create a mask seal. Therefore, an assistant may be needed to squeeze the bag, or the machine's ventilator can be used. In such cases, the thumbs hold the mask down, and the fingertips or knuckles displace the jaw forward (Figure 19-10). Obstruction during expiration may be due to excessive downward pressure from the mask or from a ball-valve effect of the jaw thrust. The former can be relieved by decreasing the pressure on the mask, and the latter by releasing the jaw thrust during this phase of the respiratory cycle. It is often difficult to form an adequate mask fit with the cheeks of edentulous patients. Positive-pressure ventilation using a mask should normally be limited to 20 cm of H₂O to avoid stomach inflation.

Most patients' airways can be maintained with a face mask and an oral or nasal airway. Mask ventilation for long periods may result in pressure injury to branches of the trigeminal or facial nerves. Because of the absence of positive airway pressures during spontaneous ventilation, only minimal downward force on the face mask is required to create an adequate seal. If the face mask and mask straps are used for extended periods, the position should be

regularly changed to prevent injury. Care should be used to avoid mask or finger contact with the eye, and the eyes should be taped shut to minimize the risk of corneal abrasions.

POSITIONING

When manipulating the airway, correct patient positioning is required. Relative alignment of the oral and pharyngeal axes is achieved by having the patient in the "sniffing" position. When cervical spine pathology is suspected, the head must be kept in a neutral position during all airway manipulations. In-line stabilization of the neck must be maintained during airway management in these patients, unless appropriate films have been reviewed and cleared by a radiologist or neurological or spine surgeon. Patients with morbid obesity should be positioned on a 30° upward ramp, as the functional residual capacity (FRC) of obese patients deteriorates in the supine position, leading to more rapid deoxygenation should ventilation be impaired.

PREOXYGENATION

When possible, preoxygenation with face mask oxygen should precede all airway management interventions. Oxygen is delivered by mask for several minutes prior to anesthetic induction. In this way, the functional residual capacity, the patient's oxygen reserve, is purged of nitrogen. Up to 90% of the normal FRC of 2 L following preoxygenation is filled with O₂. Considering the normal oxygen demand of 200–250 mL/min, the preoxygenated patient may have a 5–8 min oxygen reserve. Increasing the duration of apnea without desaturation improves safety, if ventilation following anesthetic induction is delayed. Conditions that increase oxygen demand (eg, sepsis, pregnancy) and decrease FRC (eg, morbid obesity, pregnancy) reduce the apneic period before desaturation ensues.

BAG AND MASK VENTILATION

Bag and mask ventilation (BMV) is the first step in airway management in most situations, with the exception of patients undergoing rapid sequence

intubation. Rapid sequence inductions avoid BMV to avoid stomach inflation and to reduce the potential for the aspiration of gastric contents in nonfasted patients and those with delayed gastric emptying. In emergency situations, BMV precedes attempts at intubation in an effort to oxygenate the patient, with the understanding that there is an implicit risk of aspiration.

As noted above, the anesthetist's left hand supports the mask on the patient's face. The face is lifted into the mask with the third, fourth, and fifth fingers of the anesthesia provider's left hand. The fingers are placed on the mandible, and the jaw is thrust forward, lifting the base of the tongue away from the posterior pharynx opening the airway. The thumb and index finger sit on top of the mask. If the airway is patent, squeezing the bag will result in the rise of the chest. If ventilation is ineffective (no sign of chest rising, no end-tidal CO₂ detected, no mist in the clear mask), oral or nasal airways can be placed to relieve airway obstruction secondary to redundant pharyngeal tissues. Difficult mask ventilation is often found in patients with morbid obesity, beards, and craniofacial deformities.

In years past, anesthetics were routinely delivered solely by mask administration. In recent decades, a variety of supraglottic devices has permitted both airway rescue (when BMV is not possible) and routine anesthetic airway management (when intubation is not thought to be necessary).

SUPRAGLOTTIC AIRWAY DEVICES

Supraglottic airway devices (SADs) are used with both spontaneously and ventilated patients during anesthesia. They have also been employed as conduits to aid endotracheal intubation when both BMV and endotracheal intubation have failed. All SADs consist of a tube that is connected to a respiratory circuit or breathing bag, which is attached to a hypopharyngeal device that seals and directs airflow to the glottis, trachea, and lungs. Additionally, these airway devices occlude the esophagus with varying degrees of effectiveness, reducing gas distension of the stomach. Different sealing devices to

prevent airflow from exiting through the mouth are also available. Some are equipped with a port to suction gastric contents. None offer the protection from aspiration pneumonitis offered by a properly sited, cuffed endotracheal tube.

Laryngeal Mask Airway

A laryngeal mask airway (LMA) consists of a wide-bore tube whose proximal end connects to a breathing circuit with a standard 15-mm connector, and whose distal end is attached to an elliptical cuff that can be inflated through a pilot tube. The deflated cuff is lubricated and inserted blindly into the hypopharynx so that, once inflated, the cuff forms a low-pressure seal around the entrance to the larynx. This requires anesthetic depth and muscle relaxation slightly greater than that required for the insertion of an oral airway. Although insertion is relatively simple (Figure 19-11), attention to detail will improve the success rate (Table 19-2). An ideally positioned cuff is bordered by the base of the tongue superiorly, the pyriform sinuses laterally, and the upper esophageal sphincter inferiorly. If the esophagus lies within the rim of the cuff, gastric distention and regurgitation become possible. Anatomic variations prevent adequate functioning in some patients. However, if an LMA is not functioning properly after attempts to improve the "fit" of the LMA have failed, most practitioners will try another LMA one size larger or smaller. The shaft can be secured with tape to the skin of the face.

2 The LMA partially protects the larynx from pharyngeal secretions (but *not* gastric regurgitation), and it should remain in place until the patient has regained airway reflexes. This is usually signaled by coughing and mouth opening on command. The LMA is available in many sizes (Table 19-3).

The LMA provides an alternative to ventilation through a face mask or TT (Table 19-4). Relative contraindications for the LMA include patients with pharyngeal pathology (eg, abscess), pharyngeal obstruction, full stomachs (eg, pregnancy, hiatal hernia), or low pulmonary compliance (eg, restrictive airways disease) requiring peak inspiratory pressures greater than 30 cm H₂O. Traditionally, the LMA has been avoided in patients

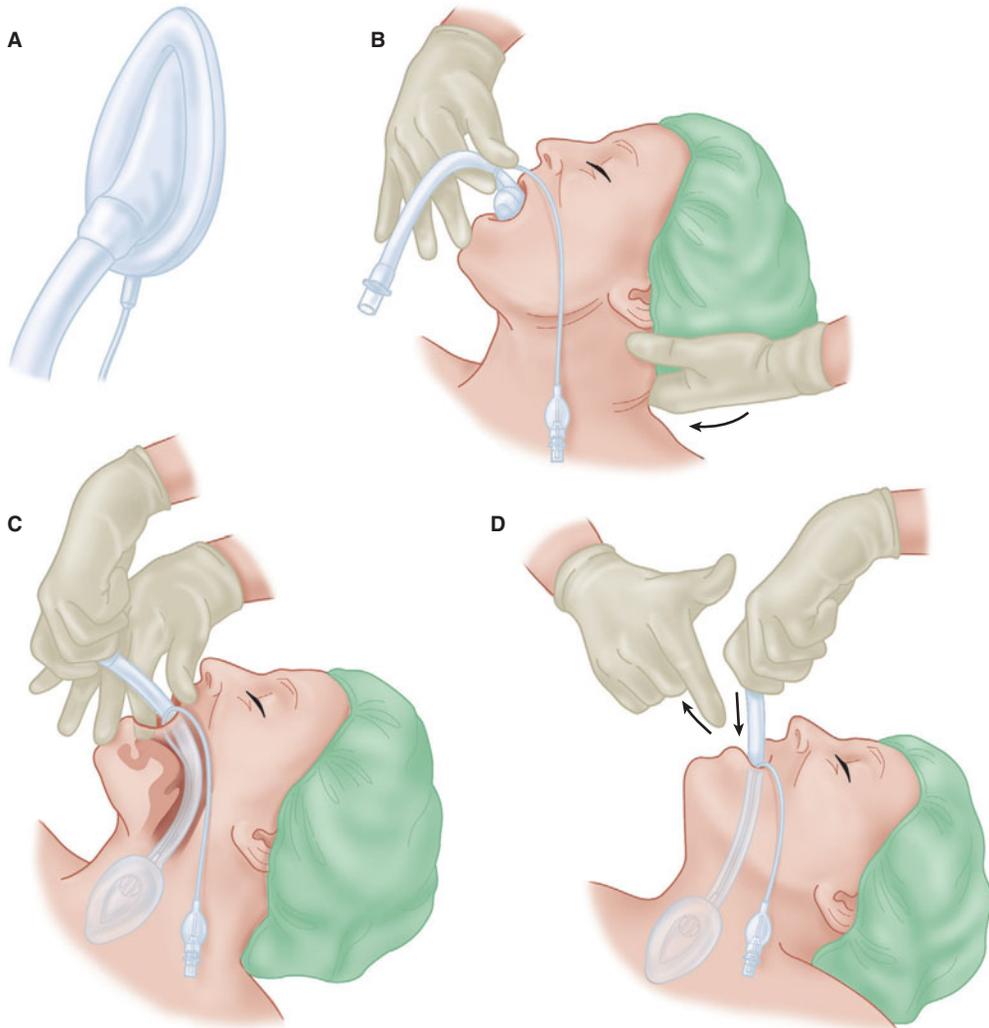

FIGURE 19-11 **A:** The laryngeal mask ready for insertion. The cuff should be deflated tightly with the rim facing away from the mask aperture. There should be no folds near the tip. **B:** Initial insertion of the laryngeal mask. Under direct vision, the mask tip is pressed upward against the hard palate. The middle finger may be used to push the lower jaw downward. The mask is pressed forward as it is advanced into the pharynx to ensure that the tip remains flattened and avoids the tongue. The jaw should not be held open once the mask is inside the

mouth. The nonintubating hand can be used to stabilize the occiput. **C:** By withdrawing the other fingers and with a slight pronation of the forearm, it is usually possible to push the mask fully into position in one fluid movement. Note that the neck is kept flexed and the head extended. **D:** The laryngeal mask is grasped with the other hand and the index finger withdrawn. The hand holding the tube presses gently downward until resistance is encountered. (Reproduced, with permission, from LMA North America.)

with bronchospasm or high airway resistance, but new evidence suggests that because it is not placed in the trachea, use of an LMA is associated with less bronchospasm than a TT. Although it is clearly not

a substitute for tracheal intubation, the LMA has proven particularly helpful as a life-saving temporizing measure in patients with difficult airways (those who cannot be ventilated or intubated) because of

TABLE 19–2 Successful insertion of a laryngeal mask airway depends upon attention to several details.

1. Choose the appropriate size (Table 19–3) and check for leaks before insertion.
2. The leading edge of the deflated cuff should be wrinkle free and facing away from the aperture (Figure 19–11A).
3. Lubricate only the back side of the cuff.
4. Ensure adequate anesthesia before attempting insertion.
5. Place patient's head in sniffing position (Figure 19–11B and Figure 19–23).
6. Use your index finger to guide the cuff along the hard palate and down into the hypopharynx until an increased resistance is felt (Figure 19–11C). The longitudinal black line should *always* be pointing directly cephalad (ie, facing the patient's upper lip).
7. Inflate with the correct amount of air (Table 19–3).
8. Ensure adequate anesthetic depth during patient positioning.
9. Obstruction after insertion is usually due to a down-folded epiglottis or transient laryngospasm.
10. Avoid pharyngeal suction, cuff deflation, or laryngeal mask removal until the patient is awake (eg, opening mouth on command).

its ease of insertion and relatively high success rate (95% to 99%). It has been used as a conduit for an intubating stylet (eg, gum-elastic bougie), ventilating jet stylet, flexible FOB, or small-diameter (6.0-mm) TT. Several LMAs are available that have been modified to facilitate placement of a larger TT, with or without the use of a FOB. Insertion can be

TABLE 19–3 A variety of laryngeal masks with different cuff volumes are available for different sized patients.

Mask Size	Patient Size	Weight (kg)	Cuff Volume (mL)
1	Infant	<6.5	2–4
2	Child	6.5–20	Up to 10
2½	Child	20–30	Up to 15
3	Small adult	>30	Up to 20
4	Normal adult	<70	Up to 30
5	Larger adult	>70	Up to 30

performed under topical anesthesia and bilateral superior laryngeal nerve blocks, if the airway must be secured while the patient is awake.

Variations in LMA design include:

- The ProSeal LMA, which permits passage of a gastric tube to decompress the stomach
- The I-Gel, which uses a gel occluder rather than inflatable cuff
- The Fastrach intubation LMA, which is designed to facilitate endotracheal intubation through the LMA device
- The LMA CTrach, which incorporates a camera to facilitate passage of an endotracheal tube

TABLE 19–4 Advantages and disadvantages of the laryngeal mask airway compared with face mask ventilation or tracheal intubation.¹

	Advantages	Disadvantages
Compared with face mask	<ul style="list-style-type: none"> Hands-free operation Better seal in bearded patients Less cumbersome in ENT surgery Often easier to maintain airway Protects against airway secretions Less facial nerve and eye trauma Less operating room pollution 	<ul style="list-style-type: none"> More invasive More risk of airway trauma Requires new skill Deeper anesthesia required Requires some TMJ mobility N₂O diffusion into cuff Multiple contraindications
Compared with tracheal intubation	<ul style="list-style-type: none"> Less invasive Very useful in difficult intubations Less tooth and laryngeal trauma Less laryngospasm and bronchospasm Does not require muscle relaxation Does not require neck mobility No risk of esophageal or endobronchial intubation 	<ul style="list-style-type: none"> Increased risk of gastrointestinal aspiration Less safe in prone or jackknife positions Limits maximum PPV Less secure airway Greater risk of gas leak and pollution Can cause gastric distention

¹ENT, ear, nose, and throat; TMJ, temporomandibular joint; PPV, positive-pressure ventilation.

Sore throat is a common side effect following SAD use. Injuries to the lingual, hypoglossal, and recurrent laryngeal nerve have been reported. Correct device sizing, avoidance of cuff hyperinflation, and gentle movement of the jaw during placement may reduce the likelihood of such injuries.

Esophageal–Tracheal Combitube

The esophageal–tracheal Combitube consists of two fused tubes, each with a 15-mm connector on its proximal end (Figure 19–12). The longer blue tube has an occluded distal tip that forces gas to exit through a series of side perforations. The shorter clear tube has an open tip and no side perforations. The Combitube is usually inserted blindly through the mouth and advanced until the two black rings on the shaft lie between the upper and lower teeth. The Combitube has two inflatable cuffs, a 100-mL proximal cuff and a 15-mL distal cuff, both of which should be fully inflated after placement. The distal lumen of the Combitube usually comes to lie in the esophagus approximately 95% of the time so that ventilation through the longer blue tube will force gas out of the side perforations and into the larynx. The shorter, clear tube can be used for gastric

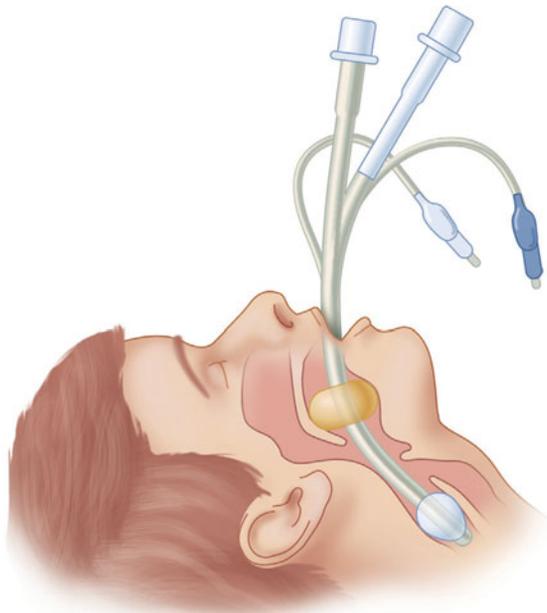

FIGURE 19–12 Combitube.

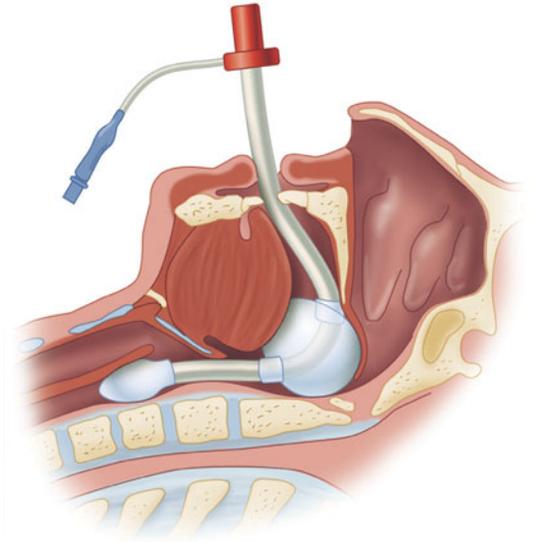

FIGURE 19–13 King laryngeal tube.

decompression. Alternatively, if the Combitube enters the trachea, ventilation through the clear tube will direct gas into the trachea.

King Laryngeal Tube

King laryngeal tubes (LTs) consist of tube with a small esophageal balloon and a larger balloon for placement in the hypopharynx (Figure 19–13). Both tubes inflate through one inflation line. The lungs are inflated from air that exits between the two balloons. A suction port distal to the esophageal balloon is present, permitting decompression of the stomach. The LT is inserted and the cuffs inflated. Should ventilation prove difficult, the LT is likely inserted too deep. Slightly withdrawing the device until compliance improves ameliorates the situation.

ENDOTRACHEAL INTUBATION

Endotracheal intubation is employed both for the conduct of general anesthesia and to facilitate the ventilator management of the critically ill.

Tracheal Tubes

Standards govern TT manufacturing (American National Standard for Anesthetic Equipment; ANSI Z-79). TTs are most commonly made from polyvinyl chloride. In the past, TTs were marked “I.T.” or

FIGURE 19-14 Murphy tracheal tube.

“Z-79” to indicate that they had been implant tested to ensure nontoxicity. The shape and rigidity of TTs can be altered by inserting a stylet. The patient end of the tube is beveled to aid visualization and insertion through the vocal cords. Murphy tubes have a hole (the Murphy eye) to decrease the risk of occlusion, should the distal tube opening about the carina or trachea (Figure 19-14).

Resistance to airflow depends primarily on tube diameter, but is also affected by tube length and curvature. TT size is usually designated in millimeters of internal diameter, or, less commonly, in the French scale (external diameter in millimeters multiplied by 3). The choice of tube diameter is always a compromise between maximizing flow with a larger size and minimizing airway trauma with a smaller size (Table 19-5).

Most adult TTs have a cuff inflation system consisting of a valve, pilot balloon, inflating tube, and

cuff (Figure 19-14). The valve prevents air loss after cuff inflation. The pilot balloon provides a gross indication of cuff inflation. The inflating tube connects the valve to the cuff and is incorporated into the tube’s wall. By creating a tracheal seal, TT cuffs permit positive-pressure ventilation and reduce the likelihood of aspiration. Uncuffed tubes are often used in infants and young children to minimize the risk of pressure injury and postintubation croup; however, in recent years, cuffed pediatric tubes have been increasingly favored.

There are two major types of cuffs: high pressure (low volume) and low pressure (high volume). High-pressure cuffs are associated with more ischemic damage to the tracheal mucosa and are less suitable for intubations of long duration. Low-pressure cuffs may increase the likelihood of sore throat (larger mucosal contact area), aspiration, spontaneous extubation, and difficult insertion (because of the floppy cuff). Nonetheless, because of their lower incidence of mucosal damage, low-pressure cuffs are generally employed.

Cuff pressure depends on several factors: inflation volume, the diameter of the cuff in relation to the trachea, tracheal and cuff compliance, and intrathoracic pressure (cuff pressures increase with coughing). Cuff pressure may increase during general anesthesia from diffusion of nitrous oxide from the tracheal mucosa into the TT cuff.

TTs have been modified for a variety of specialized applications. Flexible, spiral-wound, wire-reinforced TTs (armored tubes) resist kinking and

TABLE 19-5 Oral tracheal tube size guidelines.

Age	Internal Diameter (mm)	Cut Length (cm)
Full-term infant	3.5	12
Child	$4 + \frac{\text{Age}}{4}$	$14 + \frac{\text{Age}}{2}$
Adult		
Female	7.0–7.5	24
Male	7.5–9.0	24

may prove valuable in some head and neck surgical procedures or in the prone patient. If an armored tube becomes kinked from extreme pressure (eg, an awake patient biting it), however, the lumen will often remain permanently occluded, and the tube will need replacement. Other specialized tubes include micro-laryngeal tubes, double-lumen endotracheal tubes (to facilitate lung isolation and one-lung ventilation), endotracheal tubes equipped with bronchial blockers (to facilitate lung isolation and one-lung ventilation), metal tubes designed for laser airway surgery to reduce fire hazards, and preformed curved tubes for nasal and oral intubation in head and neck surgery.

LARYNGOSCOPES

A laryngoscope is an instrument used to examine the larynx and to facilitate intubation of the trachea. The handle usually contains batteries to light a bulb on the blade tip (Figure 19-15), or, alternately, to power a fiberoptic bundle that terminates at the tip of the blade. Light from a fiberoptic bundle tends to be more precisely directed and less diffuse. Also, laryngoscopes with fiberoptic light bundles in their blades can be made magnetic resonance imaging compatible. The Macintosh and Miller blades are the most popular curved and straight designs, respectively, in

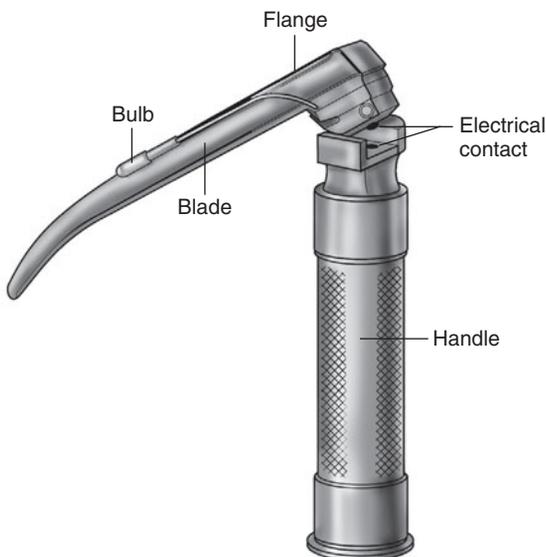

FIGURE 19-15 A rigid laryngoscope.

the United States. The choice of blade depends on personal preference and patient anatomy. Because no blade is perfect for all situations, the clinician should become familiar and proficient with a variety of blade designs (Figure 19-16).

VIDEO LARYNGOSCOPES

In recent years, a myriad of laryngoscopy devices that utilize video technology have revolutionized management of the airway. Direct laryngoscopy with a Macintosh or Miller blade mandates appropriate alignment of the oral, pharyngeal, and laryngeal structures to facilitate a direct view of the glottis. Various maneuvers, such as the “sniffing” position and external movement of the larynx with cricoid pressure during direct laryngoscopy, are used to improve the view. Video- or optically-based laryngoscopes have either a video chip (DCI system, GlideScope, McGrath, Airway) or a lens/mirror (Airtraq) at the tip of the intubation blade to transmit a view of the glottis to the operator. These devices differ in the angulation of the blade, the presence of a channel to guide the tube to the glottis, and the single use or multiuse nature of the device.

Video or indirect laryngoscopy most likely offers minimal advantage in patients with uncomplicated airways. However, use in these patients is valuable as a training guide for learners, especially when the trainee is performing a direct laryngoscopy with the device while the instructor views the glottis on the video screen. Additionally, use in uncomplicated airway management patients improves familiarity with the device for times when direct laryngoscopy is not possible.

Indirect laryngoscopes generally improve visualization of laryngeal structures in difficult airways; however, visualization does not always lead to successful intubation. An endotracheal tube stylet is recommended when video laryngoscopy is to be performed. Some devices come with stylets designed to facilitate intubation with that particular device. Bending the stylet and endotracheal tube in a manner similar to the bend in the curve of the blade often facilitates passage of the endotracheal tube into the trachea. Even when the glottic opening is seen clearly, directing the endotracheal tube into

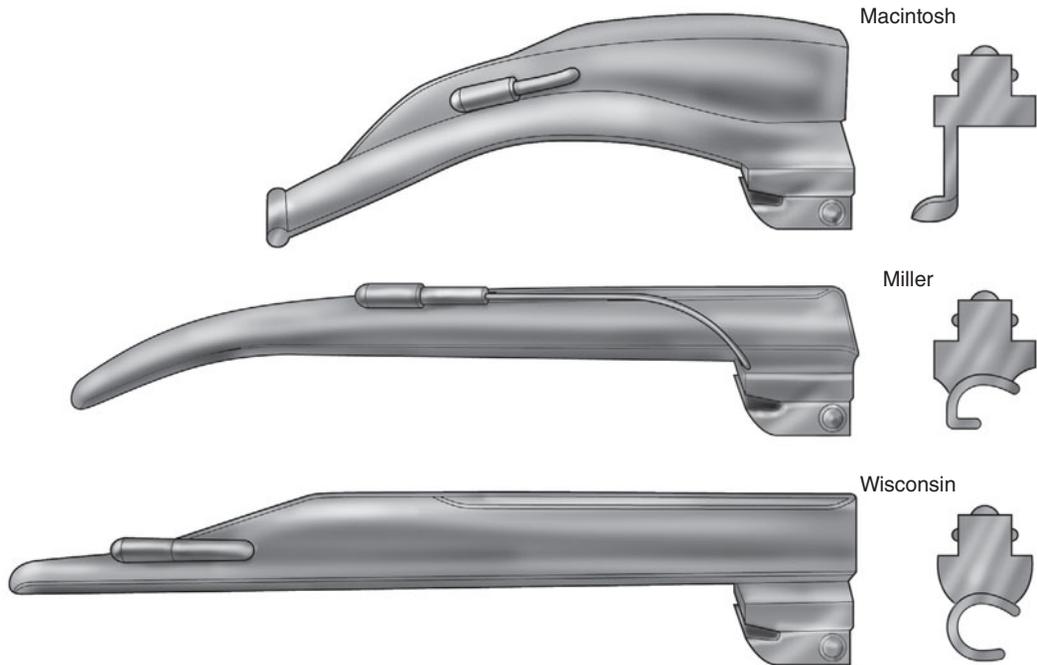

FIGURE 19-16 An assortment of laryngoscope blades.

the trachea can be difficult. Should the tube become caught on the arytenoids, slightly pulling the blade farther out may better permit tube passage.

Indirect laryngoscopy may result in less displacement of the cervical spine; however, all precautions associated with airway manipulation in a patient with a possible cervical spine fracture should be maintained.

Varieties of indirect laryngoscopes include:

- Various Macintosh and Miller blades in pediatric and adult sizes have video capability in the Storz DCI system. The system can also incorporate an optical intubating stylet (Figure 19-17). The blades are similar to conventional intubation blades, permitting direct laryngoscopy and indirect video laryngoscopy. Assistants and instructors are able to see the view obtained by the operator and adjust their maneuvers accordingly to facilitate intubation or to provide instruction, respectively.
- The McGrath laryngoscope is a portable video laryngoscope with a blade length that can be

adjusted to facilitate a child of age 5 years up to an adult (Figure 19-18). The blade can be disconnected from the handle to facilitate its insertion in morbidly obese patients in whom the space between the upper chest and head is reduced. The blade is inserted midline, with the laryngeal structures viewed at a distance to enhance intubation success.

FIGURE 19-17 Optical intubating stylet.

FIGURE 19-18 McGrath laryngoscope.

- The GlideScope comes with disposable adult- and pediatric-sized blades (**Figure 19-19**). The blade is inserted midline and advanced until glottic structures are identified. The GlideScope has a 60° angle, preventing direct laryngoscopy and necessitating the use of stylet that is similar in shape to the blade.
- Airtraq is a single-use optical laryngoscope available in pediatric and adult sizes (**Figure 19-20**). The device has a channel to guide the endotracheal tube to the glottis. This device is inserted midline. Success is more likely when the device is not positioned too close to the glottis.
- Video intubating stylets have a video capability and light source. The stylet is introduced, and the glottis identified. Intubation with a video stylet may result in less cervical spine movement than with other techniques.

Flexible Fiberoptic Bronchoscopes

In some situations—for example, patients with unstable cervical spines, poor range of motion of the temporomandibular joint, or certain congenital

FIGURE 19-19 Glidescope.

or acquired upper airway anomalies—laryngoscopy with direct or indirect laryngoscopes may be undesirable or impossible. A flexible FOB allows indirect visualization of the larynx in such cases or in any situation in which awake intubation is planned (**Figure 19-21**). Bronchoscopes are constructed of coated glass fibers that transmit light and images by internal reflection (ie, a light beam becomes trapped

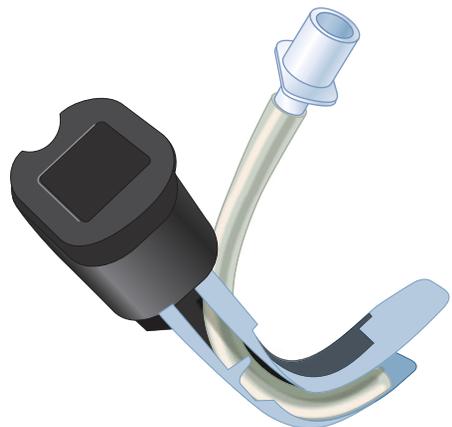

FIGURE 19-20 Airtraq optical laryngoscope.

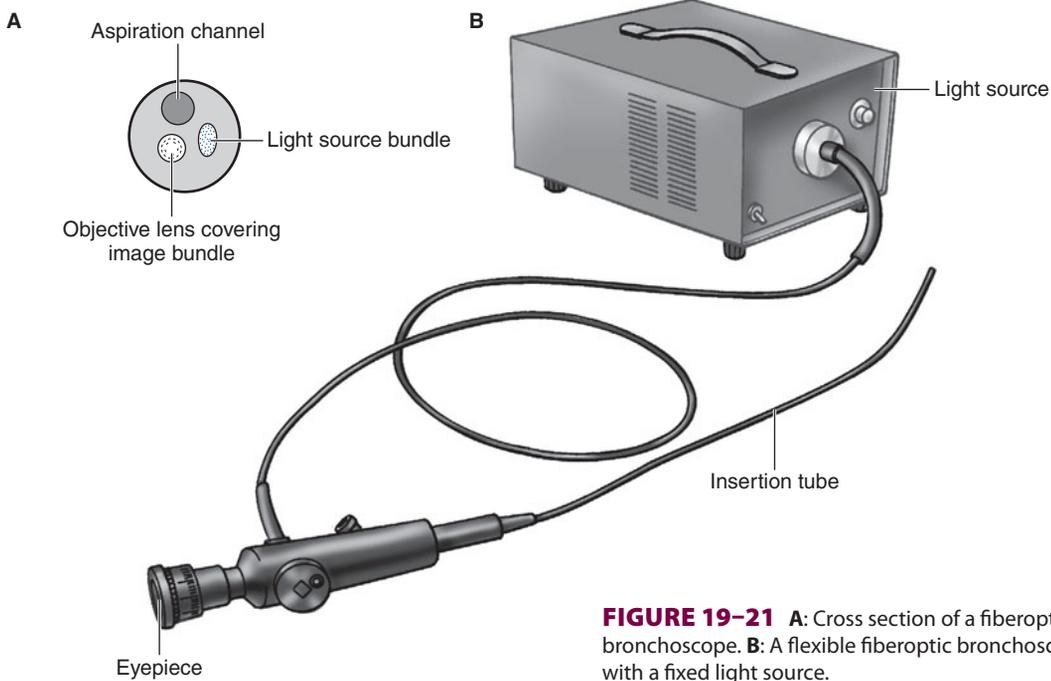

FIGURE 19-21 A: Cross section of a fiberoptic bronchoscope. B: A flexible fiberoptic bronchoscope with a fixed light source.

within a fiber and exits unchanged at the opposite end). The insertion tube contains two bundles of fibers, each consisting of 10,000 to 15,000 fibers. One bundle transmits light from the light source (light source or incoherent bundle), which is either external to the device or contained within the handle (Figure 19-21B), whereas the other provides a high-resolution image (image or coherent bundle). Directional manipulation of the insertion tube is accomplished with angulation wires. Aspiration channels allow suctioning of secretions, insufflation of oxygen, or instillation of local anesthetic. Aspiration channels can be difficult to clean, and, if not properly cleaned and sterilized after each use, may provide a nidus for infection.

TECHNIQUES OF DIRECT AND INDIRECT LARYNGOSCOPY & INTUBATION

Indications for Intubation

Inserting a tube into the trachea has become a routine part of delivering a general anesthetic. Intubation is

not a risk-free procedure, and not all patients receiving general anesthesia require it. A TT is generally placed to protect the airway and for airway access. Intubation is indicated in patients who are at risk of aspiration and in those undergoing surgical procedures involving body cavities or the head and neck. Mask ventilation or ventilation with an LMA is usually satisfactory for short minor procedures such as cystoscopy, examination under anesthesia, inguinal hernia repairs, extremity surgery, and so forth.

Preparation for Direct Laryngoscopy

Preparation for intubation includes checking equipment and properly positioning the patient. The TT should be examined. The tube's cuff inflation system can be tested by inflating the cuff using a 10-mL syringe. Maintenance of cuff pressure *after detaching the syringe* ensures proper cuff and valve function. Some anesthesiologists cut the TT to a preset length to decrease the dead space, the risk of bronchial intubation, and the risk of occlusion from tube kinking (Table 19-5). The connector should be pushed firmly into the tube to decrease the likelihood of disconnection. If a stylet is used, it should be inserted

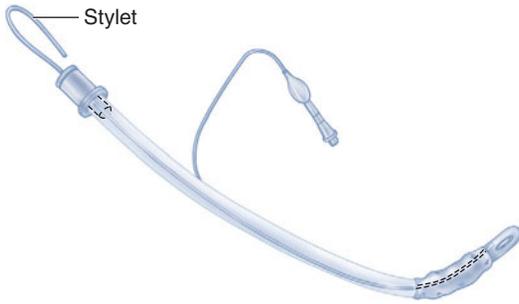

FIGURE 19-22 A tracheal tube with a stylet bent to resemble a hockey stick.

into the TT, which is then bent to resemble a hockey stick (**Figure 19-22**). This shape facilitates intubation of an anteriorly positioned larynx. The desired blade is locked onto the laryngoscope handle, and bulb function is tested. The light intensity should remain constant even if the bulb is jiggled. A blinking light signals a poor electrical contact, whereas

fading indicates depleted batteries. An extra handle, blade, TT (one size smaller than the anticipated optimal size), and stylet should be immediately available. A functioning suction unit is needed to clear the airway in case of unexpected secretions, blood, or emesis.

Successful intubation often depends on correct patient positioning. The patient's head should be level with the anesthesiologist's waist or higher to prevent unnecessary back strain during laryngoscopy.

Direct laryngoscopy displaces pharyngeal soft tissues to create a direct line of vision from the mouth to the glottic opening. Moderate head elevation (5–10 cm above the surgical table) and extension of the atlantooccipital joint place the patient in the desired sniffing position (**Figure 19-23**). The lower portion of the cervical spine is flexed by resting the head on a pillow or other soft support.

Preparation for induction and intubation also involves routine preoxygenation. Administration of 100% oxygen provides an extra margin of safety in

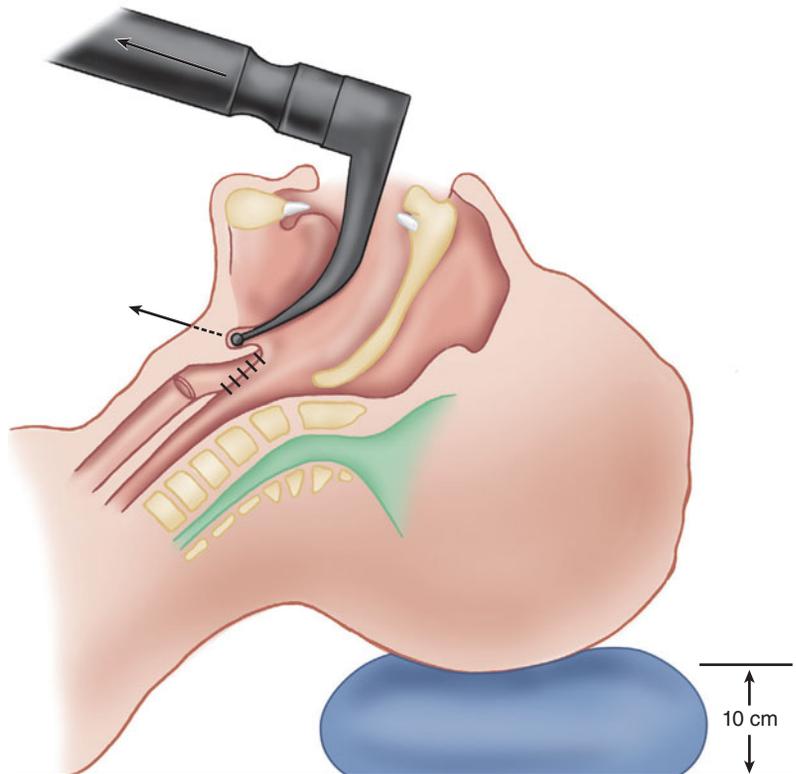

FIGURE 19-23 The sniffing position and intubation with a Macintosh blade. (Modified and reproduced, with permission, from Dorsch JA, Dorsch SE: *Understanding Anesthesia Equipment: Construction, Care, and Complications*. Williams & Wilkins, 1991.)

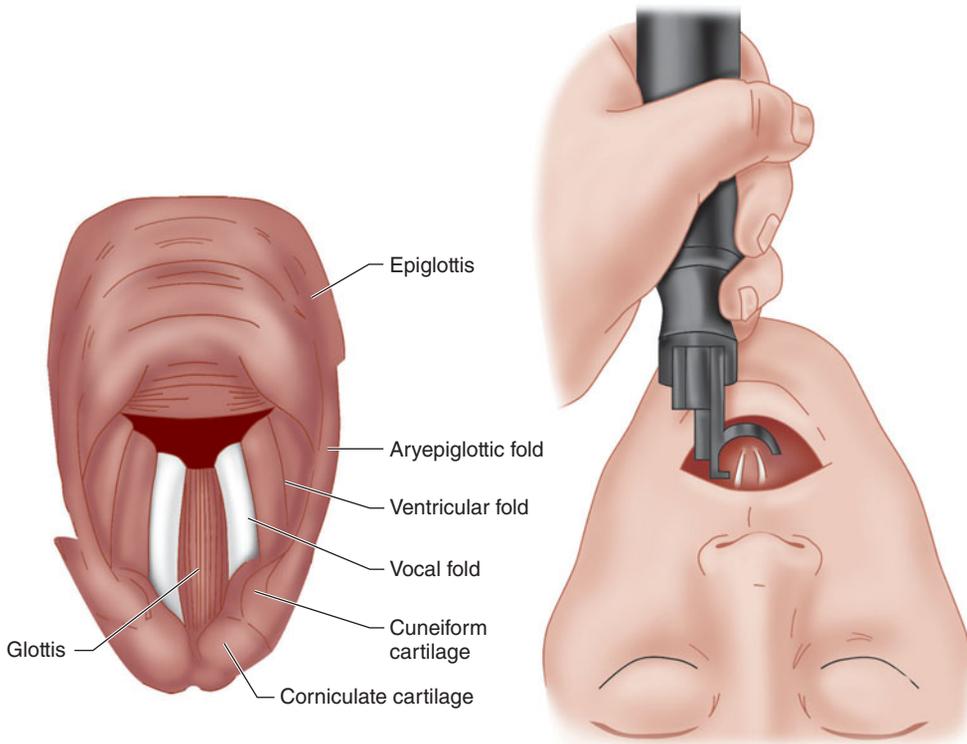

FIGURE 19-24 Typical view of the glottis during laryngoscopy with a curved blade. (Modified and reproduced, with permission, from Barash PG: *Clinical Anesthesia*, 4th ed. Lippincott, 2001.)

case the patient is not easily ventilated after induction. Preoxygenation can be omitted in patients who object to the face mask; however, failing to preoxygenate increases the risk of rapid desaturation following apnea.

Because general anesthesia abolishes the protective corneal reflex, care must be taken during this period not to injure the patient's eyes by unintentionally abrading the cornea. Thus, the eyes are routinely taped shut, often after applying an ophthalmic ointment before manipulation of the airway.

Orotracheal Intubation

The laryngoscope is held in the left hand. With the patient's mouth opened the blade is introduced into the right side of the oropharynx—with care to avoid the teeth. The tongue is swept to the left and up into the floor of the pharynx by the blade's flange. Successful sweeping of the tongue leftward

clears the view for TT placement. The tip of a curved blade is usually inserted into the vallecula, and the straight blade tip covers the epiglottis. With either blade, the handle is raised up and away from the patient in a plane perpendicular to the patient's mandible to expose the vocal cords (**Figure 19-24**). Trapping a lip between the teeth and the blade and leverage on the teeth are avoided. The TT is taken with the right hand, and its tip is passed through the abducted vocal cords. The “backward, upward, rightward, pressure” (BURP) maneuver applied externally moves an anteriorly positioned glottis posterior to facilitate visualization of the glottis. The TT cuff should lie in the upper trachea, but beyond the larynx. The laryngoscope is withdrawn, again with care to avoid tooth damage. The cuff is inflated with the least amount of air necessary to create a seal during positive-pressure ventilation to minimize the

3

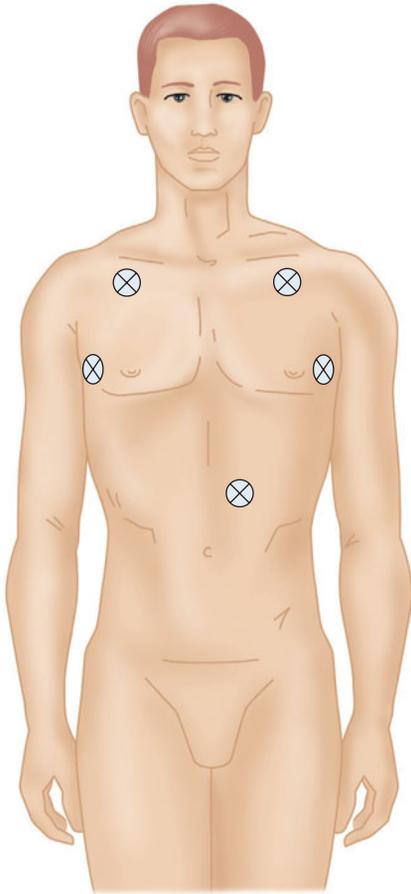

FIGURE 19-25 Sites for auscultation of breath sounds at the apices and over the stomach.

pressure transmitted to the tracheal mucosa. Overinflation beyond 30 mm Hg may inhibit capillary blood flow, injuring the trachea. Compressing the pilot balloon with the fingers is *not* a reliable method of determining whether cuff pressure is either sufficient or excessive.

After intubation, the chest and epigastrium are immediately auscultated, and a capnographic tracing (the definitive test) is monitored to ensure intratracheal location ([Figure 19-25](#)). If there is doubt as to whether the tube is in the esophagus or trachea, repeat the laryngoscopy to confirm placement. End-tidal CO_2 will not be produced if there is no cardiac output. FOB through the tube and

visualization of the tracheal rings and carina will likewise confirm correct placement. Otherwise, the tube is taped or tied to secure its position.

- 4 Although the persistent detection of CO_2 by a capnograph is the best confirmation of tracheal placement of a TT, it cannot exclude bronchial intubation. The earliest evidence of bronchial intubation often is an increase in peak inspiratory pressure. Proper tube location can be reconfirmed by palpating the cuff in the sternal notch while compressing the pilot balloon with the other hand.
- 5 The cuff should not be felt above the level of the cricoid cartilage, because a prolonged intralaryngeal location may result in postoperative hoarseness and increases the risk of accidental extubation. Tube position can also be documented by chest radiography.

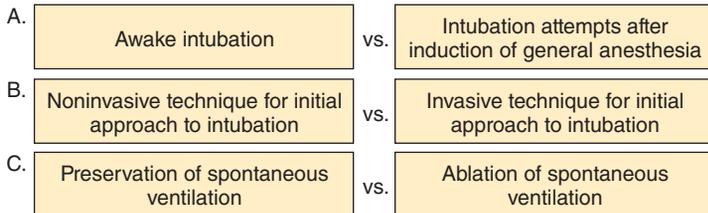

The description presented here assumes an unconscious patient. Oral intubation is usually poorly tolerated by awake, fit patients. Intravenous sedation, application of a local anesthetic spray in the oropharynx, regional nerve block, and constant reassurance will improve patient acceptance.

A failed intubation should not be followed by identical repeated attempts. Changes must be made to increase the likelihood of success, such as repositioning the patient, decreasing the tube size, adding a stylet, selecting a different blade, using an indirect laryngoscope, attempting a nasal route, or requesting the assistance of another anesthesiologist. If the patient is also difficult to ventilate with a mask, alternative forms of airway management (eg, LMA, Combitube, cricothyrotomy with jet ventilation, tracheostomy) must be immediately pursued. The guidelines developed by the American Society of Anesthesiologists for the management of a difficult airway include a treatment plan algorithm ([Figure 19-26](#)).

Use of video or indirect laryngoscopes is dependent upon the design of the device. Some devices are placed midline without the requirement to sweep the tongue from view. Other devices contain channels to direct the endotracheal tube to the glottic opening. Practitioners should be familiar with the features of available devices well in advance of using one in a difficult airway situation. The combined use of a video laryngoscope and an intubation

Difficult Airway Algorithm

1. Assess the likelihood and clinical impact of basic management problems.
 - A. Difficult ventilation
 - B. Difficult intubation
 - C. Difficulty with patient cooperation or consent
 - D. Difficult tracheostomy
2. Actively pursue opportunities to deliver supplemental oxygen throughout the process of difficult airway management.
3. Consider the relative merits and feasibility of basic management choices:

4. Develop primary and alternative strategies.

Anesthesiologists Task Force on Management of the Difficult Airway. Practice guidelines for management of the difficult airway: an updated report by the American Society of Anesthesiologists Task Force on Management of the Difficult Airway. *Anesthesiology* 2003;98:1269.)

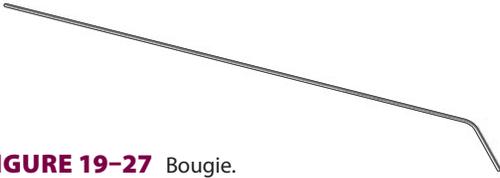

FIGURE 19-27 Bougie.

bougie often can facilitate intubation, when the endotracheal tube cannot be directed into the glottis despite good visualization of the laryngeal opening (**Figure 19-27**).

Nasotracheal Intubation

Nasal intubation is similar to oral intubation except that the TT is advanced through the nose and nasopharynx into the oropharynx before laryngoscopy. The nostril through which the patient breathes most easily is selected in advance and prepared. Phenylephrine nose drops (0.5% or 0.25%) vasoconstrict vessels and shrink mucous membranes. If the patient is awake, local anesthetic ointment (for the nostril), spray (for the oropharynx), and nerve blocks can also be utilized.

A TT lubricated with water-soluble jelly is introduced along the floor of the nose, below the inferior turbinate, *at an angle perpendicular to the face*. The tube's bevel should be directed laterally away from the turbinates. To ensure that the tube passes along the floor of the nasal cavity, the proximal end of the TT should be pulled cephalad. The tube is gradually advanced, until its tip can be visualized in the oropharynx. Laryngoscopy, as discussed, reveals the abducted vocal cords. Often the distal end of the TT can be pushed into the trachea without difficulty. If difficulty is encountered, the tip of the tube may be directed through the vocal cords with Magill forceps, being careful not to damage the cuff. Nasal passage of TTs, airways, or nasogastric catheters carries greater risk in patients with severe mid-facial trauma because of the risk of intracranial placement (**Figure 19-28**).

Although less used today, blind nasal intubation of spontaneously breathing patients can be employed. In this technique, after applying topical anesthetic to the nostril and pharynx, a breathing tube is passed through the nasopharynx. Using

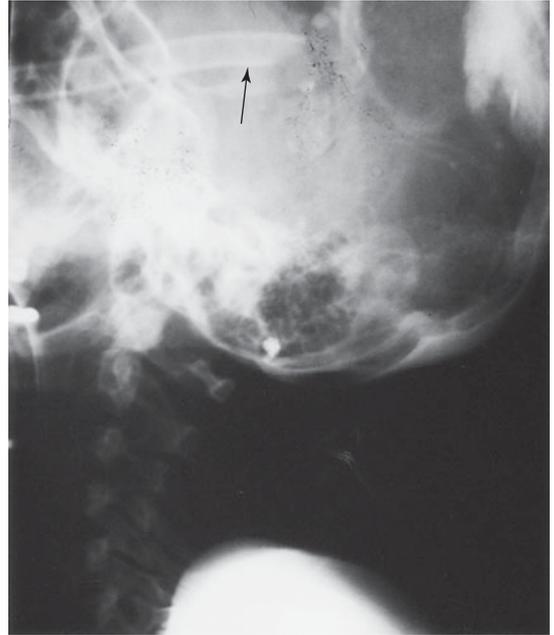

FIGURE 19-28 Radiograph demonstrating a 7.0-mm tracheal tube placed through the cribriform plate into the cranial vault in a patient with a basilar skull fracture.

breath sounds as a guide, it is directed toward the glottis. When breath sounds are maximal, the anesthetist advances the tube during inspiration in an effort to blindly pass the tube into the trachea.

Flexible Fiberoptic Intubation

Fiberoptic intubation (FOI) is routinely performed in awake or sedated patients with problematic airways. FOI is ideal for:

- A small mouth opening
- Minimizing cervical spine movement in trauma or rheumatoid arthritis
- Upper airway obstruction, such as angioedema or tumor mass
- Facial deformities, facial trauma

FOI can be performed awake or asleep via oral or nasal routes.

- Awake FOI: predicted inability to ventilate by mask, upper airway obstruction

- Asleep FOI: Failed intubation, desire for minimal C spine movement in patients who refuse awake intubation
- Oral FOI: Facial, skull injuries
- Nasal FOI: A poor mouth opening

When FOI is considered, careful planning is necessary, as it will likely add to the anesthesia time prior to surgery. Patients should be informed of the need for awake intubation as a part of the informed consent process.

The airway is anesthetized with a local anesthetic spray, and patient sedation is provided, as tolerated. Dexmedetomidine has the advantage of preserving respiration while providing sedation. Airway anesthesia is discussed in the Case Discussion below.

If nasal FOI is planned, both nostrils are prepared with vasoconstrictive drops. The nostril through which the patient breathes more easily is identified. Oxygen can be insufflated through the suction port and down the aspiration channel of the FOB to improve oxygenation and blow secretions away from the tip.

Alternatively, a large nasal airway (eg, 36F) can be inserted in the contralateral nostril. The breathing circuit can be directly connected to the end of this nasal airway to administer 100% oxygen during laryngoscopy. If the patient is unconscious and not breathing spontaneously, the mouth can be closed and ventilation attempted through the single nasal airway. When this technique is used, adequacy of ventilation and oxygenation should be confirmed by capnography and pulse oximetry. The lubricated shaft of the FOB is introduced into the TT lumen. It is important to keep the shaft of the bronchoscope relatively straight (**Figure 19–29**) so that if the head of the bronchoscope is rotated in one direction, the distal end will move to a similar degree and in the same direction. As the tip of the FOB passes through the distal end of the TT, the epiglottis or glottis should be visible. The tip of the bronchoscope is manipulated, as needed, to pass the abducted cords.

Having an assistant thrust the jaw forward or apply cricoid pressure may improve visualization in difficult cases. If the patient is breathing

FIGURE 19–29 Correct technique for manipulating a fiberoptic bronchoscope through a tracheal tube is shown in the top panel; avoid curvature in the bronchoscope, which makes manipulation difficult.

spontaneously, grasping the tongue with gauze and pulling it forward may also facilitate intubation.

Once in the trachea, the FOB is advanced to within sight of the carina. The presence of tracheal rings and the carina is proof of proper positioning. The TT is pushed off the FOB. The acute angle around the arytenoid cartilage and epiglottis may prevent easy advancement of the tube. Use of an armored tube usually decreases this problem due to its greater lateral flexibility and more obtusely angled distal end. Proper TT position is confirmed by viewing the tip of the tube an appropriate distance (3 cm in adults) above the carina before the FOB is withdrawn.

Oral FOI proceeds similarly, with the aid of various oral airway devices to direct the FOB toward the glottis and to reduce obstruction of the view by the tongue.

FIGURE 19-31 Cricothyrotomy. Incision at wire entry site. Remove catheter and make incision at the wire entry site. (Photo contributor: Lawrence B. Stack, MD.)

SURGICAL AIRWAY TECHNIQUES

“Invasive” airways are required when the “can’t intubate, can’t ventilate” scenario presents and may be performed in anticipation of such circumstances in selected patients. The options include: surgical cricothyrotomy, catheter or needle cricothyrotomy, transtracheal catheter with jet ventilation, and retrograde intubation.

Surgical cricothyrotomy refers to surgical incision of the CTM and placement of a breathing tube. More recently, several needle/dilator cricothyrotomy kits have become available. Unlike surgical cricothyrotomy, where a horizontal incision is made across the CTM, these kits utilize the Seldinger catheter/wire/dilator technique. A catheter attached to a syringe is inserted across the CTM (**Figure 19-30**). When air is aspirated, a guidewire is passed through the catheter into the trachea (**Figure 19-31**). A dilator is then passed over the guidewire, and a breathing tube placed (**Figure 19-32**).

Catheter-based salvage procedures can also be performed. A 16- or 14-gauge intravenous cannula is attached to a syringe and passed through the CTM toward the carina. Air is aspirated. If a jet ventilation system is available, it can be attached. The catheter **MUST** be secured, otherwise the jet pressure will push the catheter out of the airway, leading to

potentially disastrous subcutaneous emphysema. Short (1 s) bursts of oxygen ventilate the patient. Sufficient outflow of expired air must be assured to avoid barotrauma. Patients ventilated in this manner may develop subcutaneous or mediastinal emphysema and may become hypercapneic despite adequate oxygenation. Transtracheal jet ventilation will usually require conversion to a surgical airway or tracheal intubation.

Should a jet ventilation system not be available, a 3-mL syringe can be attached to the catheter and the syringe plunger removed. A 7.0-mm internal

FIGURE 19-32 Cricothyrotomy. Insert tracheostomy tube/introducer. Insert both devices over the wire and into the trachea. (Photo contributor: Lawrence B. Stack, MD.)

diameter TT connector can be inserted into the syringe and attached to a breathing circuit or an ambu bag. As with the jet ventilation system, adequate exhalation must occur to avoid barotraumas.

Retrograde intubation is another approach to secure an airway. A wire is passed via a catheter placed in the CTM. The wire is angulated cephalad and emerges either through the mouth or nose. The distal end of the wire is secured with a clamp to prevent it from passing through the CTM. The wire can then be threaded into an FOB with a loaded endotracheal tube to facilitate and confirm placement. Conversely, a small endotracheal tube can be guided by the wire into the trachea. Once placed, the wire is removed. Alternatively, an epidural catheter can be placed via an epidural needle in the CTM. After the distal end is retrieved from the mouth, an endotracheal tube may be passed over the catheter into the trachea.

PROBLEMS FOLLOWING INTUBATION

Following apparently successful intubation, several scenarios may develop that require immediate attention. Anesthesia staff **MUST** confirm that the tube is correctly placed with bilateral ventilation immediately following placement. Detection of end-tidal CO_2 remains the gold standard in this regard, with the caveat that cardiac output must be present for end-tidal CO_2 production.

Decreases in oxygen saturation can occur following tube placement. This is often secondary to endobronchial intubation, especially in small children and babies. Decreased oxygen saturation perioperatively may be due to inadequate oxygen delivery (oxygen not turned on, patient not ventilated) or to ventilation/perfusion mismatch (almost any form of lung disease). When saturation declines, the patient's chest is auscultated to confirm bilateral tube placement and to listen for wheezes, rhonchi, and rales consistent with lung pathology. The breathing circuit is checked. An intraoperative chest radiograph may be needed to identify the cause of desaturation. Intraoperative fiberoptic bronchoscopy can also be performed and used to confirm proper tube placement and to clear mucous plugs. Bronchodilators and deeper planes of inhalation anesthetics are

administered to treat bronchospasm. Obese patients may desaturate secondary to a reduced FRC and atelectasis. Application of positive end-expiratory pressure may improve oxygenation.

Should the end-tidal CO_2 decline suddenly, pulmonary (thrombus) or venous air embolism should be considered. Likewise, other causes of a sudden decline in cardiac output or a leak in the circuit should be considered.

A rising end-tidal CO_2 may be secondary to hypoventilation or increased CO_2 production, as occurs with malignant hyperthermia, sepsis, a depleted CO_2 absorber, or breathing circuit malfunction.

Increases in airway pressure may indicate an obstructed or kinked endotracheal tube or reduced pulmonary compliance. The endotracheal tube should be suctioned to confirm that it is patent and the lungs auscultated to detect signs of bronchospasm, pulmonary edema, endobronchial intubation, or pneumothorax.

Decreases in airway pressure can occur secondary to leaks in the breathing circuit or inadvertent extubation.

TECHNIQUES OF EXTUBATION

Most often, extubation should be performed when a patient is either deeply anesthetized or awake. In either case, adequate recovery from neuromuscular blocking agents should be established prior to extubation. If neuromuscular blocking agents are used, the patient has at least a period of controlled mechanical ventilation and likely must be weaned from the ventilator before extubation can occur.

Extubation during a light plane of anesthesia (ie, a state between deep and awake) is avoided because of an increased risk of laryngospasm. The distinction between deep and light anesthesia is usually apparent during pharyngeal suctioning: any reaction to suctioning (eg, breath holding, coughing) signals a light plane of anesthesia, whereas no reaction is characteristic of a deep plane. Similarly, eye opening or purposeful movements imply that the patient is sufficiently awake for extubation.

Extubating an awake patient is usually associated with coughing (bucking) on the TT. This

reaction increases the heart rate, central venous pressure, arterial blood pressure, intracranial pressure, intraabdominal pressure, and intraocular pressure. It may also cause wound dehiscence and increased bleeding. The presence of a TT in an awake asthmatic patient may trigger bronchospasm. Some practitioners attempt to decrease the likelihood of these effects by administering 1.5 mg/kg of intravenous lidocaine 1–2 min before suctioning and extubation; however, extubation during deep anesthesia may be preferable in patients who cannot tolerate these effects (provided such patients are not at risk of aspiration and/or do not have airways that may be difficult to control after removal of the TT).

Regardless of whether the tube is removed when the patient is deeply anesthetized or awake, the patient's pharynx should be thoroughly suctioned before extubation to decrease the potential for aspiration of blood and secretions. In addition, patients should be ventilated with 100% oxygen in case it becomes difficult to establish an airway after the TT is removed. Just prior to extubation, the TT is untaped or untied and its cuff is deflated. The tube is withdrawn in a single smooth motion, and a face mask is applied to deliver oxygen. Oxygen delivery by face mask is maintained during the period of transportation to the postanesthesia care area.

COMPLICATIONS OF LARYNGOSCOPY & INTUBATION

The complications of laryngoscopy and intubation include hypoxia, hypercarbia, dental and airway trauma, tube malpositioning, physiological responses to airway instrumentation, or tube malfunction. These complications can occur during laryngoscopy and intubation, while the tube is in place, or following extubation (Table 19–6).

Airway Trauma

Instrumentation with a metal laryngoscope blade and insertion of a stiff TT often traumatizes delicate airway tissues. Tooth damage is a common cause of (relatively small) malpractice claims against anesthesiologists. Laryngoscopy and intubation can lead

Laryngospasm	
Negative-pressure pulmonary edema	

to a range of complications from sore throat to tracheal stenosis. Most of these are due to prolonged external pressure on sensitive airway structures. When these pressures exceed the capillary–arteriolar blood pressure (approximately 30 mm Hg), tissue ischemia can lead to a sequence of inflammation, ulceration, granulation, and stenosis. Inflation of a TT cuff to the minimum pressure that creates a seal during routine positive-pressure ventilation (usually at least 20 mm Hg) reduces tracheal blood flow by 75% at the cuff site. Further cuff inflation or induced hypotension can totally eliminate mucosal blood flow.

Postintubation croup caused by glottic, laryngeal, or tracheal edema is particularly serious in children. The efficacy of corticosteroids (eg, dexamethasone—0.2 mg/kg, up to a maximum of 12 mg) in preventing postextubation airway edema remains controversial; however, corticosteroids have been demonstrated to be efficacious in children with croup from other causes. Vocal cord paralysis from cuff compression or other trauma to the recurrent laryngeal nerve results in hoarseness and increases the risk of aspiration. The incidence of postoperative hoarseness seems to increase with obesity, difficult intubations, and anesthetics of long duration. Curiously, applying a water-soluble lubricant or a local anesthetic-containing gel to the tip or cuff of the TT does not decrease the incidence of postoperative sore throat or hoarseness, and, in some studies, actually increased the incidence of these complications. Smaller tubes (size 6.5 in women and size 7.0 in men) are associated with fewer complaints of postoperative sore throat. Repeated attempts at laryngoscopy during a difficult intubation may lead to periglottic edema and the inability to ventilate with a face mask, thus turning a bad situation into a life-threatening one.

Errors of Tracheal Tube Positioning

6 Unrecognized esophageal intubation can produce catastrophic results. Prevention of this complication depends on direct visualization of the tip of the TT passing through the vocal cords, careful auscultation for the presence of bilateral breath sounds and the absence of gastric gurgling while ventilating through the TT, analysis of exhaled gas for the presence of CO₂ (the most reliable automated method), chest radiography, or the use of an FOB.

Even though it is confirmed that the tube is in the trachea, it may not be correctly positioned. Overly “deep” insertion usually results in intubation of the right (rather than left) main-stem bronchus because of the right bronchus’ less acute angle with

7 the trachea. Clues to the diagnosis of bronchial intubation include unilateral breath sounds, unexpected hypoxia with pulse oximetry (unreliable with high inspired oxygen concentrations), inability to palpate the TT cuff in the sternal notch during cuff inflation, and decreased breathing-bag compliance (high peak inspiratory pressures).

In contrast, inadequate insertion depth will position the cuff in the larynx, predisposing the patient to laryngeal trauma. Inadequate depth of insertion can be detected by palpating the cuff over the thyroid cartilage.

Because no one technique protects against all possibilities for misplacing a TT, minimal testing should include chest auscultation, routine capnography, and occasionally cuff palpation.

If the patient is repositioned, tube placement must be reconfirmed. Neck extension or lateral rotation most often moves a TT away from the carina, whereas neck flexion most often moves the tube toward the carina.

At no time should excessive force be employed during intubation. Esophageal intubations can result in esophageal rupture and mediastinitis. Mediastinitis presents as severe sore throat, fever, sepsis, and subcutaneous air often manifesting as crepitus. Early intervention is necessary to avoid mortality. If esophageal perforation is suspected, consultation with an otolaryngologist or thoracic surgeon is recommended.

Physiological Responses to Airway Instrumentation

Laryngoscopy and tracheal intubation violate the patient’s protective airway reflexes and predictably lead to hypertension and tachycardia when performed under “light” planes of general anesthesia. The insertion of an LMA is typically associated with less hemodynamic change. Hemodynamic changes can be attenuated by intravenous administration of lidocaine, opioids, or β -blockers or deeper planes of inhalation anesthesia in the minutes before laryngoscopy. Hypotensive agents, including sodium nitroprusside, nitroglycerin, esmolol and nicardipine, have also been shown to effectively attenuate the transient hypertensive response associated with laryngoscopy and intubation. Cardiac arrhythmias—particularly ventricular bigeminy—sometimes occur during intubation and may indicate light anesthesia.

Laryngospasm is a forceful involuntary spasm of the laryngeal musculature caused by sensory stimulation of the superior laryngeal nerve. Triggering stimuli include pharyngeal secretions

or passing a TT through the larynx during extubation. Laryngospasm is usually prevented by extubating patients either deeply asleep or fully awake, but it can occur—albeit rarely—in an awake patient. Treatment of laryngospasm includes providing gentle positive-pressure ventilation with an anesthesia bag and mask using 100% oxygen or administering intravenous lidocaine (1–1.5 mg/kg). If laryngospasm persists and hypoxia develops, small doses of succinylcholine (0.25–0.5 mg/kg) may be required (perhaps in combination with small doses of propofol or another anesthetic) to relax the laryngeal muscles and to allow controlled

8 ventilation. The large negative intrathoracic pressures generated by a struggling patient during laryngospasm can result in the development of negative-pressure pulmonary edema, even in healthy patients.

Whereas laryngospasm may result from an abnormally sensitive reflex, aspiration can result from depression of laryngeal reflexes following prolonged intubation and general anesthesia.

Bronchospasm is another reflex response to intubation and is most common in asthmatic patients. Bronchospasm can sometimes be a clue to bronchial intubation. Other pathophysiological effects of intubation include increased intracranial and intraocular pressures.

Tracheal Tube Malfunction

TTs do not always function as intended. Polyvinyl chloride tubes may be ignited by cautery or laser in an oxygen/nitrous oxide-enriched environment. Valve or cuff damage is not unusual and should be excluded prior to insertion. TT obstruction can result from kinking, from foreign body aspiration, or from thick or inspissated secretions in the lumen.

CASE DISCUSSION

Evaluation & Management of a Difficult Airway

A 17-year-old girl presents for emergency drainage of a submandibular abscess.

TABLE 19-7 Conditions associated with difficult intubations.

Tumors

Micrognathia
Prognathism
Large tongue
Arched palate
Short neck
Prominent upper incisors

¹Can occur postoperatively in patients who have had any neck surgery.

²Also affects arytenoids making them immobile.

What are some important anesthetic considerations during the preoperative evaluation of a patient with an abnormal airway?

Induction of general anesthesia followed by direct laryngoscopy and oral intubation is dangerous, if not impossible, in several situations. (Table 19-7). To determine the optimal intubation technique, the anesthesiologist must elicit an airway history and carefully examine the patient's head and neck. Any available prior anesthesia records should be reviewed for previous problems in airway management. If a facial deformity is severe enough to preclude a good mask seal, positive-pressure ventilation may be impossible.

Furthermore, patients with hypopharyngeal disease are more dependent on awake muscle tone to maintain airway patency. These two groups of patients should generally not be allowed to become apneic—including induction of anesthesia, sedation, or muscle paralysis—until their airway is secured.

If there is an abnormal limitation of the temporomandibular joint that may not improve with muscle paralysis, a nasal approach with an FOB should be considered. Infection confined to the floor of the mouth usually does not preclude nasal intubation. If the hypopharynx is involved to the level of the hyoid bone, however, any trans-laryngeal attempt will be difficult. Other clues to a potentially difficult laryngoscopy include limited neck extension ($<35^\circ$), a distance between the tip of the patient's mandible and hyoid bone of less than 7 cm, a sternomental distance of less than 12.5 cm with the head fully extended and the mouth closed, and a poorly visualized uvula during voluntary tongue protrusion. It must be stressed that because no examination technique is foolproof and the signs of a difficult airway may be subtle, the anesthesiologist must always be prepared for unanticipated difficulties.

The anesthesiologist should also evaluate the patient for signs of airway obstruction (eg, chest retraction, stridor) and hypoxia (agitation, restlessness, anxiety, lethargy). Aspiration pneumonia

is more likely if the patient has recently eaten or if pus is draining from an abscess into the mouth. In either case, techniques that ablate laryngeal reflexes (eg, topical anesthesia) should be avoided.

Cervical trauma or disease is a factor that should be evaluated prior to direct laryngoscopy. Cervical arthritis or previous cervical fusion may make it difficult for the head to be put in the sniffing position; these patients are candidates for bronchoscopy to secure the airway, as discussed previously. Trauma patients with unstable necks or whose neck has not yet been “cleared” are also candidates for bronchoscopy for tracheal intubation. Alternatively, laryngoscopy with in-line stabilization can be performed (**Figure 19–33**).

In the case under discussion, physical examination reveals extensive facial edema that limits the mandible's range of motion. Mask fit does not seem to be impaired, however. Lateral radiographs of the head and neck suggest that the infection has spread over the larynx. Frank pus is observed in the mouth.

Which intubation technique is indicated?

Routine oral and nasal intubations have been described for anesthetized patients. Both of these can also be performed in awake patients. Whether the patient is awake or asleep or whether intubation is to be oral or nasal, it can be performed with

FIGURE 19–33 Technique for airway management of a patient with suspected spinal cord injury. One individual holds the head firmly with the patient on a backboard, the cervical collar left alone if in place, ensuring that neither the head nor neck moves with direct laryngoscopy. A second person applies cricoid pressure and the third performs laryngoscopy and intubation.

direct laryngoscopy, fiberoptic visualization, or video laryngoscopy techniques.

Intubation may be difficult in this patient; however, there is pus draining into the mouth, and positive-pressure ventilation may be impossible. Induction of anesthesia should, therefore, be delayed until after the airway has been secured. Therefore, the alternatives are awake fiberoptic intubation, awake video laryngoscopy, or awake use of optical stylets. The final decision depends on the availability of equipment and the experiences and preferences of the anesthesia caregivers.

Regardless of which alternative is chosen, an emergency surgical airway may be necessary. Therefore, an experienced team, including a surgeon, should be in the operating room, all necessary equipment should be available and unwrapped, and the neck should be prepped and draped.

What premedication would be appropriate for this patient?

Any loss of consciousness or interference with airway reflexes could result in airway obstruction or aspiration. Glycopyrrolate would be a good choice of premedication because it minimizes upper airway secretions without crossing the blood–brain barrier. Parenteral sedatives should be very carefully titrated. Dexmedetomidine and ketamine preserve respiratory effort and are frequently used as sedatives. Psychological preparation of the patient, including explaining each step planned in securing the airway, may improve patient cooperation.

What nerve blocks could be helpful during an awake intubation?

The lingual and some pharyngeal branches of the glossopharyngeal nerve that provide sensation to the posterior third of the tongue and oropharynx are easily blocked by bilateral injection of 2 mL of local anesthetic into the base of the palatoglossal arch (also known as the anterior tonsillar pillar) with a 25-gauge spinal needle (Figure 19–34).

Bilateral **superior laryngeal nerve blocks** and a transtracheal block would anesthetize the airway

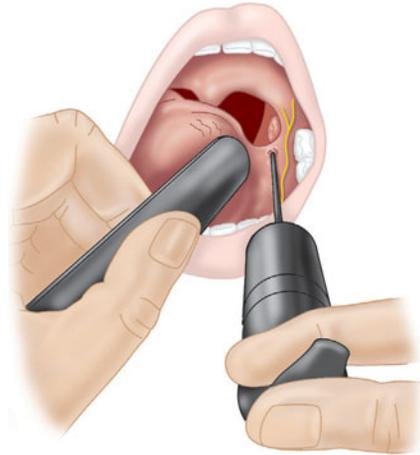

FIGURE 19–34 Nerve block. While the tongue is laterally retracted with a tongue blade, the base of the palatoglossal arch is infiltrated with local anesthetic to block the lingual and pharyngeal branches of the glossopharyngeal nerve. Note that the lingual branches of the glossopharyngeal nerve are not the same as the lingual nerve, which is a branch of the trigeminal nerve.

below the epiglottis (Figure 19–35). The hyoid bone is located, and 3 mL of 2% lidocaine is infiltrated 1 cm below each greater cornu, where the internal branch of the superior laryngeal nerves penetrates the thyrohyoid membrane.

A transtracheal block is performed by identifying and penetrating the CTM while the neck is extended. After confirmation of an intratracheal position by aspiration of air, 4 mL of 4% lidocaine is injected into the trachea at end expiration. A deep inhalation and cough immediately following injection distribute the anesthetic throughout the trachea. Although these blocks may allow the awake patient to tolerate intubation better, they also obtund protective cough reflexes, depress the swallowing reflex, and may lead to aspiration. Topical anesthesia of the pharynx may induce a transient obstruction from the loss of reflex regulation of airway caliber at the level of the glottis.

Because of this patient's increased risk for aspiration, local anesthesia might best be limited to

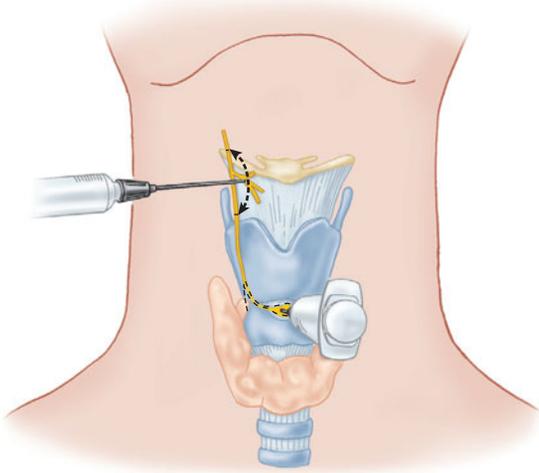

FIGURE 19-35 Superior laryngeal nerve block and transtracheal block.

the nasal passages. Four percent cocaine has no advantages compared with a mixture of 4% lidocaine and 0.25% phenylephrine and can cause cardiovascular side effects. The maximum safe dose of local anesthetic should be calculated—and not exceeded. Local anesthetic is applied to the nasal mucosa with cotton-tipped applicators until a nasal airway that has been lubricated with lidocaine jelly can be placed into the naris with minimal discomfort. Benzocaine spray is frequently used to topicalize the airway, but can produce methemoglobinemia.

Why is it necessary to be prepared for a surgical airway?

Laryngospasm is always a possible complication of intubation in the nonparalyzed patient, even if the patient remains awake. Laryngospasm may make positive-pressure ventilation with a mask impossible. If succinylcholine is administered to break the spasm, the consequent relaxation of pharyngeal muscles may lead to upper airway obstruction and continued inability to ventilate. In this situation, an emergency cricothyrotomy may be lifesaving.

What are some alternative techniques that might be successful?

Other possible strategies include the retrograde passage of a long guidewire or epidural catheter through a needle inserted across the CTM. The catheter is guided cephalad into the pharynx and out through the nose or mouth. A TT is passed over the catheter, which is withdrawn after the tube has entered the larynx. Variations of this technique include passing the retrograde wire through the suction port of a flexible FOB or the lumen of a reintubation stylet that has been preloaded with a TT. These thicker shafts help the TT negotiate the bend into the larynx more easily. Obviously, a vast array of specialized airway equipment exists and must be readily available for management of difficult airways (Table 19-8). Either of these techniques would have been difficult in the patient described in this case

TABLE 19-8 Suggested contents of the portable storage unit for difficult airway management.^{1,2}

- Rigid laryngoscope blades of alternate design and size from those routinely used.
- Tracheal tubes of assorted size.
- Tracheal tube guides. Examples include (but are not limited to) semirigid stylets with or without a hollow core for jet ventilation, light wands, and forceps designed to manipulate the distal portion of the tracheal tube.
- Laryngeal mask airways of assorted sizes.
- Fiberoptic intubation equipment and assorted video and indirect laryngoscopes.
- Retrograde intubation equipment.
- At least one device suitable for emergency nonsurgical airway ventilation. Examples include (but are not limited to) transtracheal jet ventilator, hollow jet ventilation stylet, and Combitube.
- Equipment suitable for emergency surgical airway access (eg, cricothyrotomy).
- An exhaled CO₂ detector.

because of the swelling and anatomic distortion of the neck that can accompany a submandibular abscess.

What are some approaches when the airway is unexpectedly difficult?

The unexpected difficult airway can present both in elective surgical patients and also in emergency intubations in intensive care units, the emergency department, or general hospital wards. Should video laryngoscopy fail even after attempts with an intubating bougie, an intubating LMA should be attempted (Figure 19–36). If ventilation is adequate, an FOB can be loaded with a TT and passed through the LMA into the trachea. Correct tube position is confirmed by visualization of the carina.

Cardiovascular Physiology & Anesthesia

KEY CONCEPTS

- 1** In contrast to action potentials in axons, the spike in cardiac action potentials is followed by a plateau phase that lasts 0.2–0.3 sec. Whereas the action potential for skeletal muscle and nerves is due to the abrupt opening of voltage-gated sodium channels in the cell membrane, in cardiac muscle it is initiated by voltage-gated sodium channels (the spike) and maintained by voltage-gated calcium channels (the plateau).
- 2** Potent inhalational agents depress sinoatrial (SA) node automaticity. These agents seem to have only modest direct effects on the atrioventricular (AV) node, prolonging conduction time and increasing refractoriness. This combination of effects likely explains the frequent occurrence of junctional tachycardia when an anticholinergic agent is administered for sinus bradycardia during inhalation anesthesia; junctional pacemakers are accelerated more than those in the SA node.
- 3** Studies suggest that volatile anesthetics depress cardiac contractility by decreasing the entry of Ca^{2+} into cells during depolarization (affecting T- and L-type calcium channels), altering the kinetics of its release and uptake into the sarcoplasmic reticulum, and decreasing the sensitivity of contractile proteins to calcium.
- 4** Because the normal cardiac index (CI) has a wide range, it is a relatively insensitive measurement of ventricular performance. Abnormalities in CI therefore usually reflect gross ventricular impairment.
- 5** In the absence of hypoxia or severe anemia, measurement of mixed venous oxygen tension (or saturation) is an excellent estimate of the adequacy of cardiac output.
- 6** Patients with reduced ventricular compliance are most affected by loss of a normally timed atrial systole.
- 7** Cardiac output in patients with marked right or left ventricular impairment is very sensitive to acute increases in afterload.
- 8** The ventricular ejection fraction, the fraction of the end-diastolic ventricular volume ejected, is the most commonly used clinical measurement of systolic function.
- 9** Left ventricular diastolic function can be assessed clinically by Doppler echocardiography in a transthoracic or transesophageal examination.

10 Because the endocardium is subjected to the greatest intramural pressures during systole, it tends to be most vulnerable to ischemia during decreases in coronary perfusion pressure.

11 The failing heart becomes increasingly dependent on circulating catecholamines. Abrupt withdrawal in sympathetic outflow or decreases in circulating catecholamine levels, such as can occur following induction of anesthesia, may lead to acute cardiac decompensation.

Anesthesiologists must have a thorough understanding of cardiovascular physiology both for its scientific significance in anesthesia and for its practical applications to patient management. Anesthetic successes and failures are often directly related to the skill of the practitioner in manipulating cardiovascular physiology. This chapter reviews the physiology of the heart and the systemic circulation and the pathophysiology of heart failure.

The circulatory system consists of the heart, blood vessels, and blood. Its function is to provide oxygen and nutrients to the tissues and to carry away the products of metabolism. The heart propels blood through two vascular systems arranged in series. In the normally low-pressure pulmonary circulation, venous blood flows past the alveolar-capillary membrane, takes up oxygen, and eliminates CO_2 . In the high pressure systemic circulation, oxygenated arterial blood is pumped to metabolizing tissues, and the by-products of metabolism are taken up for elimination by the lungs, kidneys, or liver.

The Heart

Although anatomically one organ, the heart can be functionally divided into right and left pumps, each consisting of an atrium and a ventricle. The atria serve as both conduits and priming pumps, whereas the ventricles act as the major pumping chambers. The right ventricle receives systemic venous (deoxygenated) blood and pumps it into the pulmonary circulation, whereas the left ventricle receives pulmonary venous (oxygenated) blood and

pumps it into the systemic circulation. Four valves normally ensure unidirectional flow through each chamber. The normal pumping action of the heart is the result of a complex series of electrically driven and mechanical events. Electrical events precede mechanical ones.

The heart consists of specialized striated muscle in a connective tissue skeleton. Cardiac muscle can be divided into atrial, ventricular, and specialized pacemaker and conducting cells. The self-excitatory nature of cardiac muscle cells and their unique organization allow the heart to function as a highly efficient pump. Serial low-resistance connections (intercalated disks) between individual myocardial cells allow the rapid and orderly spread of depolarization in each pumping chamber. Electrical activity readily spreads from one atrium to another and from one ventricle to another via specialized conduction pathways. The normal absence of direct connections between the atria and ventricles except through the atrioventricular (AV) node delays conduction and enables atrial contraction to prime the ventricle.

CARDIAC ACTION POTENTIALS

At rest, the myocardial cell membrane is nominally permeable to K^+ , but is relatively impermeable to Na^+ . A membrane-bound Na^+-K^+ -adenosine triphosphatase (ATPase) concentrates K^+ intracellularly in exchange for extrusion of Na^+ out of the cell. Intracellular Na^+ concentration is kept low, whereas intracellular K^+ concentration is kept high relative to the extracellular space. The relative impermeability

of the membrane to calcium also maintains a high extracellular to cytoplasmic calcium gradient. Movement of K^+ out of the cell and down its concentration gradient results in a net loss of positive charges from inside the cell. An electrical potential is established across the cell membrane, with the inside of the cell negative with respect to the extracellular environment, because anions do not accompany K^+ . Thus, the resting membrane potential represents the balance between two opposing forces: the movement of K^+ down its concentration gradient and the electrical attraction of the negatively charged intracellular space for the positively charged potassium ions.

The normal ventricular cell resting membrane potential is -80 to -90 mV. As with other excitable tissues (nerve and skeletal muscle), when the cell membrane potential becomes less negative and reaches a threshold value, a characteristic action potential (depolarization) develops (Figure 20-1 and Table 20-1). The action potential transiently raises the membrane potential of the myocardial cell **1** to $+20$ mV. In contrast to action potentials in axons, the spike in cardiac action potentials is followed by a plateau phase that lasts 0.2–0.3 sec. Whereas the action potential for skeletal muscle and nerves is due to the abrupt opening of voltage-gated sodium channels in the cell membrane, in cardiac muscle, it is initiated by voltage-gated sodium channels (the spike) and maintained by voltage-gated calcium channels (the plateau). Depolarization is also accompanied by a transient decrease in potassium permeability. Subsequent restoration of normal potassium permeability and termination of sodium and calcium channel permeability eventually restores the membrane potential to its resting value.

Following depolarization, the cells are typically refractory to subsequent normal depolarizing stimuli until “phase 4.” The effective refractory period is the minimum interval between two depolarizing impulses that will propagate. In fast-conducting myocardial cells, this period is generally closely correlated with the duration of the action potential. In contrast, the effective refractory period in more slowly conducting myocardial cells can outlast the duration of the action potential.

Table 20-2 lists some of the multiple types of ion channels in cardiac muscle membrane. Some

are activated by a change in cell membrane voltage, whereas others open only when bound by ligands. T-type (transient) voltage-gated calcium channels play a role in phase 0 of depolarization. During the plateau phase (phase 2), Ca^{2+} inflow occurs through slow L-type (long-lasting), voltage-gated calcium channels. Three major types of potassium channels are responsible for repolarization. The first results in a transient outward K^+ current (I_{To}), the second is responsible for a short rectifying current (I_{Kr}), and the third produces a slowly acting rectifying current (I_{Ks}) that helps to restore the cell membrane potential to its resting value.

INITIATION & CONDUCTION OF THE CARDIAC IMPULSE

The cardiac impulse normally originates in the sinoatrial (SA) node, a group of specialized pacemaker cells in the sulcus terminalis, located posteriorly at the junction of the right atrium and the superior vena cava. These cells seem to have an outer membrane that leaks Na^+ (and possibly Ca^{2+}). The slow influx of Na^+ , which results in a less negative resting membrane potential (-50 to -60 mV), has three important consequences: near constant inactivation of voltage-gated sodium channels, an action potential with a threshold of -40 mV that is primarily due to ion movement across the slow calcium channels, and regular spontaneous depolarizations. During each cycle, intracellular leakage of Na^+ causes the cell membrane to become progressively less negative; when the threshold potential is reached, calcium channels open, K^+ permeability decreases, and an action potential develops. Restoration of normal K^+ permeability returns the cells in the SA node to their normal resting membrane potential.

The impulse generated at the SA node is normally rapidly conducted across the atria and to the AV node. Specialized atrial fibers may speed up conduction to both the left atrium and the AV node. The AV node, which is located in the septal wall of the right atrium, just anterior to the opening of the coronary sinus and above the insertion of the septal leaflet of the tricuspid valve, is actually made up of three distinct areas: an upper junctional (AN) region, a middle nodal (N) region, and a lower junctional (NH) region. Although the N region does not

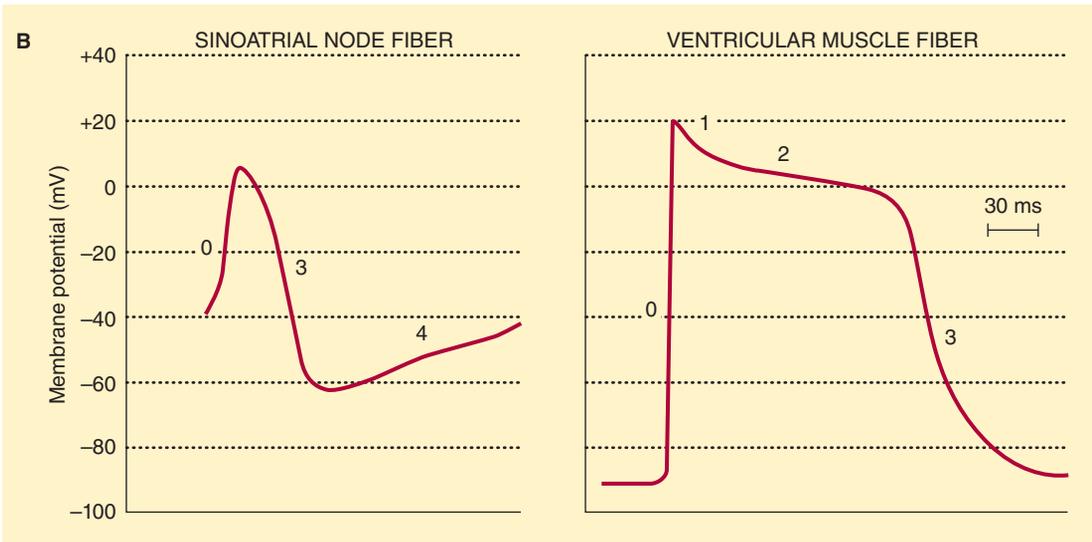

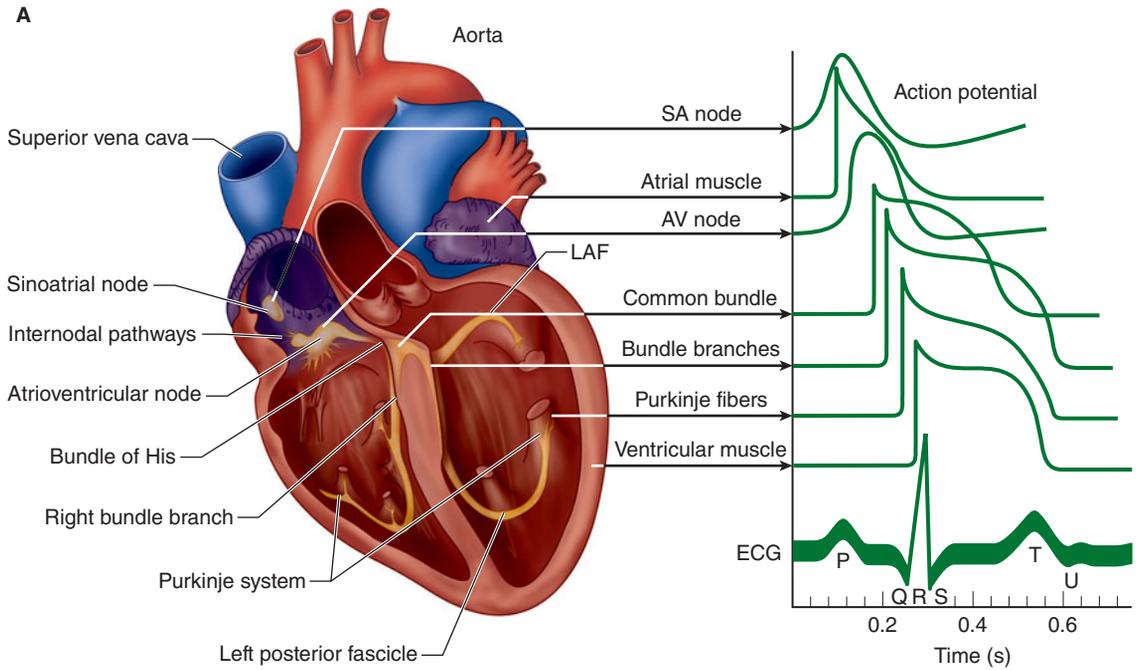

FIGURE 20–1 Cardiac action potentials. **A:** Note the characteristic contours of action potentials recorded from different parts of the heart. **B:** Pacemaker cells in the sinoatrial (SA) node lack the same distinct phases as atrial and ventricular muscle cells and display prominent

spontaneous diastolic depolarization. See Table 20–1 for an explanation of the different phases of the action potential. (Modified and reproduced, with permission, from Barrett KE: *Ganong's Review of Medical Physiology*, 24th ed., McGraw-Hill, 2012.)

TABLE 20-1 Cardiac action potential.

Phase	Name	Event	Cellular Ion Movement
0	Upstroke	Activation (opening) of voltage-gated Na ⁺ channels	Na ⁺ entry and decreased permeability to K ⁺
1	Early rapid repolarization	Inactivation of Na ⁺ channel and transient increase in K ⁺ permeability	K ⁺ out (I _{To})
2	Plateau	Activation of slow calcium channels	Ca ²⁺ entry
3	Final repolarization	Inactivation of calcium channels and increased permeability to K ⁺	K ⁺ out
4	Resting potential	Normal permeability restored (atrial and ventricular cells)	Na ⁺ -K ⁺ -ATPase pumps K ⁺ in and Na ⁺ out
	Diastolic repolarization	Intrinsic slow leakage of Ca ²⁺ into cells that spontaneously depolarize	Ca ²⁺ in

possess intrinsic spontaneous activity (automaticity), both junctional areas do. The normally slower rate of spontaneous depolarization in AV junctional areas (40–60 times/min) allows the faster SA node to control heart rate. Any factor that decreases the rate of SA node depolarization or increases the automaticity of AV junctional areas allows the junctional areas to function as the pacemaker for the heart.

Impulses from the SA node normally reach the AV node after about 0.04 sec, but leave after another 0.11 sec. This delay is the result of the slowly conducting small myocardial fibers within the AV node, which depend on slow calcium channels for propagation of the action potential. In contrast, conduction of the impulse between adjoining cells in the atria and in the ventricles is due primarily to activation of sodium channels. The lower fibers of the AV node combine to form the common bundle of His. This specialized group of fibers passes into the

²ATP, adenosine triphosphate.

interventricular septum before dividing into left and right branches to form the complex network of Purkinje fibers that depolarizes both ventricles. In sharp contrast to AV nodal tissue, His–Purkinje fibers have the fastest conduction velocities in the heart, resulting in nearly simultaneous depolarization of the entire endocardium of both ventricles (normally within 0.03 s). Synchronized depolarization of the lateral and septal walls of the left ventricle promotes effective ventricular contraction. The spread of the impulse from the endocardium to the epicardium through ventricular muscle requires an additional 0.03 sec. Thus, an impulse arising from the SA node normally requires less than 0.2 sec to depolarize the entire heart.

2 Potent inhaled anesthetics depress SA node automaticity. These agents seem to have only modest direct effects on the AV node, prolonging conduction time and increasing refractoriness. This combination of effects likely explains the occurrence of junctional tachycardia when an anticholinergic is administered for sinus bradycardia during inhalation anesthesia; junctional pacemakers are accelerated more than those in the SA node. The electrophysiological effects of volatile agents on Purkinje fibers and ventricular muscle are complex due to autonomic interactions. Both antiarrhythmic and arrhythmogenic properties are described. The former may be due to direct depression of Ca²⁺ influxes,

whereas the latter generally involves potentiation of catecholamines, especially with halothane. The arrhythmogenic effect requires activation of both α_1 - and β -adrenergic receptors. Intravenous induction agents have limited electrophysiological effects in usual clinical doses. Opioids, particularly fentanyl and sufentanil, can depress cardiac conduction, increasing AV node conduction and the refractory period and prolonging the duration of the Purkinje fiber action potential.

Local anesthetics have important electrophysiological effects on the heart at blood concentrations that are generally associated with systemic toxicity. In the case of lidocaine, electrophysiological effects at low blood concentrations can be therapeutic. At high blood concentrations, local anesthetics depress conduction by binding to sodium channels; at extremely high concentrations, they also depress the SA node. The most potent local anesthetics—bupivacaine, etidocaine, and to a lesser degree, ropivacaine—seem to have the most potent effects on the heart, particularly on Purkinje fibers and ventricular muscle. Bupivacaine binds open or inactivated sodium channels and dissociates from them slowly. It can cause profound sinus bradycardia and sinus node arrest and malignant ventricular arrhythmias; furthermore, it can depress left ventricular contractility. Twenty percent lipid emulsions have been used to treat local anesthetic cardiac toxicity. The mechanisms of action of this therapy are unclear, although possibilities include serving as a lipid reservoir and decreasing lipophilic toxic local anesthetics in the myocardium.

Calcium channel blockers are organic compounds that block Ca^{2+} influx through L-type but not T-type channels. Dihydropyridine blockers, such as nifedipine, simply plug the channel, whereas other agents, such as verapamil, and to a lesser extent, diltiazem, preferentially bind the channel in its depolarized inactivated state (use-dependent blockade).

MECHANISM OF CONTRACTION

Myocardial cells contract as a result of the interaction of two overlapping, rigid contractile proteins, actin and myosin. These proteins are fixed in position within each cell during both contraction and relaxation. Dystrophin, a large intracellular protein,

connects actin to the cell membrane (sarcolemma). Cell shortening occurs when the actin and myosin are allowed to fully interact and slide over one another. This interaction is normally prevented by two regulatory proteins, troponin and tropomyosin; troponin is composed of three subunits (troponin I, troponin C, and troponin T). Troponin is attached to actin at regular intervals, whereas tropomyosin lies within the center of the actin structure. An increase in intracellular Ca^{2+} concentration (from about 10^{-7} to 10^{-5} mol/L) promotes contraction as Ca^{2+} ions bind troponin C. The resulting conformational change in these regulatory proteins exposes the active sites on actin that allow interaction with myosin bridges (points of overlapping). The active site on myosin functions as a magnesium-dependent ATPase whose activity is enhanced by the increase in intracellular Ca^{2+} concentration. A series of attachments and disengagements occur as each myosin bridge advances over successive active sites on actin. Adenosine triphosphate (ATP) is consumed during each attachment. Relaxation occurs as Ca^{2+} is actively pumped back into the sarcoplasmic reticulum by a Ca^{2+} - Mg^{2+} -ATPase; the resulting drop in intracellular Ca^{2+} concentration allows the troponin-tropomyosin complex to again prevent the interaction between actin and myosin.

Excitation–Contraction Coupling

The quantity of Ca^{2+} ions required to initiate contraction exceeds that entering the cell through slow calcium channels during phase 2. The small amount that does enter through slow calcium channels triggers the release of much larger amounts of Ca^{2+} stored intracellularly (calcium-dependent calcium release) within cisterns in the sarcoplasmic reticulum.

The action potential of muscle cells depolarizes their T systems, tubular extensions of the cell membrane that transverse the cell in close approximation to the muscle fibrils, via dihydropyridine receptors (voltage-gated calcium channels). This initial increase in intracellular Ca^{2+} triggers an even greater Ca^{2+} inflow across ryanodine receptors, a nonvoltage-dependent calcium channel in the sarcoplasmic reticulum. The force of contraction is directly dependent on the magnitude of the initial Ca^{2+} inflow. During relaxation, when the slow channels close, a

membrane-bound ATPase actively transports Ca^{2+} back into the sarcoplasmic reticulum. Ca^{2+} is also extruded extracellularly by an exchange of intracellular Ca^{2+} for extracellular sodium by an ATPase in the cell membrane. Thus, relaxation of the heart also requires ATP.

The quantity of intracellular Ca^{2+} available, its rate of delivery, and its rate of removal determine, respectively, the maximum tension developed, the rate of contraction, and the rate of relaxation. Sympathetic stimulation increases the force of contraction by raising intracellular Ca^{2+} concentration via a β_1 -adrenergic receptor-mediated increase in intracellular cyclic adenosine monophosphate (cAMP) through the action of a stimulatory G protein. The increase in cAMP recruits additional open calcium channels. Moreover, adrenergic agonists enhance the rate of relaxation by enhancing Ca^{2+} reuptake by the sarcoplasmic reticulum. Phosphodiesterase inhibitors, such as inamrinone, enoximone, and milrinone, produce similar effects by preventing the breakdown of intracellular cAMP. Digitalis glycosides increase intracellular Ca^{2+} concentration through inhibition of the membrane-bound Na^+ - K^+ -ATPase; the resulting small increase in intracellular Na^+ allows for a greater influx of Ca^{2+} via the Na^+ - Ca^{2+} exchange mechanism. Glucagon enhances contractility by increasing intracellular cAMP levels via activation of a specific nonadrenergic receptor. The new agent levosimendan is a calcium sensitizer that enhances contractility by binding to troponin C. In contrast, release of acetylcholine following vagal stimulation depresses contractility through increased cyclic guanosine monophosphate (cGMP) levels and inhibition of adenylyl cyclase; these effects are mediated by an inhibitory G protein. Acidosis blocks slow calcium channels and therefore also depresses cardiac contractility by unfavorably altering intracellular Ca^{2+} kinetics.

3 Studies suggest that volatile anesthetics depress cardiac contractility by decreasing the entry of Ca^{2+} into cells during depolarization (affecting T- and L-type calcium channels), altering the kinetics of its release and uptake into the sarcoplasmic reticulum, and decreasing the sensitivity of contractile proteins to Ca^{2+} . Halothane and enflurane seem to depress contractility more than isoflurane, sevoflurane, and desflurane. Anesthetic-induced

cardiac depression is potentiated by hypocalcemia, β -adrenergic blockade, and calcium channel blockers. Nitrous oxide also produces concentration-dependent decreases in contractility by reducing the availability of intracellular Ca^{2+} during contraction. The mechanisms of direct cardiac depression from intravenous anesthetics are not well established, but presumably involve similar actions. Of all the major intravenous induction agents, ketamine seems to have the least direct depressant effect on contractility. Local anesthetic agents also depress cardiac contractility by reducing Ca^{2+} influx and release in a dose-dependent fashion. The more potent (at nerve block) agents, such as bupivacaine, tetracaine, and ropivacaine, more significantly depress left ventricular contractility than less potent (at nerve block) agents, such as lidocaine or chloroprocaine.

INNERVATION OF THE HEART

Parasympathetic fibers primarily innervate the atria and conducting tissues. Acetylcholine acts on specific cardiac muscarinic receptors (M_2) to produce negative chronotropic, dromotropic, and inotropic effects. In contrast, sympathetic fibers are more widely distributed throughout the heart. Cardiac sympathetic fibers originate in the thoracic spinal cord (T1–T4) and travel to the heart initially through the cervical (stellate) ganglia and from the ganglia as the cardiac nerves. Norepinephrine release causes positive chronotropic, dromotropic, and inotropic effects primarily through activation of β_1 -adrenergic receptors. β_2 -Adrenergic receptors are normally fewer in number and are found primarily in the atria; activation increases heart rate and, to a lesser extent, contractility.

Cardiac autonomic innervation has an apparent *sidedness*, because the right sympathetic and right vagus nerves primarily affect the SA node, whereas the left sympathetic and vagus nerves principally affect the AV node. Vagal effects frequently have a very rapid onset and resolution, whereas sympathetic influences generally have a more gradual onset and dissipation. Sinus arrhythmia is a cyclic variation in heart rate that corresponds to respiration (increasing with inspiration and decreasing during expiration); it is due to cyclic changes in vagal tone.

THE CARDIAC CYCLE

The cardiac cycle can be defined by both electrical and mechanical events (Figure 20–2). *Systole* refers to contraction and *diastole* refers to relaxation. Most

diastolic ventricular filling occurs passively before atrial contraction. Contraction of the atria normally contributes 20% to 30% of ventricular filling. **Three waves can generally be identified on atrial pressure tracings** (Figure 20–2). The *a* wave is due to

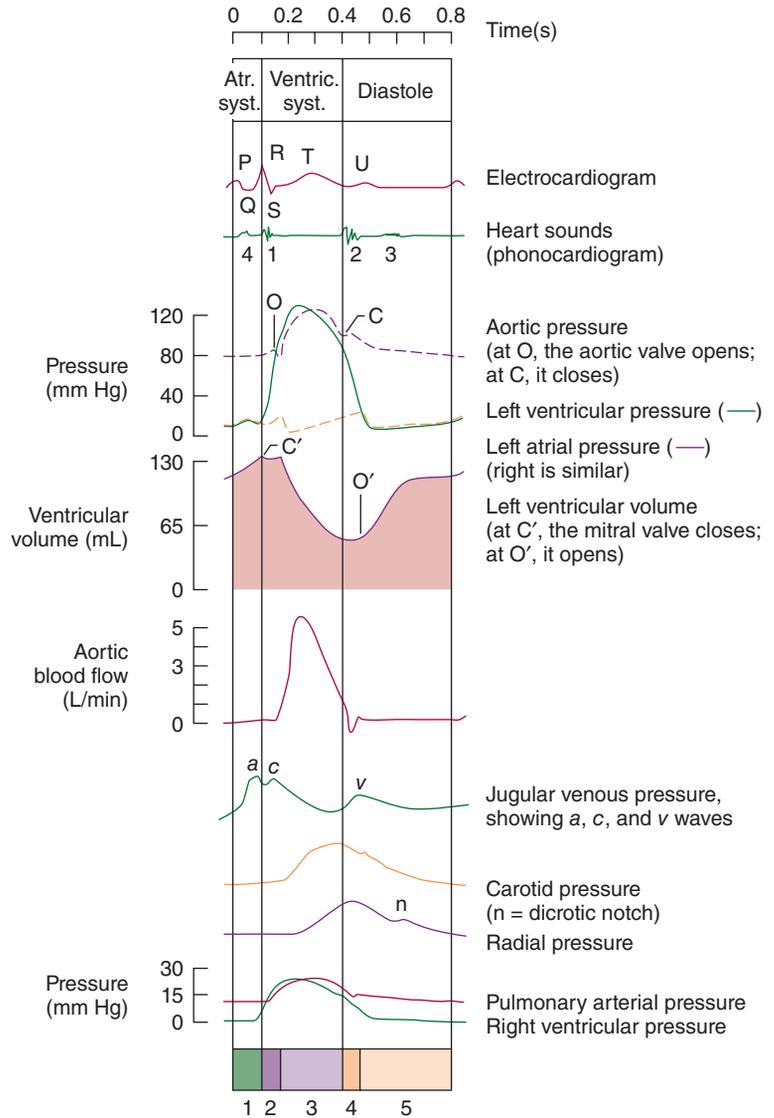

FIGURE 20–2 The normal cardiac cycle. Note the correspondence between electrical and mechanical events. (Modified and reproduced, with permission, from Barrett KE: *Ganong's Review of Medical Physiology*, 24th ed. McGraw-Hill, 2012.)

- Phases of cardiac cycle
1. Atrial systole
 2. Isometric contraction
 3. Ejection
 4. Isometric relaxation
 5. Filling

atrial systole. The *c* wave coincides with ventricular contraction and is said to be caused by bulging of the AV valve into the atrium. The *v* wave is the result of pressure buildup from venous return before the AV valve opens again. The *x* descent is the decline in pressure between the *c* and *v* waves and is thought to be due to a pulling down of the atrium by ventricular contraction. Incompetence of the AV valve on either side of the heart abolishes the *x* descent on that side, resulting in a prominent *cv* wave. The *y* descent follows the *v* wave and represents the decline in atrial pressure as the AV valve opens. The notch in the aortic pressure tracing is referred to as the *incisura* and is said to represent the brief pressure change from transient backflow of blood into the left ventricle just before aortic valve closure.

DETERMINANTS OF VENTRICULAR PERFORMANCE

Discussions of ventricular function usually refer to the left ventricle, but the same concepts apply to the right ventricle. Although the ventricles are often thought of as functioning separately, their interdependence has clearly been demonstrated. Moreover, factors affecting systolic and diastolic functions can be differentiated: Systolic function involves ventricular ejection, whereas diastolic function is related to ventricular filling.

Ventricular systolic function is often (erroneously) equated with cardiac output, which can be defined as the volume of blood pumped by the heart per minute. Because the two ventricles function in series, their outputs are normally equal. Cardiac output (CO) is expressed by the following equation:

$$CO = SV \times HR$$

where *SV* is the stroke volume (the volume pumped per contraction) and *HR* is heart rate. To compensate for variations in body size, CO is often expressed in terms of total body surface area:

$$CI = \frac{CO}{BSA}$$

where CI is the cardiac index and BSA is body surface area. BSA is usually obtained from nomograms

based on height and weight (**Figure 20-3**). Normal CI is 2.5–4.2 L/min/m². Because the normal CI has a wide range, it is a relatively insensitive measurement of ventricular performance. Abnormalities in CI therefore usually reflect gross ventricular impairment. A more accurate assessment can be obtained if the response of the cardiac output to exercise is evaluated. Under these conditions, failure of the cardiac output to increase and keep up with oxygen consumption is reflected by a decreasing mixed venous oxygen saturation. A decrease in mixed venous oxygen saturation in response to increased demand usually reflects inadequate tissue perfusion. Thus, in the absence of hypoxia or severe anemia, measurement of mixed venous oxygen tension (or saturation) is an excellent estimate of the adequacy of cardiac output.

1. Heart Rate

When stroke volume remains constant, cardiac output is directly proportional to heart rate. Heart rate is an intrinsic function of the SA node (spontaneous depolarization), but is modified by autonomic, humoral, and local factors. The normal intrinsic rate of the SA node in young adults is about 90–100 beats/min, but it decreases with age based on the following formula:

$$\text{Normal intrinsic heart rate} = 118 \text{ beats/min} - (0.57 \times \text{age})$$

Enhanced vagal activity slows the heart rate via stimulation of M₂ cholinergic receptors, whereas enhanced sympathetic activity increases the heart rate mainly through activation of β₁-adrenergic receptors and, to lesser extent, β₂-adrenergic receptors (see above).

2. Stroke Volume

Stroke volume is normally determined by three major factors: preload, afterload, and contractility. This analysis is analogous to laboratory observations on skeletal muscle preparations. Preload is muscle length prior to contraction, whereas afterload is the tension against which the muscle must

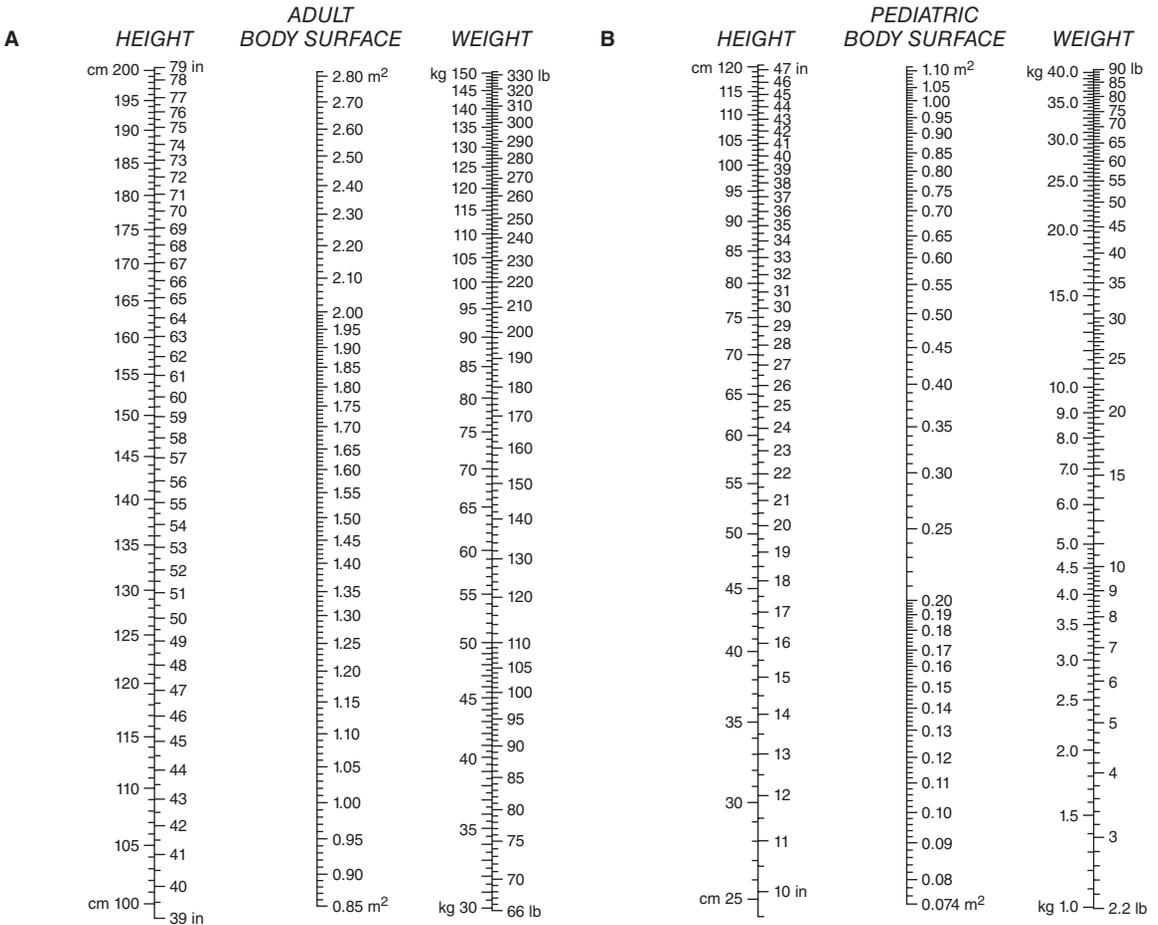

FIGURE 20-3 Nomograms for calculating body surface area (BSA) in adult (A) and pediatric (B) patients. (Data from the formula of Du Bois and Du Bois: Arch Intern Med 1916;17:863. Copyright 1916, American Medical Association.)

contract. Contractility is an intrinsic property of the muscle that is related to the force of contraction but is independent of both preload and afterload. Because the heart is a three-dimensional multichambered pump, both ventricular geometric form and valvular dysfunction can also affect stroke volume (Table 20-3).

Preload

Ventricular preload is end-diastolic volume, which is generally dependent on ventricular filling. The relationship between cardiac output and left ventricular end-diastolic volume is known as Starling’s

law of the heart (Figure 20-4). Note that when the heart rate and contractility remain constant, cardiac output is directly proportional to preload until excessive end-diastolic volumes are reached. At that

point, cardiac output does not appreciably change—or may even decrease. Excessive distention of either ventricle can lead to excessive dilatation and incompetence of the AV valves.

A. Determinants of Ventricular Filling

Ventricular filling can be influenced by a variety of factors (Table 20-4), of which the most important is venous return. Because most of the other

factors affecting venous return are usually fixed, vascular capacity is normally its major determinant. Increases in metabolic activity reduce vascular capacity, so that venous return to the heart increases as the volume of venous capacitance vessels decreases. Changes in blood volume and venous tone are important causes of intraoperative and postoperative changes in ventricular filling and cardiac output. Any factor that alters the normally small venous pressure gradient favoring blood return to the heart also affects cardiac filling. Such factors include changes in intrathoracic pressure (positive-pressure ventilation or thoracotomy), posture (positioning during surgery), and pericardial pressure (pericardial disease).

The most important determinant of right ventricular preload is venous return. **In the absence of significant pulmonary or right ventricular dysfunction, venous return is also the major determinant of left ventricular preload.** Normally, the end-diastolic volumes of both ventricles are similar,

TABLE 20-4 Factors affecting ventricular preload.

Blood volume
Distribution of blood volume
Posture
Intrathoracic pressure
Pericardial pressure
Venous tone
Rhythm (atrial contraction)
Heart rate

and, normally, the venous return is numerically equivalent to the cardiac output.

Both heart rate and rhythm can also affect ventricular preload. Increases in heart rate are associated with proportionately greater reductions in diastole than systole. Ventricular filling therefore progressively becomes impaired at increased heart rates (>120 beats/min in adults). Absent (atrial fibrillation), ineffective (atrial flutter), or altered timing of atrial contraction (low atrial or junctional rhythms) can also reduce ventricular filling by 20% to 30%. Patients with reduced ventricular compliance are more affected by the loss of a normally timed atrial systole than are those with normal ventricular compliance.

B. Diastolic Function and Ventricular Compliance

Left ventricular end-diastolic pressure (LVEDP) can be used as a measure of preload only if the relationship between ventricular volume and pressure (ventricular compliance) is constant. However, ventricular compliance is normally nonlinear (Figure 20-5). Impaired diastolic function reduces ventricular compliance. Therefore, the same LVEDP that corresponds to a normal preload in a normal patient may correspond to a decreased preload in a patient with impaired diastolic function.

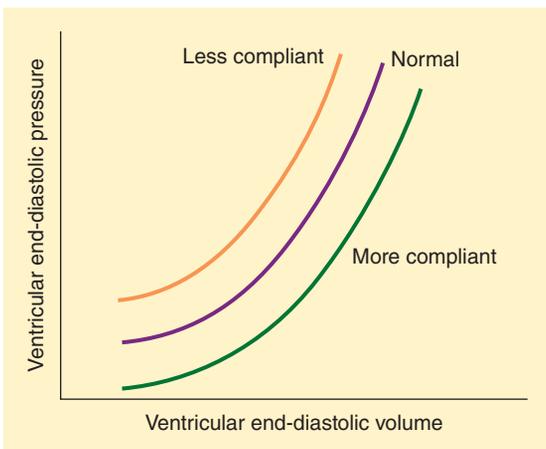

FIGURE 20-5 Normal and abnormal ventricular compliance.

Many factors are known to influence ventricular diastolic function and compliance. Nonetheless, measurement of LVEDP or other pressures approximating LVEDP (such as pulmonary artery occlusion pressure) are potential means of estimating left ventricular preload. Changes in central venous pressure can be used as a rough index for changes in right and left ventricular preload in most normal individuals.

Factors affecting ventricular compliance can be separated into those related to the rate of relaxation (early diastolic compliance) and passive stiffness of the ventricles (late diastolic compliance). Hypertrophy (from hypertension or aortic valve stenosis), ischemia, and asynchrony reduce early compliance; hypertrophy and fibrosis reduce late compliance. Extrinsic factors (such as pericardial disease, excessive distention of the contralateral ventricle, increased airway or pleural pressure, tumors, and surgical compression) can also reduce ventricular compliance. Because of its normally thinner wall, the right ventricle is more compliant than the left.

Afterload

Afterload for the intact heart is commonly equated with either ventricular wall tension during systole or arterial impedance to ejection. Wall tension may be thought of as the pressure the ventricle must overcome to reduce its cavity volume. If the ventricle is assumed to be spherical, ventricular wall tension can be expressed by Laplace's law:

$$\text{Circumferential stress} = \frac{P \times R}{2 \times H}$$

where P is intraventricular pressure, R is the ventricular radius, and H is wall thickness. Although the normal ventricle is usually ellipsoidal, this relationship is still useful. The larger the ventricular radius, the greater the wall tension required to develop the same ventricular pressure. Conversely, an increase in wall thickness reduces ventricular wall tension.

Systolic intraventricular pressure is dependent on the force of ventricular contraction; the viscoelastic properties of the aorta, its proximal branches,

and blood (viscosity and density); and **systemic vascular resistance (SVR)**. Arteriolar tone is the primary determinant of SVR. Because viscoelastic properties are generally fixed in any given patient, left ventricular afterload is usually equated clinically with SVR, which is calculated by the following equation:

$$\text{SVR} = 80 \times \frac{\text{MAP} - \text{CVP}}{\text{CO}}$$

where MAP is mean arterial pressure in millimeters of mercury, CVP is central venous pressure in millimeters of mercury, and CO is cardiac output in liters per minute. Normal SVR is 900–1500 dyn · s cm⁻⁵. Systolic blood pressure may also be used as an approximation of left ventricular afterload in the absence of chronic changes in the size, shape, or thickness of the ventricular wall or acute changes in systemic vascular resistance. Some clinicians prefer to use CI instead of CO in calculating a systemic vascular resistance index (SVRI), so that SVRI = SVR × BSA.

Right ventricular afterload is mainly dependent on pulmonary vascular resistance (PVR) and is expressed by the following equation:

$$\text{PVR} = 80 \times \frac{\text{PAP} - \text{LAP}}{\text{CO}}$$

where PAP is mean pulmonary artery pressure and LAP is left atrial pressure. In practice, pulmonary capillary wedge pressure (PCWP) is usually substituted as an approximation for LAP. Normal PVR is 50–150 dyn · s cm⁻⁵.

Cardiac output is inversely related to large changes in afterload on the left ventricle; however, small increases or decreases in afterload may have no effect at all on cardiac output. Because of its thinner wall, the right ventricle is more sensitive to changes in afterload than is the left ventricle.

7 Cardiac output in patients with marked right or left ventricular impairment is very sensitive to acute increases in afterload. The latter is particularly true in the presence of drug- or ischemia-induced myocardial depression or chronic heart failure.

Contractility

Cardiac contractility (inotropy) is the intrinsic ability of the myocardium to pump in the absence of changes in preload or afterload. Contractility is related to the rate of myocardial muscle shortening, which is, in turn, dependent on the intracellular Ca²⁺ concentration during systole. Increases in heart rate can also enhance contractility under some conditions, perhaps because of the increased availability of intracellular Ca²⁺.

Contractility can be altered by neural, humoral, or pharmacological influences. Sympathetic nervous system activity normally has the most important effect on contractility. Sympathetic fibers innervate atrial and ventricular muscle, as well as nodal tissues. In addition to its positive chronotropic effect, norepinephrine release also enhances contractility primarily via β₁-receptor activation. α-Adrenergic receptors are also present in the myocardium, but seem to have only minor positive inotropic and chronotropic effects. Sympathomimetic drugs and secretion of epinephrine from the adrenal glands similarly increase contractility via β₁-receptor activation.

Myocardial contractility is depressed by hypoxia, acidosis, depletion of catecholamine stores within the heart, and loss of functioning muscle mass as a result of ischemia or infarction. At large enough doses, most anesthetics and antiarrhythmic agents are negative inotropes (ie, they decrease contractility).

Wall Motion Abnormalities

Regional wall motion abnormalities cause a breakdown of the analogy between the intact heart and skeletal muscle preparations. Such abnormalities may be due to ischemia, scarring, hypertrophy, or altered conduction. When the ventricular cavity does not collapse symmetrically or fully, emptying becomes impaired. Hypokinesis (decreased contraction), akinesis (failure to contract), and dyskinesis (paradoxical bulging) during systole reflect increasing degrees of contraction abnormalities. Although contractility may be normal or even enhanced in some areas, abnormalities in other areas of the ventricle can impair emptying and reduce stroke volume. The severity of the impairment depends on the size and number of abnormally contracting areas.

Valvular Dysfunction

Valvular dysfunction can involve any one of the four valves in the heart and can include stenosis, regurgitation (incompetence), or both. Stenosis of an AV valve (tricuspid or mitral) reduces stroke volume primarily by decreasing ventricular preload, whereas stenosis of a semilunar valve (pulmonary or aortic) reduces stroke volume primarily by increasing ventricular afterload. In contrast, valvular regurgitation can reduce stroke volume without changes in preload, afterload, or contractility and without wall motion abnormalities. The effective stroke volume is reduced by the regurgitant volume with every contraction. When an AV valve is incompetent, a significant part of the ventricular end-diastolic volume can flow backward into the atrium during systole; the stroke volume is reduced by the regurgitant volume. Similarly, when a semilunar valve is incompetent, a fraction of end-diastolic volume arises from backward flow into the ventricle during diastole.

ASSESSMENT OF VENTRICULAR FUNCTION

1. Ventricular Function Curves

Plotting cardiac output or stroke volume against preload is useful in evaluating pathological states and understanding drug therapy. Normal right and left ventricular function curves are shown in **Figure 20-6**.

Ventricular pressure–volume diagrams are useful because they dissociate contractility from both preload and afterload. Two points are identified on such diagrams: the end-systolic point (ESP) and the end-diastolic point (EDP) (**Figure 20-7**). ESP is reflective of systolic function, whereas EDP is more reflective of diastolic function. For any given contractile state, all ESPs are on the same line (ie, the relationship between end-systolic volume and end-systolic pressure is fixed).

2. Assessment of Systolic Function

The change in ventricular pressure over time during systole (dp/dt) is defined by the first derivative of the ventricular pressure curve and is often used

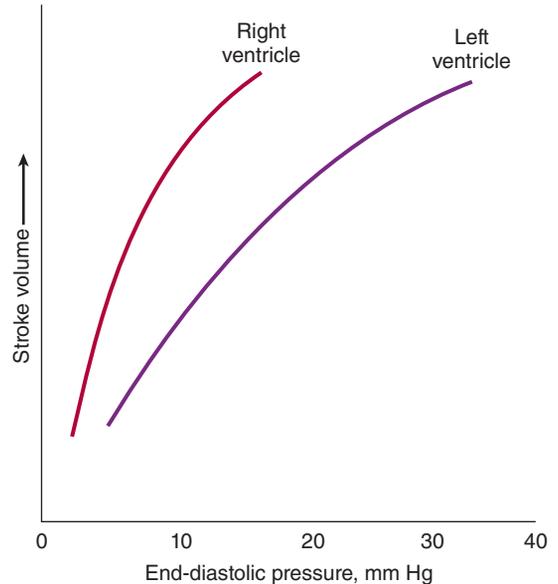

FIGURE 20-6 Function curves for the left and right ventricles.

as a measure of contractility. Contractility is directly proportional to dp/dt , but accurate measurement of this value requires a high-fidelity (“Millar”) ventricular catheter; however, it can be estimated with echocardiography. Although arterial pressure tracings are distorted due to properties of the vascular tree, the initial rate of rise in pressure (the slope) can serve as a rough approximation; the more proximally the arterial line catheter is located in the arterial tree, the more accurate the extrapolation will be. The usefulness of dp/dt is also limited in that it may be affected by preload, afterload, and heart rate.

Ejection Fraction

8 The ventricular ejection fraction (EF), the fraction of the end-diastolic ventricular volume ejected, is the most commonly used clinical measurement of systolic function. EF can be calculated by the following equation:

$$EF = \frac{EDV - ESV}{EDV}$$

where EDV is left ventricular diastolic volume and ESV is end-systolic volume. Normal EF is

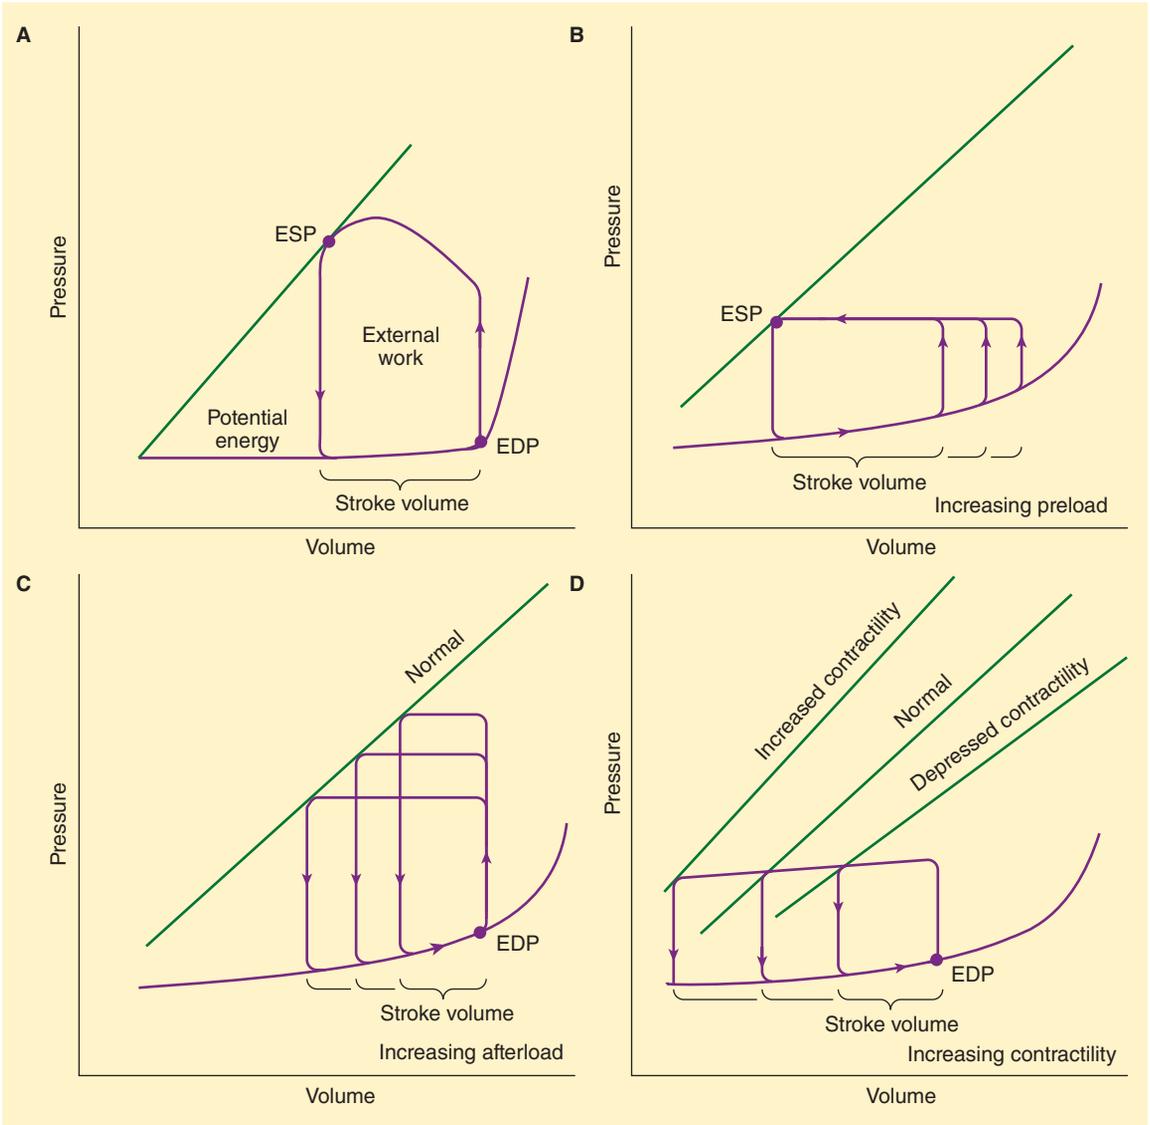

FIGURE 20-7 Ventricular pressure-volume diagrams. **A:** A single ventricular contraction. Note that stroke volume represents change in volume on the x-axis (difference between end-systolic volume and end-diastolic volume). Note also that the circumscribed area represents external work performed by the ventricle.

approximately 0.67 ± 0.08 . Measurements can be made preoperatively from cardiac catheterization, radionuclide studies, or transthoracic (TTE) or transesophageal echocardiography (TEE).

Pulmonary artery catheters with fast-response thermistors allow measurement of the right ventricular EF. Unfortunately, when pulmonary vascular resistance increases, decreases in right ventricular

E, early diastolic flow; A, peak atrial systolic flow; IVRT, isovolumic relaxation time; DT_E, deceleration time of E.

EF may reflect afterload rather than contractility. Left ventricular EF is not an accurate measure of ventricular contractility in the presence of mitral insufficiency.

3. Assessment of Diastolic Function

9 Left ventricular diastolic function can be assessed clinically by Doppler echocardiography on a transthoracic or transesophageal examination. Flow velocities are measured across the mitral valve during diastole. Three patterns of diastolic dysfunction are generally recognized based on isovolumetric relaxation time, the ratio of peak early diastolic flow (E) to peak atrial systolic flow (A), and the deceleration time (DT) of E (DT_E) (Figure 20-8). Tissue Doppler is frequently used to distinguish “pseudonormal” from normal diastolic function. Tissue Doppler is also an excellent way to detect “conventional” diastolic dysfunction. An e’ wave peak velocity of less than 8 cm/sec is associated with impaired diastolic function. An E/e’ wave ratio that is greater than 15 is consistent with elevated left ventricular end-diastolic pressure (Figure 20-9).

Systemic Circulation

The systemic vasculature can be divided functionally into arteries, arterioles, capillaries, and veins. Arteries are the high-pressure conduits that supply the various organs. Arterioles are the small vessels that directly feed and control blood flow through each capillary bed. Capillaries are thin-walled vessels that allow the exchange of nutrients between blood and tissues. Veins return blood from capillary beds to the heart.

The distribution of blood between the various components of the circulatory system is shown in Table 20-5. Note that most of the blood volume is in the systemic circulation—specifically, within systemic veins. Changes in systemic venous tone allow these vessels to function as a reservoir for blood. Following significant blood or fluid losses, a sympathetically mediated increase in venous tone reduces the caliber of these vessels and shifts blood into other parts of the vascular system. Conversely, venodilation allows these vessels to accommodate increases in blood volume. Sympathetic control of venous tone is an important determinant of venous

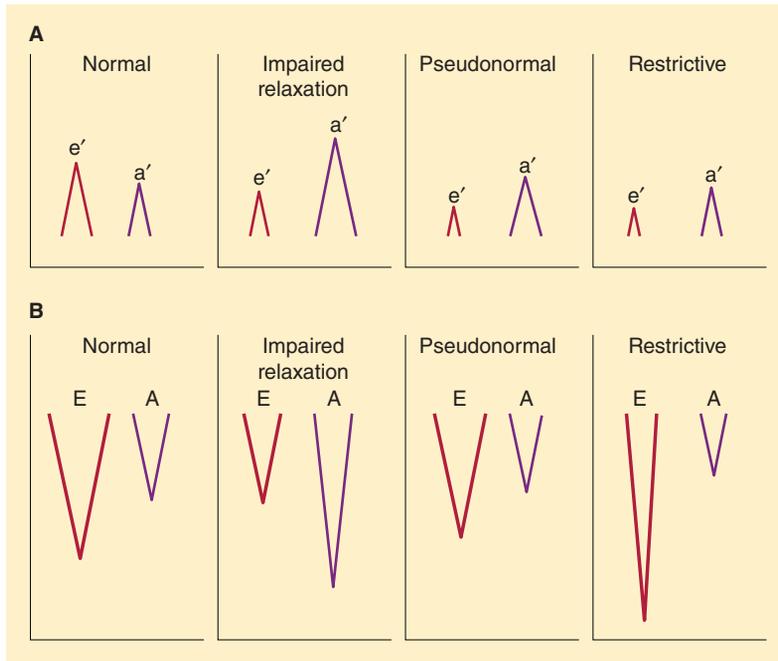

FIGURE 20-9 Tissue Doppler. **A:** Tissue Doppler at the lateral mitral annulus. During diastole the annulus moves toward the transesophageal examination transducer in the esophagus. Thus the e' and a' waves of diastolic filling are positive deflections above the baseline. **B:** When transesophageal examination is used to measure transmitral diastolic inflow, the E and A waves of early

and late filling are below the baseline because flow is moving away from the Doppler probe in the esophagus. Tissue Doppler can be used to distinguish normal from pseudonormal diastolic inflow pattern because the e' wave remains depressed as diastolic dysfunction progresses.

return to the heart. Reduced venous tone following induction of anesthesia frequently results in venous pooling of blood and contributes to hypotension.

A multiplicity of factors influences blood flow in the vascular tree. These include mechanisms of local and metabolic control, endothelium-derived factors, the autonomic nervous system, and circulating hormones.

TABLE 20-5 Distribution of blood volume.

Heart	7%
Pulmonary circulation	9%
Systemic circulation

AUTOREGULATION

Most tissue beds regulate their own blood flow (autoregulation). Arterioles generally dilate in response to reduced perfusion pressure or increased tissue demand. Conversely, arterioles constrict in response to increased pressure or reduced tissue demand. These phenomena are likely due to both an intrinsic response of vascular smooth muscle to stretch and the accumulation of vasodilatory metabolic by-products. The latter may include K^+ , H^+ , CO_2 , adenosine, and lactate.

ENDOTHELIUM-DERIVED FACTORS

The vascular endothelium is metabolically active in elaborating or modifying substances that directly or indirectly play a major role in controlling blood

pressure and flow. These include vasodilators (eg, nitric oxide, prostacyclin [PGI_2]), vasoconstrictors (eg, endothelins, thromboxane A_2), anticoagulants (eg, thrombomodulin, protein C), fibrinolytics (eg, tissue plasminogen activator), and factors that inhibit platelet aggregation (eg, nitric oxide and PGI_2). Nitric oxide is synthesized from arginine by nitric oxide synthetase. This substance has a number of functions. In the circulation, it is a potent vasodilator. It binds guanylate cyclase, increasing cGMP levels and producing vasodilation. Endothelially derived vasoconstrictors (endothelins) are released in response to thrombin and epinephrine.

AUTONOMIC CONTROL OF THE SYSTEMIC VASCULATURE

Although the parasympathetic system can exert important influences on the circulation, autonomic control of the vasculature is primarily sympathetic. Sympathetic outflow to the circulation passes out of the spinal cord at all thoracic segments and the first two lumbar segments. These fibers reach blood vessels via specific autonomic nerves or by traveling along spinal nerves. Sympathetic fibers innervate all parts of the vasculature except for capillaries. Their principal function is to regulate vascular tone. Variations of arterial vascular tone serve to regulate blood pressure and the distribution of blood flow to the various organs, whereas variations in venous tone alter vascular capacity, venous pooling, and venous return to the heart.

The vasculature has sympathetic vasoconstrictor and vasodilator fibers, but the former are more important physiologically in most tissue beds. Sympathetic-induced vasoconstriction (via α_1 -adrenergic receptors) can be potent in skeletal muscle, kidneys, gut, and skin; it is least active in the brain and heart. The most important vasodilatory fibers are those feeding skeletal muscle, mediating increased blood flow (via β_2 -adrenergic receptors) in response to exercise. Vasodepressor (vasovagal) syncope, which can occur following intense emotional strain associated with high sympathetic tone, results from reflex activation of both vagal and sympathetic vasodilator fibers.

Vascular tone and autonomic influences on the heart are controlled by vasomotor centers in the reticular formation of the medulla and lower pons. Distinct vasoconstrictor and vasodilator areas have been identified. Vasoconstriction is mediated by the anterolateral areas of the lower pons and upper medulla. They are also responsible for adrenal secretion of catecholamines, as well as the enhancement of cardiac automaticity and contractility. Vasodilatory areas, which are located in the lower medulla, are also adrenergic, but function by projecting inhibitory fibers upward to the vasoconstrictor areas. Vasomotor output is modified by inputs from throughout the central nervous system, including the hypothalamus, cerebral cortex, and the other areas in the brainstem. Areas in the posterolateral medulla receive input from both the vagal and the glossopharyngeal nerves and play an important role in mediating a variety of circulatory reflexes. The sympathetic system normally maintains some tonic vasoconstriction on the vascular tree. Loss of this tone following induction of anesthesia or sympathectomy frequently contributes to perioperative hypotension.

ARTERIAL BLOOD PRESSURE

Systemic blood flow is pulsatile in large arteries because of the heart's cyclic activity; by the time blood reaches the systemic capillaries, flow is continuous (laminar). The mean pressure falls to less than 20 mm Hg in the large systemic veins that return blood to the heart. The largest pressure drop, nearly 50%, is across the arterioles, and the arterioles account for the majority of SVR.

MAP is proportionate to the product of $\text{SVR} \times \text{CO}$. This relationship is based on an analogy to Ohm's law, as applied to the circulation:

$$\text{MAP} - \text{CVP} \approx \text{SVR} \times \text{CO}$$

Because CVP is normally very small compared with MAP, the former can usually be ignored. From this relationship, it is readily apparent that hypotension is the result of a decrease in SVR, CO, or both: To maintain arterial blood pressure, a decrease in either SVR or CO must be compensated by an increase in the other. MAP can be measured as the integrated mean of the arterial pressure waveform.

Alternatively, MAP may be estimated by the following formula:

$$\text{MAP} = \text{Diastolic pressure} + \frac{\text{Pulse pressure}}{3}$$

where pulse pressure is the difference between systolic and diastolic blood pressure. Arterial pulse pressure is directly related to stroke volume, but is inversely proportional to the compliance of the arterial tree. Thus, decreases in pulse pressure may be due to a decrease in stroke volume, an increase in SVR, or both. Increased pulse pressure increases shear stress on vessel walls, potentially leading to atherosclerotic plaque rupture and thrombosis or rupture of aneurysms. Increased pulse pressure in patients undergoing cardiac surgery has been associated with adverse renal and neurological outcomes.

Transmission of the arterial pressure wave from large arteries to smaller vessels in the periphery is faster than the actual movement of blood; the pressure wave velocity is 15 times the velocity of blood in the aorta. Moreover, reflections of the propagating waves off arterial walls widen pulse pressure before the pulse wave is completely dampened in very small arteries.

Control of Arterial Blood Pressure

Arterial blood pressure is regulated by a series of immediate, intermediate, and long-term adjustments that involve complex neural, humoral, and renal mechanisms.

A. Immediate Control

Minute-to-minute control of blood pressure is primarily the function of autonomic nervous system reflexes. Changes in blood pressure are sensed both centrally (in hypothalamic and brainstem areas) and peripherally by specialized sensors (baroreceptors). Decreases in arterial blood pressure result in increased sympathetic tone, increased adrenal secretion of epinephrine, and reduced vagal activity. **The resulting systemic vasoconstriction, increased heart rate, and enhanced cardiac contractility serve to increase blood pressure.**

Peripheral baroreceptors are located at the bifurcation of the common carotid arteries and the aortic arch. Elevations in blood pressure increase

baroreceptor discharge, inhibiting systemic vasoconstriction and enhancing vagal tone (**baroreceptor reflex**). Reductions in blood pressure decrease baroreceptor discharge, allowing vasoconstriction and reduction of vagal tone. Carotid baroreceptors send afferent signals to circulatory brainstem centers via Hering's nerve (a branch of the glossopharyngeal nerve), whereas aortic baroreceptor afferent signals travel along the vagus nerve. Of the two peripheral sensors, the carotid baroreceptor is physiologically more important and is primarily responsible for minimizing changes in blood pressure that are caused by acute events, such as a change in posture. Carotid baroreceptors sense MAP most effectively between pressures of 80 and 160 mm Hg. Adaptation to acute changes in blood pressure occurs over the course of 1–2 days, rendering this reflex ineffective for longer term blood pressure control. All volatile anesthetics depress the normal baroreceptor response, but isoflurane and desflurane seem to have less effect. Cardiopulmonary stretch receptors located in the atria, left ventricle, and pulmonary circulation can cause a similar effect.

B. Intermediate Control

In the course of a few minutes, sustained decreases in arterial pressure, together with enhanced sympathetic outflow, activate the renin–angiotensin–aldosterone system, increase secretion of arginine vasopressin (AVP), and alter normal capillary fluid exchange. Both angiotensin II and AVP are potent arteriolar vasoconstrictors. Their immediate action is to increase SVR. In contrast to formation of angiotensin II, which responds to relatively smaller changes, sufficient AVP secretion to produce vasoconstriction will only occur in response to more marked degrees of hypotension. Angiotensin constricts arterioles via AT₁ receptors. AVP mediates vasoconstriction via V₁ receptors and exerts its antidiuretic effect via V₂ receptors.

Sustained changes in arterial blood pressure can also alter fluid exchange in tissues by their secondary effects on capillary pressures. Hypertension increases interstitial movement of intravascular fluid, whereas hypotension increases reabsorption of interstitial fluid. Such compensatory changes in intravascular volume can reduce fluctuations in

blood pressure, particularly in the absence of adequate renal function (see below).

C. Long-Term Control

The effects of slower renal mechanisms become apparent within hours of sustained changes in arterial pressure. As a result, the kidneys alter total body sodium and water balance to restore blood pressure to normal. Hypotension results in sodium (and water) retention, whereas hypertension generally increases sodium excretion in normal individuals.

ANATOMY & PHYSIOLOGY OF THE CORONARY CIRCULATION

1. Anatomy

Myocardial blood supply is derived entirely from the right and left coronary arteries (Figure 20-10). Blood flows from epicardial to endocardial vessels. After perfusing the myocardium, blood returns to the right atrium via the coronary sinus and the anterior cardiac veins. A small amount of blood returns directly into the chambers of the heart by way of the thebesian veins.

The right coronary artery (RCA) normally supplies the right atrium, most of the right ventricle, and a variable portion of the left ventricle (inferior wall). In 85% of persons, the RCA gives rise to the posterior descending artery (PDA), which supplies the superior-posterior interventricular septum and inferior wall—a right dominant circulation; in the remaining 15% of persons, the PDA is a branch of the left coronary artery—a left dominant circulation.

The left coronary artery normally supplies the left atrium and most of the interventricular septum and left ventricle (septal, anterior, and lateral walls). After a short course, the left main coronary artery bifurcates into the left anterior descending artery (LAD) and the circumflex artery (CX); the LAD supplies the septum and anterior wall and the CX supplies the lateral wall. In a left dominant circulation, the CX wraps around the AV groove and continues down as the PDA to also supply most of the posterior septum and inferior wall.

The arterial supply to the SA node may be derived from either the RCA (60% of individuals)

or the LAD (the remaining 40%). The AV node is usually supplied by the RCA (85% to 90%) or, less frequently, by the CX (10% to 15%); the bundle of His has a dual blood supply derived from the PDA and LAD. The anterior papillary muscle of the mitral valve also has a dual blood supply that is fed by diagonal branches of the LAD and marginal branches of the CX. In contrast, the posterior papillary of the mitral valve is usually supplied only by the PDA and is therefore much more vulnerable to ischemic dysfunction.

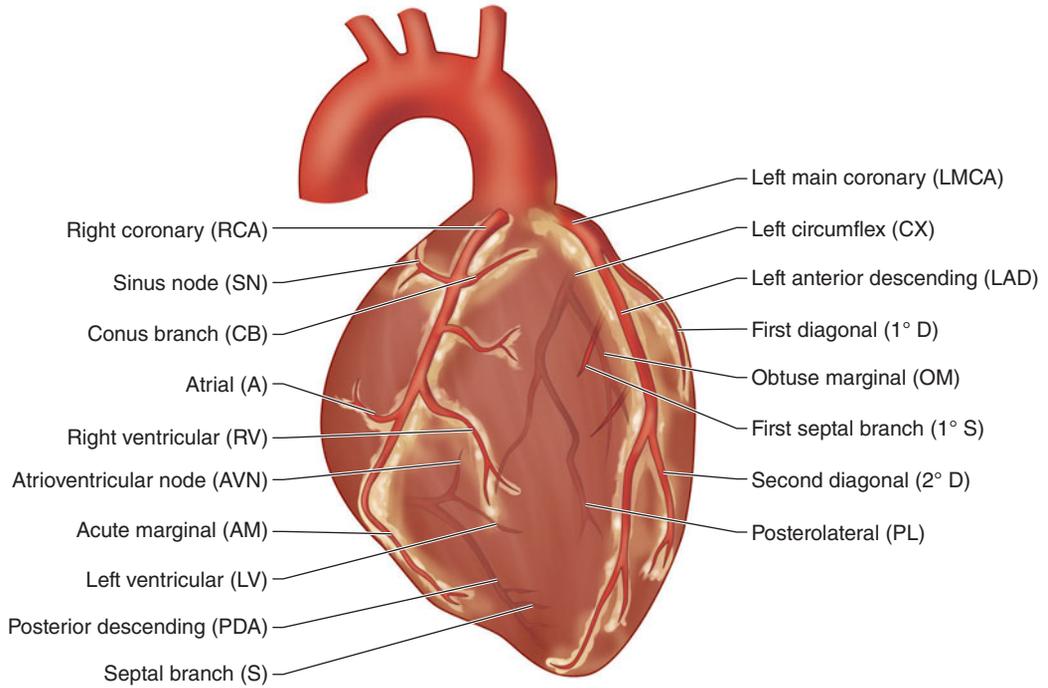

2. Determinants of Coronary Perfusion

Coronary perfusion is unique in that it is intermittent rather than continuous, as it is in other organs. During contraction, intramyocardial pressures in the left ventricle approach systemic arterial pressure. The force of left ventricular contraction almost completely occludes the intramyocardial part of the coronary arteries; in fact, blood flow may transiently reverse in epicardial vessels. Even during the latter part of diastole, left ventricular pressure eventually exceeds venous (right atrial) pressure. **Thus, coronary perfusion pressure is usually determined by the difference between aortic pressure and ventricular pressure**, and the left ventricle is perfused almost entirely during diastole. In contrast, the right ventricle is perfused during both systole and diastole (Figure 20-11). Moreover, as a determinant of myocardial blood flow, arterial diastolic pressure is more important than MAP:

$$\text{Coronary perfusion pressure} = \text{Arterial diastolic pressure} - \text{LVEDP}$$

Decreases in aortic pressure or increases in ventricular end-diastolic pressure can reduce coronary perfusion pressure. Increases in heart rate also decrease coronary perfusion because of the disproportionately greater reduction in diastolic time as heart rate increases (Figure 20-12). Because it is subjected to the greatest intramural pressures during systole, the endocardium tends to be most vulnerable to ischemia during decreases in coronary perfusion pressure.

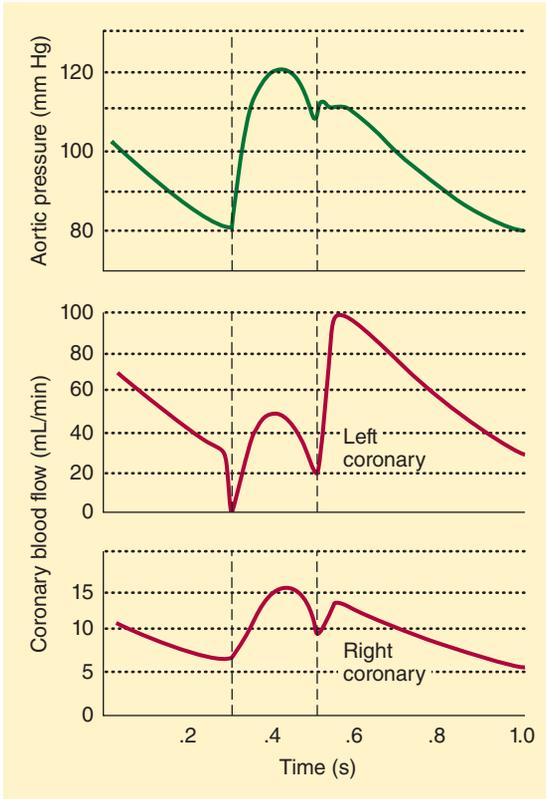

FIGURE 20-11 Coronary blood flow during the cardiac cycle. (Modified and reproduced, with permission, from Pappano A, Wier W: *Cardiovascular Physiology*, 10th ed. Mosby, 2013.)

Control of Coronary Blood Flow

Coronary blood flow normally parallels myocardial metabolic demand. In the average adult man, coronary blood flow is approximately 250 mL/min at rest. The myocardium regulates its own blood flow closely between perfusion pressures of 50 and 120 mm Hg. Beyond this range, blood flow becomes increasingly pressure dependent.

Under normal conditions, changes in blood flow are entirely due to variations in coronary arterial tone (resistance) in response to metabolic demand. Hypoxia—either directly, or indirectly through the release of adenosine—causes coronary vasodilation. Autonomic influences are generally weak. Both α_1 - and β_2 -adrenergic receptors are present in the coronary arteries. The α_1 -receptors

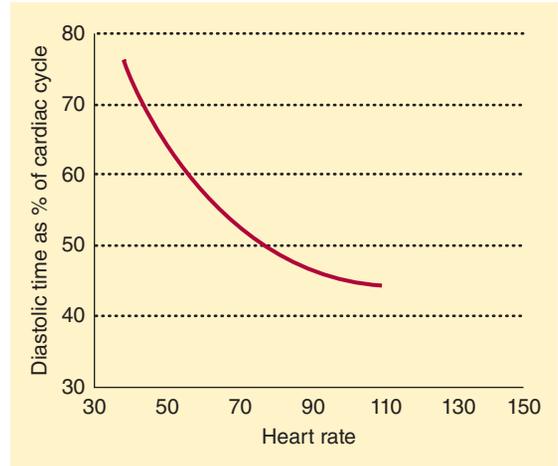

FIGURE 20-12 The relationship between diastolic time and heart rate.

are primarily located on larger epicardial vessels, whereas the β_2 -receptors are mainly found on the smaller intramuscular and subendocardial vessels. Sympathetic stimulation generally increases myocardial blood flow because of an increase in metabolic demand and a predominance of β_2 -receptor activation. Parasympathetic effects on the coronary vasculature are generally minor and weakly vasodilatory.

3. Myocardial Oxygen Balance

Myocardial oxygen demand is usually the most important determinant of myocardial blood flow. Relative contributions to oxygen requirements include basal requirements (20%), electrical activity (1%), volume work (15%), and pressure work (64%). The myocardium usually extracts 65% of the oxygen in arterial blood, compared with 25% in most other tissues. Coronary sinus oxygen saturation is usually 30%. Therefore, the myocardium (unlike other tissues) cannot compensate for reductions in blood flow by extracting more oxygen from hemoglobin. Any increases in myocardial metabolic demand must be met by an increase in coronary blood flow. **Table 20-6** lists the most important factors in myocardial oxygen demand and supply. Note that the heart rate and, to a lesser extent, ventricular

end-diastolic pressure are important determinants of both supply and demand.

EFFECTS OF ANESTHETIC AGENTS

Most volatile anesthetic agents are coronary vasodilators. Their effect on coronary blood flow is variable because of their direct vasodilating properties, reduction of myocardial metabolic requirements (and secondary decrease due to autoregulation), and effects on arterial blood pressure. The mechanism is not clear, and these effects are unlikely to have any clinical importance. Halothane and isoflurane seem to have the greatest effect; the former primarily affects large coronary vessels, whereas the latter affects mostly smaller vessels. Vasodilation due to desflurane seems to be primarily autonomically mediated, whereas sevoflurane seems to lack coronary vasodilating properties. Dose-dependent abolition of autoregulation may be greatest with isoflurane.

Volatile agents exert beneficial effects in experimental myocardial ischemia and infarction. They reduce myocardial oxygen requirements and protect against reperfusion injury; these effects are mediated by activation of ATP-sensitive K^+ (K_{ATP}) channels. Some evidence also suggests that volatile anesthetics enhance recovery of the “stunned” myocardium

(hypocontractile, but recoverable, myocardium after ischemia). Moreover, although volatile anesthetics decrease myocardial contractility, they can be potentially beneficial in patients with heart failure because most of them decrease preload and afterload.

The Pathophysiology of Heart Failure

Systolic heart failure occurs when the heart is unable to pump a sufficient amount of blood to meet the body’s metabolic requirements. Clinical manifestations usually reflect the effects of the low cardiac output on tissues (eg, fatigue, dyspnea, oxygen debt, acidosis), the damming-up of blood behind the failing ventricle (dependent edema or pulmonary venous congestion), or both. The left ventricle is most commonly the primary cause, often with secondary involvement of the right ventricle. Isolated right ventricular failure can occur in the setting of advanced disease of the lung parenchyma or pulmonary vasculature. Left ventricular failure is most commonly the result of myocardial dysfunction, usually from coronary artery disease, but may also be the result of viral disease, toxins, untreated hypertension, valvular dysfunction, arrhythmias, or pericardial disease.

Diastolic dysfunction can be present in the absence of signs or symptoms of heart failure. Symptoms arising from diastolic dysfunction are the result of atrial hypertension (Figure 20–13). Failure of the heart to relax during diastole leads to elevated left ventricular end-diastolic pressure, which is transmitted to the left atrium and pulmonary vasculature. Common causes of diastolic dysfunction include hypertension, coronary artery disease, hypertrophic cardiomyopathy, valvular heart disease, and pericardial disease. Although diastolic dysfunction can occasionally cause symptoms of heart failure, even in the presence of normal systolic function (normal left ventricular ejection fraction), it nearly always occurs in association with systolic dysfunction in patients with heart failure.

Diastolic dysfunction is diagnosed echocardiographically. Placing the pulse wave Doppler sample gate at the tips of the mitral valve during

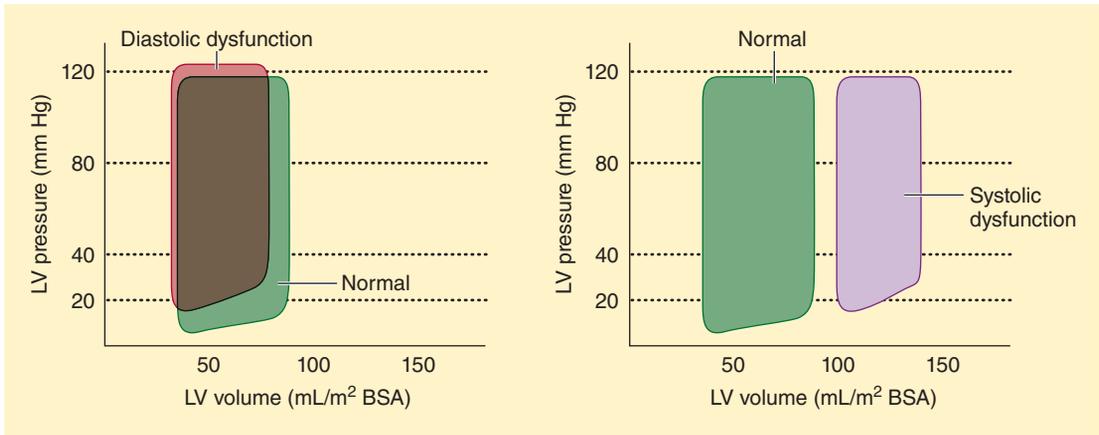

FIGURE 20-13 Ventricular pressure–volume relationships in isolated systolic and diastolic dysfunction.

left ventricular filling will produce the characteristic diastolic flow pattern (Figure 20-9). In patients with normal diastolic function, the ratio between the peak velocities of the early (E) and the atrial (A) waves is from 0.8 to 2. In the early stages of diastolic dysfunction, the primary abnormality is impaired relaxation. When left ventricular relaxation is delayed, the initial pressure gradient between the left atrium and the left ventricle is reduced, resulting in a decline in early filling, and, consequently, a reduced peak E wave velocity. The A wave velocity is increased relative to the E wave, and the E/A ratio is reduced. As diastolic dysfunction advances, the left atrial pressure increases, restoring the gradient between the left atrium and left ventricle with an apparent restoration of the normal E/A ratio. This pattern is characterized as “pseudonormalized.” Using the E/A ratio alone cannot distinguish between a normal and pseudonormalized pattern of diastolic inflow. As diastolic dysfunction worsens further, a restrictive pattern is obtained. In this scenario, the left ventricle is so stiff that pressure builds in the left atrium, resulting in a dramatic peak of early filling and a prominent, tall, narrow E wave. Because the ventricle is so poorly compliant, the atrial contraction contributes little to filling, resulting in a diminished A wave and an E/A ratio greater than 2:1.

Doppler patterns of pulmonary venous flow have been used to distinguish between a

pseudonormalized and normal E/A ratio. Currently, most echocardiographers use tissue Doppler to examine the movement of the lateral annulus of the mitral valve during ventricular filling (Figure 20-9). Tissue Doppler allows the echocardiographer to determine both the velocity and the direction of the movement of the heart. During systole, the heart contracts toward the apex, away from a TEE transducer in the esophagus. This motion produces the s' wave of systole. During early and late diastolic filling, the heart moves toward the transducer producing the e' and a' waves. Like the inflow patterns achieved with pulse wave Doppler, characteristic patterns of diastolic dysfunction are reflected in the tissue Doppler trace. An e' wave less than 8 cm/sec is consistent with diastolic dysfunction. Of note, the tissue Doppler trace does not produce a pseudonormalized pattern permitting the echocardiographer to readily distinguish between normal and abnormal diastolic function.

Cardiac output *may* be reduced at rest with heart failure, but the key point is that the heart is incapable of appropriately *increasing* cardiac output and oxygen delivery in response to demand. Inadequate oxygen delivery to tissues is reflected by a low mixed venous oxygen tension and an increase in the arteriovenous oxygen content difference. In compensated heart failure, the arteriovenous difference may be normal at rest, but it rapidly widens during stress or exercise.

Heart failure is less commonly associated with an elevated cardiac output. This form of heart failure is most often seen with sepsis, thyrotoxicosis, and other hypermetabolic states, which are typically associated with a low SVR.

COMPENSATORY MECHANISMS

Compensatory mechanisms generally present in patients with heart failure include increased preload, activation of the sympathetic nervous system and the renin–angiotensin–aldosterone system, and increased release of AVP. Although these mechanisms can initially compensate for mild to moderate cardiac dysfunction, with increasing severity of dysfunction, they may actually contribute to the cardiac impairment. Many of the drug treatments of chronic heart failure serve to counteract these mechanisms.

Increased Preload

An increase in ventricular size not only reflects an inability to keep up with an increased circulating blood volume, but also serves to increase stroke volume by moving the heart up the Starling curve (see Figure 20–4). Even when EF is reduced, an increase in ventricular end-diastolic volume can maintain a normal stroke volume. Worsening venous congestion caused by the pooling of blood behind the failing ventricle and excessive ventricular dilatation can rapidly lead to clinical deterioration. Left ventricular failure results in pulmonary vascular congestion and progressive transudation of fluid, first into the pulmonary interstitium and then into alveoli (pulmonary edema). Right ventricular failure leads to systemic venous hypertension, which results in peripheral edema, hepatic congestion and dysfunction, and ascites. Dilatation of the annulus of either AV valve leads to valvular regurgitation, further impairing ventricular output.

Increased Sympathetic Tone

Sympathetic activation increases release of norepinephrine from nerve endings in the heart and the

adrenal secretion of epinephrine into the circulation. Plasma catecholamine levels are generally directly proportional to the degree of left ventricular dysfunction. Although enhanced sympathetic outflow can initially maintain cardiac output by increasing heart rate and contractility, worsening ventricular function elicits increasing degrees of vasoconstriction in an effort to maintain arterial blood pressure. The associated increase in afterload, however, reduces cardiac output and exacerbates the ventricular failure.

Chronic sympathetic activation in patients with heart failure eventually decreases the response of adrenergic receptors to catecholamines (receptor uncoupling), the number of receptors (down-regulation), and cardiac catecholamine stores. **11** Nonetheless, the failing heart becomes increasingly dependent on circulating catecholamines. Abrupt withdrawal in sympathetic outflow or decreases in circulating catecholamine levels, such as can occur following induction of anesthesia, may lead to acute cardiac decompensation. A reduced density of M_2 receptors also decreases parasympathetic influences on the heart.

Sympathetic activation tends to redistribute systemic blood flow output away from the skin, gut, kidneys, and skeletal muscle to the heart and brain. Decreased renal perfusion, together with β_1 -adrenergic activity at the juxtaglomerular apparatus, activates the renin–angiotensin–aldosterone axis, which leads to sodium retention and interstitial edema. Moreover, vasoconstriction secondary to elevated angiotensin II levels increases left ventricular afterload and causes further deterioration of systolic function. The latter partially accounts for the efficacy of angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers in heart failure. Symptoms may also improve in some patients with careful, low-dose β -adrenergic blockade. Outcomes in heart failure are improved by administration of ACE inhibitors (and/or angiotensin receptor blockers), certain long-acting β -blockers (carvedilol or extended release metoprolol), and aldosterone inhibitors (spironolactone or eplerenone).

Circulating AVP levels, often markedly increased in patients with severe heart failure, will

increase ventricular afterload and are responsible for a defect in free water clearance that is commonly associated with hyponatremia.

Brain natriuretic peptide (BNP) is produced in the heart in response to myocyte distention. Elevated BNP concentration (>500 pg/mL) usually indicates heart failure, and measurement of BNP concentration can be used to distinguish between heart failure and lung disease as a cause of dyspnea. Recombinant BNP was developed as a vasodilator and inhibitor of the renin–angiotensin–aldosterone system for use in patients with severe decompensated heart failure, but outcomes were not improved with its use.

Ventricular Hypertrophy

Ventricular hypertrophy can occur with or without dilatation, depending on the type of stress imposed on the ventricle. When the heart is subjected to either pressure or volume overload, the initial response is to increase sarcomere length and optimally overlap actin and myosin. With time, ventricular muscle mass begins to increase in response to the abnormal stress.

In the volume-overloaded ventricle, the problem is an increase in diastolic wall stress. The increase in ventricular muscle mass is sufficient only to compensate for the increase in diameter: The ratio of the ventricular radius to wall thickness is unchanged. Sarcomeres replicate mainly in series, resulting in eccentric hypertrophy. Although ventricular EF remains depressed, the increase in end-diastolic volume can maintain normal at-rest stroke volume (and cardiac output).

The problem in a pressure-overloaded ventricle is an increase in systolic wall stress. In this case, sarcomeres mainly replicate in parallel, resulting in concentric hypertrophy: The hypertrophy is such that the ratio of myocardial wall thickness to ventricular radius increases. As can be seen from Laplace's law, systolic wall stress can then be normalized. Ventricular hypertrophy, particularly that caused by pressure overload, usually results in progressive diastolic dysfunction. The most common reasons for isolated left ventricular hypertrophy are hypertension and aortic stenosis.

CASE DISCUSSION

A Patient With a Short P–R Interval

A 38-year-old man is scheduled for endoscopic sinus surgery following a recent onset of headaches. He gives a history of having passed out at least once during one of these headaches. A preoperative electrocardiogram (ECG) is normal, except for a P–R interval of 0.116 sec with normal P-wave morphology.

What is the significance of the short P–R interval?

The P–R interval, which is measured from the beginning of atrial depolarization (P wave) to the beginning of ventricular depolarization (QRS complex), usually represents the time required for depolarization of both atria, the AV node, and the His–Purkinje system. Although the P–R interval can vary with heart rate, it is normally 0.12–0.2 sec in duration. Abnormally short P–R intervals can be seen with either low atrial (or upper AV junctional) rhythms or preexcitation phenomena. The two can usually be differentiated by P-wave morphology: With a low atrial rhythm, atrial depolarization is retrograde, resulting in an inverted P wave in leads II, III, and aVF; with preexcitation, the P wave is normal during sinus rhythm. If the pacemaker rhythm originates from a lower AV junctional focus, the P wave may be lost in the QRS complex or may follow the QRS.

What is preexcitation?

Preexcitation usually refers to early depolarization of the ventricles by an abnormal conduction pathway from the atria. Rarely, more than one such pathway is present. The most common form of preexcitation is due to the presence of an accessory pathway (bundle of Kent) that connects one of the atria with one of the ventricles. This abnormal connection between the atria and ventricles allows electrical impulses to bypass the AV node (hence the term bypass tract). The ability to conduct impulses along the bypass tract can be quite variable and may be only intermittent or rate dependent. Bypass tracts can conduct in both directions, retrograde only (ventricle to atrium), or,

rarely, anterograde only (atrium to ventricle). The name Wolff–Parkinson–White (WPW) syndrome is often applied to ventricular preexcitation associated with tachyarrhythmias.

How does preexcitation shorten the P–R interval?

In patients with preexcitation, the normal cardiac impulse originating from the SA node is conducted simultaneously through the normal (AV nodal) and anomalous (bypass tract) pathways. Because conduction is more rapid in the anomalous pathway than in the AV nodal pathway, the cardiac impulse rapidly reaches and depolarizes the area of the ventricles where the bypass tract ends. This early depolarization of the ventricle is reflected by a short P–R interval and a slurred initial deflection (δ wave) in the QRS complex. The spread of the anomalous impulse to the rest of the ventricle is delayed because it must be conducted by ordinary ventricular muscle, not by the much faster Purkinje system. The remainder of the ventricle is then depolarized by the normal impulse from the AV node as it catches up with the preexcitation front. Although the P–R interval is shortened, the resulting QRS is slightly prolonged and represents a fusion complex of normal and abnormal ventricular depolarizations.

The P–R interval in patients with preexcitation depends on relative conduction times between the AV nodal pathway and the bypass pathway. If conduction through the former is fast, preexcitation (and the δ wave) is less prominent, and QRS will be relatively normal. If conduction is delayed in the AV nodal pathway, preexcitation is more prominent, and more of the ventricle will be depolarized by the abnormally conducted impulse. When the AV nodal pathway is completely blocked, the entire ventricle is depolarized by the bypass pathway, resulting in a very short P–R interval, a very prominent δ wave, and a wide, bizarre QRS complex. Other factors that can affect the degree of preexcitation include interatrial conduction time, the distance of the atrial end of the bypass tract from the SA node, and autonomic tone. The P–R interval is often normal or only

slightly shortened with a left lateral bypass tract (the most common location). Preexcitation may be more apparent at fast heart rates because conduction slows through the AV node with increasing heart rates. Secondary ST-segment and T-wave changes are also common because of abnormal ventricular repolarization.

What is the clinical significance of preexcitation?

Preexcitation occurs in approximately 0.3% of the general population. An estimated 20% to 50% of affected persons develop paroxysmal tachyarrhythmias, typically paroxysmal supraventricular tachycardia (PSVT). Although most patients are otherwise normal, preexcitation can be associated with other cardiac anomalies, including Ebstein's anomaly, mitral valve prolapse, and cardiomyopathies. Depending on its conductive properties, the bypass tract in some patients may predispose them to tachyarrhythmias and even sudden death. Tachyarrhythmias include PSVT, atrial fibrillation, and, less commonly, atrial flutter. Ventricular fibrillation can be precipitated by a critically timed premature atrial beat that travels down the bypass tract and catches the ventricle at a vulnerable period. Alternatively, very rapid conduction of impulses into the ventricles by the bypass tract during atrial fibrillation can rapidly lead to myocardial ischemia, hypoperfusion, and hypoxia and culminate in ventricular fibrillation.

Recognition of the preexcitation phenomenon is also important because its QRS morphology on the surface ECG can mimic bundle branch block, right ventricular hypertrophy, ischemia, myocardial infarction, and ventricular tachycardia (during atrial fibrillation).

What is the significance of the history of syncope in this patient?

This patient should be evaluated preoperatively by a cardiologist for possible electrophysiological studies, curative radiofrequency ablation of the bypass tract, and the need for perioperative drug therapy. Such studies can identify the location of the bypass tracts, reasonably predict the potential for malignant arrhythmias by programmed

pacing, and assess the efficacy of antiarrhythmic therapy if curative ablation is not possible. Ablation is reported to be curative in over 90% of patients. A history of syncope may be ominous because it may indicate the ability to conduct impulses very rapidly through the bypass tract, leading to systemic hypoperfusion and perhaps predisposing the patient to sudden death.

Patients with only occasional asymptomatic tachyarrhythmias generally do not require investigation or prophylactic drug therapy. Those with frequent episodes of tachyarrhythmias or arrhythmias associated with significant symptoms require drug therapy and close evaluation.

How do tachyarrhythmias generally develop?

Tachyarrhythmias develop as a result of either abnormal impulse formation or abnormal impulse propagation (reentry). Abnormal impulses result from enhanced automaticity, abnormal automaticity, or triggered activity. Usually, only cells of the SA node, specialized atrial conduction pathways, AV nodal junctional areas, and the His–Purkinje system depolarize spontaneously. Because diastolic repolarization (phase 4) is fastest in the SA node, other areas of automaticity are suppressed. Enhanced or abnormal automaticity in other areas, however, can usurp pacemaker function from the SA node and lead to tachyarrhythmias. Triggered activity is the result of either early after-depolarizations (phase 2 or 3) or delayed after-depolarizations (after phase 3). It consists of small-amplitude depolarizations that can follow action potentials under some conditions in atrial, ventricular, and His–Purkinje tissue. If these after-depolarizations reach threshold potential, they can result in an extrasystole or repetitive sustained tachyarrhythmias. Factors that can promote the formation of abnormal impulses include increased catecholamine levels, electrolyte disorders (hyperkalemia, hypokalemia, and hypercalcemia), ischemia, hypoxia, mechanical stretch, and drug toxicity (particularly digoxin).

The most common mechanism for tachyarrhythmias is reentry. Four conditions are necessary to initiate and sustain reentry (Figure 20–14): (1) two areas in the myocardium that differ in

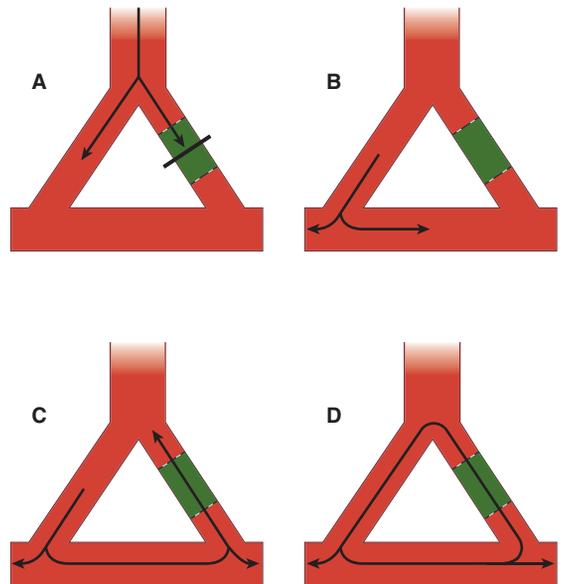

FIGURE 20–14 A–D: The mechanism of reentry. See text for description.

conductivity or refractoriness and that can form a closed electrical loop; (2) unidirectional block in one pathway (Figure 20–14A and B); (3) slow conduction or sufficient length in the circuit to allow recovery of the conduction block in the first pathway (Figure 20–14C); and (4) excitation of the initially blocked pathway to complete the loop (Figure 20–14D). Reentry is usually precipitated by a premature cardiac impulse.

What is the mechanism of PSVT in patients with WPW syndrome?

If the bypass tract is refractory during antero-grade conduction of a cardiac impulse, as during a critically timed atrial premature contraction (APC), and the impulse is conducted by the AV node, the same impulse can be conducted retrograde from the ventricle back into the atria via the bypass tract. The retrograde impulse can then depolarize the atrium and travel down the AV nodal pathway again, establishing a continuous repetitive circuit (circus movement). The impulse reciprocates between the atria and ventricles and conduction

alternates between the AV nodal pathway and the bypass tract. The term “concealed conduction” is often applied because the absence of preexcitation during this arrhythmia results in a normal QRS that lacks a δ wave.

The circus movement less commonly involves anterograde conduction through the bypass tract and retrograde conduction through the AV nodal pathway. In such instances, the QRS has a δ wave and is completely abnormal; the arrhythmia can be mistaken for ventricular tachycardia.

What other mechanisms may be responsible for PSVT?

In addition to the WPW syndrome, PSVT can be caused by AV reentrant tachycardia, AV nodal reentrant tachycardia, and SA node and atrial reentrant tachycardias. Patients with AV reentrant tachycardia have an extranodal bypass tract similar to patients with WPW syndrome, but the bypass tract conducts only retrograde; preexcitation and a δ wave are absent. The PSVT may be initiated either by an APC or a ventricular premature contraction (VPC). A retrograde P wave is usually visible because atrial depolarization always follows ventricular depolarization.

Functional differences in conduction and refractoriness may occur within the AV node, SA node, or atria; a large bypass tract is not necessary. Thus, the circus movement may occur on a smaller scale within the AV node, SA node, or atria, respectively. PSVT is always induced during AV nodal reentry by an APC with a prolonged P–R interval; a retrograde P wave is either absent or buried in the QRS complex. Another APC may terminate the arrhythmia.

PSVT associated with SA node or atrial reentry is always triggered by an APC. The P wave is usually visible and has a prolonged P–R interval. Its morphology is normal with SA nodal reentry and abnormal with atrial reentry.

How does atrial fibrillation in patients with WPW syndrome differ from the arrhythmia in other patients?

Atrial fibrillation can occur when a cardiac impulse is conducted rapidly retrograde up into

the atria and arrives to find different parts of the atria out of phase in recovery from the impulse. Once atrial fibrillation is established, conduction into the ventricles most commonly occurs through the bypass tract only; because of the accessory pathway’s ability to conduct very rapidly (unlike the AV nodal pathway), the ventricular rate is typically very rapid (180–300 beats/min). The majority of QRS complexes are bizarre, but periodic conduction of an impulse through the AV nodal pathway results in occasional normal-looking QRS complexes. Less commonly, impulses during atrial fibrillation are conducted mainly through the AV nodal pathway (resulting in mostly normal QRS complexes) or through both the bypass tract and the AV nodal pathway (resulting in a mixture of normal, fusion, and bizarre QRS complexes). As stated previously, atrial fibrillation in patients with WPW syndrome is a very dangerous arrhythmia.

What anesthetic agents can safely be used in patients with preexcitation?

Few data are available comparing the use of different anesthetic agents or techniques in patients with preexcitation. Almost all the volatile and intravenous agents have been used with equal success. Volatile anesthetics increase antegrade refractoriness in both normal and accessory pathways and increase the coupling interval (a measure of the ability of an extrasystole to induce tachycardia). Propofol, opioids, and benzodiazepines seem to have little direct electrophysiological effects, but can alter autonomic tone, generally reducing sympathetic outflow. Factors that tend to cause sympathetic stimulation and increased cardiac automaticity are undesirable. Premedication with a benzodiazepine helps reduce high sympathetic tone preoperatively. Agents that can increase sympathetic tone, such as ketamine and perhaps pancuronium in large bolus doses, should generally be avoided. Anticholinergics should be used cautiously; glycopyrrolate may be preferable to atropine. Endotracheal intubation should be carried out only after the patient is deeply anesthetized; pretreatment with a β -adrenergic blocker,

such as esmolol, may be useful. Light anesthesia, hypercapnia, acidosis, and even transient hypoxia will activate the sympathetic system and are to be avoided. A deep extubation and good post-operative analgesia (without respiratory acidosis) may also help prevent the onset of arrhythmias. When patients with preexcitation are anesthetized for electrophysiological study and surgical ablation, opioids, propofol, and benzodiazepines may be the agents least likely to alter conduction characteristics.

How are antiarrhythmic agents selected for tachyarrhythmias?

Most antiarrhythmic agents act by altering myocardial cell conduction (phase 0), repolarization (phase 3), or automaticity (phase 4). Prolongation of repolarization increases the refractoriness of cells. Many antiarrhythmic drugs also exert direct or indirect autonomic effects. Although antiarrhythmic agents are generally classified according to broad mechanisms of action or electrophysiological effects (Table 20-7), the most commonly

TABLE 20-7 Classification of antiarrhythmic agents.¹

Class	Mechanism of Action	Agents	Intravenous Loading Dose
I	Blocks voltage-gated sodium channels; decreases slope of phase 0 (V_{max})		
Ia	Moderate depression of V_{max} ; prolongs APD	Quinidine ²⁻⁴ Procainamide (Pronestyl) ^{1,4} Disopyramide (Norpace) ^{1,4}	NR 5–10 mg/kg NA
Ib	Minimal effect on V_{max} ; shorten APD	Lidocaine Phenytoin Tocainide (Tonocard) Mexiletine (Mexitil) Morizine (Ethmozine)	1–2 mg/kg 5–15 mg/kg NA NA NA
Ic	Marked depression of V_{max} ; minimal effect of APD	Flecainide (Tambacor) Propafenone (Rythmol)	NA NA
II	Blocks β -adrenergic receptors	Esmolol (Brevibloc) Metoprolol (Lopressor)	0.5 mg/kg 5–10 mg
III	Prolongs repolarization	Amiodarone (Cordarone) ⁵⁻⁷ Sotalol (Betapace) ⁸ Ibutilide (Corvert) Dofetilide (Tikosyn)	150 mg NA 1 mg NA
IV	Blocks slow calcium channels	Verapamil (Calan) Diltiazem (Cardizem)	2.5–10 mg 0.25–0.35 mg/kg
V	Various (miscellaneous agents)	Digoxin Adenosine (Adenocard)	0.5–0.75 mg 6–12 mg

¹ V_{max} , maximum velocity; APD, action potential duration; NR, not recommended; NA, not available for intravenous use.

²Also has antimuscarinic (vagolytic activity).

³Also blocks α -adrenergic receptors.

⁴Also prolongs repolarization.

⁵Also binds inactivated sodium channels.

⁶Also causes noncompetitive α - and β -adrenergic blockade.

⁷Also blocks slow calcium channels.

⁸Also has nonselective β -adrenergic blocking activity.

used classification system is not perfect because some agents have more than one mechanism of action.

Selection of an antiarrhythmic agent generally depends on whether the arrhythmia is ventricular

or supraventricular and whether acute control or chronic therapy is required. Intravenous agents are usually employed in the acute management of arrhythmias, whereas oral agents are reserved for chronic therapy (Table 20–8).

TABLE 20–8 Clinical pharmacological properties of antiarrhythmic drugs.¹

Drug	Effect on SA Nodal Rate	Effect on AV Nodal Refractory Period	PR Interval	QRS Duration	QT Interval	Usefulness in Arrhythmias

²May suppress diseased sinus nodes.

³Initial stimulation by release of endogenous norepinephrine followed by depression.

⁴Anticholinergic effect and direct depressant action.

⁵Particularly in Wolff–Parkinson–White syndrome.

⁶May be effective in atrial arrhythmias caused by digitalis.

⁷Half-life of active metabolites is much longer.

Which agents are most useful for tachyarrhythmias in patients with WPW syndrome?

Cardioversion is the treatment of choice in hemodynamically compromised patients. Adenosine is the drug of choice for PSVT because of its short duration of action. Small doses of phenylephrine (100 mcg), together with vagal maneuvers (carotid massage if not contraindicated by carotid occlusive disease), help support arterial blood pressure and may terminate the arrhythmia. The most useful pharmacological agents are class Ia drugs (eg, procainamide). These agents increase the refractory period and decrease conduction in the accessory pathway. Moreover, class Ia drugs frequently terminate and can suppress the recurrence of PSVT and atrial fibrillation. Class Ic drugs and amiodarone are also useful because they slow conduction and prolong refractoriness in both the AV node and the accessory pathway. β -Adrenergic blocking agents may also be useful, particularly in controlling ventricular rate once these rhythms are established. Verapamil and digoxin are contraindicated during atrial fibrillation or flutter in these patients because they can dangerously accelerate the ventricular response. Both types of agents decrease conduction through the AV node, favoring conduction of impulses down the accessory pathway. The bypass tract is capable of conducting impulses into the ventricles much faster than the AV nodal pathway. Digoxin may also increase the ventricular response by shortening the refractory period and increasing conduction in accessory pathways. Although verapamil can terminate PSVT, its use in this setting may be hazardous because patients can subsequently develop atrial fibrillation or flutter. Moreover, atrial fibrillation may not

be readily distinguishable from ventricular tachycardia in these patients if wide-QRS tachycardia develops.

Anesthesia for Patients with Cardiovascular Disease

KEY CONCEPTS

- 1 Cardiovascular complications account for 25% to 50% of deaths following noncardiac surgery. Perioperative myocardial infarction (MI), pulmonary edema, congestive heart failure, arrhythmias, and thromboembolism are most commonly seen in patients with preexisting cardiovascular disease.
- 2 Regardless of the level of preoperative blood pressure control, many patients with hypertension display an accentuated hypotensive response to induction of anesthesia, followed by an exaggerated hypertensive response to intubation. Hypertensive patients may display an exaggerated response to both endogenous catecholamines (from intubation or surgical stimulation) and exogenously administered sympathetic agonists.
- 3 Patients with extensive (three-vessel or left main) coronary artery disease, a history of MI, or ventricular dysfunction are at greatest risk of cardiac complications.
- 4 Holter monitoring, exercise electrocardiography, myocardial perfusion scans, and echocardiography are important in determining perioperative risk and the need for coronary angiography; however, these tests are indicated only if their outcome would alter patient care.
- 5 Sudden withdrawal of antianginal medication perioperatively—particularly β -blockers—can precipitate a sudden, rebound increase in ischemic episodes.
- 6 The overwhelming priority in managing patients with ischemic heart disease is maintaining a favorable myocardial supply–demand relationship. Autonomic-mediated increases in heart rate and blood pressure should be controlled by deep anesthesia or adrenergic blockade, and excessive reductions in coronary perfusion pressure or arterial oxygen content are to be avoided.
- 7 Intraoperative detection of ischemia depends on recognition of electrocardiographic changes, hemodynamic manifestations, or regional wall motion abnormalities on transesophageal echocardiography. New ST-segment elevations are rare during noncardiac surgery and are indicative of severe ischemia, vasospasm, or infarction.
- 8 The principal hemodynamic goals in managing mitral stenosis are to maintain a sinus rhythm (if present preoperatively) and to avoid tachycardia, large increases in cardiac output, and both hypovolemia and fluid overload by judicious administration of intravenous fluids.
- 9 Anesthetic management of mitral regurgitation should be tailored to the severity of regurgitation and to the underlying left ventricular function. Factors that exacerbate the regurgitation, such as slow heart rates and acute increases in afterload, should be avoided. Excessive volume expansion can also worsen the regurgitation by dilating the left ventricle.

—Continued next page

Continued—

- 10 Maintenance of normal sinus rhythm, heart rate, vascular resistance and intravascular volume is critical in patients with aortic stenosis. Loss of a normally timed atrial systole often leads to rapid deterioration, particularly when associated with tachycardia. Spinal and epidural anesthesia are relatively contraindicated in patients with severe aortic stenosis.
- 11 Bradycardia and increase in systemic vascular resistance (SVR) increase the regurgitant volume in patients with aortic regurgitation, whereas tachycardia can contribute to myocardial ischemia. Excessive myocardial depression should also be avoided. The compensatory increase in cardiac preload should be maintained, but excessive fluid replacement can readily result in pulmonary edema.
- 12 In patients with congenital heart disease, an increase in SVR relative to pulmonary vascular resistance (PVR) favors left-to-right shunting, whereas an increase in PVR relative to SVR favors right-to-left shunting.
- 13 The presence of shunt flow between the right and left hearts, regardless of the direction of blood flow, mandates the meticulous exclusion of air bubbles or particulate material from intravenous fluids to prevent paradoxical embolism into the cerebral or coronary circulations.
- 14 The goals of anesthetic management in patients with tetralogy of Fallot should be to maintain intravascular volume and SVR. Increases in PVR, such as might occur from acidosis or excessive airway pressures, should be avoided. The right-to-left shunting tends to slow the uptake of inhalation anesthetics; in contrast, it may accelerate the onset of intravenous agents.
- 15 The transplanted heart is totally denervated, so direct autonomic influences are absent. Moreover, the absence of reflex increases in heart rate can make patients particularly sensitive to rapid vasodilatation. Indirect vasopressors, such as ephedrine, are less effective than direct-acting agents because of the absence of catecholamine stores in myocardial neurons.

Cardiovascular diseases—particularly hypertensive, ischemic, congenital, and valvular heart disease—are among the medical illnesses most frequently encountered in anesthetic practice and are a major cause of perioperative morbidity and mortality. Management of patients with these diseases continues to challenge the ingenuity and resources of the anesthesiologist. The adrenergic response to surgical stimulation and the circulatory effects of anesthetic agents, endotracheal intubation, positive-pressure ventilation, blood loss, fluid shifts, and alterations in body temperature impose additional burdens on an often already compromised cardiovascular system. Most anesthetic agents cause cardiac depression, vasodilatation, or both. Even anesthetics that have no direct circulatory effects may cause apparent circulatory depression in severely compromised

patients who are dependent on the enhanced sympathetic activity characteristic of heart failure or acute blood loss. Decreased sympathetic activity as a consequence of the anesthetized state can lead to acute circulatory collapse.

Good anesthetic management of patients with cardiovascular disease requires a thorough knowledge of normal cardiac physiology, the circulatory effects of the various anesthetic agents, and the pathophysiology and treatment of these diseases. The same principles used in treating cardiovascular diseases in patients not undergoing surgery should be used perioperatively. In most instances, the choice of anesthetic agent is not terribly important; on the other hand, knowing how the agent is used, understanding the underlying pathophysiology, and understanding how the two interact are critical.

Patients with severe cardiovascular illnesses commonly undergo both cardiac and noncardiac surgery. The American College of Cardiology (ACC), in collaboration with the American Heart Association (AHA), have issued numerous guidelines related to the management of patients with heart disease, and many of their recommendations are relevant to patients undergoing anesthesia and invasive procedures. Because guidelines change as new evidence becomes available, anesthesiologists are advised to review the AHA website for current evidence-based indications for the management of heart disease.

Perioperative Cardiovascular Evaluation and Preparation for Noncardiac Surgery

The prevalence of cardiovascular disease increases progressively with advancing age. Moreover, the number of patients over 65 years of age is expected to increase by 25% to 35% over the next two decades. Cardiovascular complications account for 25% to 50% of deaths following noncardiac surgery.

1 Perioperative myocardial infarction (MI), pulmonary edema, systolic and diastolic heart failure, arrhythmias, and thromboembolism are the most common diagnoses in patients with preexisting cardiovascular disease. The incidence of postoperative cardiogenic pulmonary edema is approximately 2% in all patients over 40 years of age, but it is 6% in patients with a history of heart failure and 16% in patients with poorly compensated heart failure. The relatively high prevalence of cardiovascular disorders in surgical patients has given rise to attempts to define *cardiac risk* or the likelihood of intraoperative or postoperative fatal or life-threatening cardiac complications.

In 2007, the ACC/AHA Task Force Report produced revised guidelines for perioperative evaluation. The revised guidelines stated that the patient's medical history is critical in determining the requirements for preoperative cardiac evaluation and that certain conditions (eg, unstable coronary syndromes and decompensated heart failure) warrant cardiology intervention prior to all but emergency procedures (Table 21-1). The history should also review any past procedures, such as cardioverter defibrillator implants, coronary stents, and other interventions.

TABLE 21-1 Active cardiac conditions for which the patient should undergo evaluation and treatment before noncardiac surgery (class I, level of evidence: B).

Condition	Examples
Unstable coronary syndromes	Unstable or severe angina ¹ (CCS class III or IV) ² Recent MI ³
Decompensated HF (NYHA functional class IV; worsening or new-onset HF)	
Significant arrhythmias	High-grade atrioventricular block Mobitz II atrioventricular block Third-degree atrioventricular heart block Symptomatic ventricular arrhythmias Supraventricular arrhythmias (including atrial fibrillation) with uncontrolled ventricular rate (HR greater than 100 bpm at rest) Symptomatic bradycardia Newly recognized ventricular tachycardia
Severe valvular disease	Severe aortic stenosis (mean pressure gradient greater than 40 mm Hg, aortic valve area less than 1.0 cm ² , or symptomatic) Symptomatic mitral stenosis (progressive dyspnea on exertion, exertional presyncope, or HF)

CCS indicates Canadian Cardiovascular Society; HF, heart failure; HR, heart rate; MI, myocardial infarction; NYHA, New York Heart Association.

¹According to Campeau L. Letter: Grading of angina pectoris. *Circulation*. 1976;54:522-523.

²May include "stable" angina in patients who are unusually sedentary.

³The American College of Cardiology National Database Library defines recent MI as more than 7 days but less than or equal to 1 month (within 30 days).

Reproduced, with permission from Fleisher L, Beckman J, Brown K, et al: ACC/AHA 2007 guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery. *Circulation* 2007;116: 1971-1996.

TABLE 21-2 Estimated energy requirements for various activities.

Can you ...		Can you ...	
1 MET	Take care of yourself?	4 METs	Climb a flight of stairs or walk up a hill?
	Eat, dress, or use the toilet?		Walk on level ground at 4 mph (6.4 kph)?
	Walk indoors around the house?		Run a short distance?
	Walk a block or 2 on level ground at 2 to 3 mph (3.2 to 4.8 kph)?		Do heavy work around the house like scrubbing floors or lifting or moving heavy furniture?
4 METs	Do light work around the house like dusting or washing dishes?		Participate in moderate recreational activities like golf, bowling, dancing, doubles tennis, or throwing a baseball or football?
		Greater than 10 METs	Participate in strenuous sports like swimming, singles tennis, football, basketball, or skiing?

kph indicates kilometers per hour; MET, metabolic equivalent; and mph, miles per hour.

Modified and reproduced, with permission, from Hlatky MA, Boineau RE, Higginbotham MB, et al. A brief self-administered questionnaire to determine functional capacity (the Duke Activity Status Index). *Am J Cardiol.* 1989;64:651-654.

Additionally, the patient's ability to perform the tasks of daily living should be assessed as a guide to determine functional capacity. A patient with a history of cardiac disease and advanced age, but good exercise tolerance, will likely have a lower perioperative risk than a similar individual with dyspnea after minimal physical activity (Table 21-2).

The patient's history should also seek signs of other disease processes that frequently accompany heart disease. Cardiac patients often present with obstructive pulmonary disease, reduced renal function, and diabetes mellitus.

A physical examination should be performed on all patients, and the heart and lungs should be auscultated. The physical examination is especially useful in patients with certain conditions. For example, if a murmur suggestive of aortic stenosis is detected, additional ultrasound evaluation will likely be warranted, as aortic stenosis substantially increases the risks in patients undergoing noncardiac surgery.

The following conditions are associated with increased risk:

- Ischemic heart disease (history of MI, evidence on electrocardiogram [ECG], chest pain)
- Congestive heart failure (dyspnea, pulmonary edema)

- Cerebral vascular disease (stroke)
- High-risk surgery (vascular, thoracic, abdominal, orthopedic)
- Diabetes mellitus
- Preoperative creatinine >2 mg/dL

Recent ACC/AHA guidelines identify conditions that are a major cardiac risk and warrant intensive management prior to all but emergent surgery. These conditions include: unstable coronary syndromes (recent MI, unstable angina), decompensated heart failure, significant arrhythmias, and severe valvular heart disease. The ACC/AHA guidelines identify an MI within 7 days, or one within 1 month with myocardium at risk for ischemia, as "active" cardiac conditions. On the other hand, evidence of past MI with no myocardium thought at ischemic risk is considered a low risk for perioperative infarction after noncardiac surgery.

The ACC/AHA guidelines suggest a stepwise approach to preoperative cardiac evaluation. Their recommendations are classified as follows:

- Class I: Benefits >> risk
- Class IIa: Benefits >> risk, but scientific evidence incomplete

- Class IIb: Benefits \geq risk, and scientific evidence incomplete
- Class III: Risks \gg benefits

Class I recommendations are as follows:

- Patients who have a need for emergency noncardiac surgery should proceed to the operating room with perioperative surveillance and postoperative risk factor management
- Patients with active cardiac conditions should be evaluated by a cardiologist and treated according to ACC/AHA guidelines
- Patients undergoing low-risk procedures should proceed to surgery
- Patients with poor exercise tolerance (<4 metabolic equivalents [METs]) and no known risk factors should proceed to surgery

Class IIa recommendations are as follows:

- Patients with a functional capacity >4 METs and without symptoms should proceed to surgery
- Patients with a functional capacity <4 METs or those with an unknown functional capacity with three or more clinical risk factors scheduled for vascular surgery should be tested, if management is likely to change based on the results
- Patients with a functional capacity <4 METs or those with an unknown functional capacity with three or more clinical risk factors scheduled for intermediate-risk surgery should proceed to surgery with heart rate control
- Patients with a functional capacity <4 METs or those with an unknown functional capacity with one or two clinical risk factors who are scheduled for vascular or intermediate-risk surgery should proceed to surgery with heart rate control

The ACC/AHA guidelines also note, as class IIb recommendations, that noninvasive testing might be considered *if* patient management changes in patients with poor or unknown functional capacity or in patients undergoing intermediate-risk surgery

TABLE 21-3 Cardiac risk¹ stratification for noncardiac surgical procedures.

Risk Stratification	Procedure Examples
Vascular (reported cardiac risk often more than 5%)	Aortic and other major vascular surgery Peripheral vascular surgery
Intermediate (reported cardiac risk generally 1% to 5%)	Intraperitoneal and intrathoracic surgery Carotid endarterectomy Head and neck surgery Orthopedic surgery Prostate surgery
Low ² (reported cardiac risk generally less than 1%)	Endoscopic procedures Superficial procedure Cataract surgery Breast surgery Ambulatory surgery

¹Combined incidence of cardiac death and nonfatal myocardial infarction.

²These procedures do not generally require further preoperative cardiac testing.

Fleisher L, Beckman J, Brown K, et al: ACC/AHA 2007 guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery. *Circulation* 2007;116:1971-1996.

with three clinical risk factors. Likewise, such testing might be indicated in patients with one or two clinical risk factors scheduled for vascular or intermediate-risk surgery. **Table 21-3** classifies surgical procedures according to risk.

The ACC/AHA guidelines also provide specific recommendations regarding various conditions likely to be encountered perioperatively.

CORONARY ARTERY DISEASE

The ACC/AHA guidelines note that only the subset of patients with coronary artery disease (CAD) who would benefit from revascularization, irrespective of their need for a nonemergent surgical procedure, would likely benefit from preoperative coronary interventions. Consequently, the indications for the testing of such patients as candidates for a coronary intervention are unrelated to their presenting for surgery and depend only on whether such evaluation would be indicated as part of general medical management.

HYPERTENSION

Patients with hypertension frequently present for elective surgical procedures. Some will have been effectively managed, but unfortunately, many others will not have been. Hypertension is a leading cause of death and disability in most Western societies and the most prevalent preoperative medical abnormality in surgical patients, with an overall prevalence of 20% to 25%. Long-standing uncontrolled hypertension accelerates atherosclerosis and hypertensive organ damage. Hypertension is a major risk factor for cardiac, cerebral, renal, and vascular disease.

Complications of hypertension include MI, congestive heart failure, stroke, renal failure, peripheral occlusive disease, and aortic dissection. The presence of left ventricular hypertrophy (LVH) in hypertensive patients may be an important predictor of cardiac mortality. However, systolic blood pressures below 180 mm Hg, and diastolic pressures below 110 mm Hg, have not been associated with increased perioperative risks. When patients present with systolic blood pressures greater than 180 mm Hg and diastolic pressures greater than 110 mm Hg, anesthesiologists face the dilemma of delaying surgery to allow optimization of oral antihypertensive therapy, but adding the risk of a surgical delay versus proceeding with surgery and achieving blood pressure control with rapidly acting intravenous agents. Intravenous β -blockers can be useful to treat preoperative hypertension. Of note, patients with preoperative hypertension are more likely than others to develop intraoperative hypotension. This is particularly frequent in patients treated with angiotensin receptor blockers and/or angiotensin-converting enzyme (ACE) inhibitors.

Blood pressure measurements are affected by many variables, including posture, time of day or night, emotional state, recent activity, and drug intake, as well as the equipment and technique used. A diagnosis of hypertension cannot be made by one preoperative reading, but requires confirmation by a history of consistently elevated measurements. Although preoperative anxiety or pain may produce some degree of hypertension in normal patients, patients with a history of hypertension generally exhibit greater preoperative elevations in blood pressure.

TABLE 21-4 Classification of blood pressure (adults).

Category of Blood Pressure	Systolic Pressure (mm Hg)	Diastolic Pressure (mm Hg)
Normal	<130	<85
High normal	130–139	85–89
Hypertension		
Stage 1/mild	140–159	90–99
Stage 2/moderate	160–179	100–109
Stage 3/severe	180–209	110–119
Stage 4/very severe	>210	>120

Epidemiological studies demonstrate a direct and continuous correlation between both diastolic and systolic blood pressures and mortality rates. The definition of systemic hypertension is arbitrary: a consistently elevated diastolic blood pressure greater than 90 mm Hg or a systolic pressure greater than 140 mm Hg. A common classification scheme is listed in **Table 21-4**. Borderline hypertension is said to exist when the diastolic pressure is 85–89 mm Hg or the systolic pressure is 130–139 mm Hg. Whether patients with borderline hypertension are at some increased risk for cardiovascular complications remains unclear. Accelerated, or severe hypertension (stage 3), is defined as a recent, sustained, and progressive increase in blood pressure, usually with diastolic blood pressures in excess of 110–119 mm Hg. Renal dysfunction is often present in such patients. Malignant hypertension is a true medical emergency characterized by severe hypertension (>210/120 mm Hg) often associated with papilledema and encephalopathy.

Pathophysiology

Hypertension can be either idiopathic (essential), or, less commonly, secondary to other medical conditions such as renal disease, renal artery stenosis, primary hyperaldosteronism, Cushing's disease, acromegaly, pheochromocytoma, pregnancy, or estrogen therapy. Essential hypertension accounts

for 80% to 95% of cases and may be associated with an abnormal baseline elevation of cardiac output, systemic vascular resistance (SVR), or both. An evolving pattern is commonly seen over the course of the disease, where cardiac output returns to (or remains) normal, but SVR becomes abnormally high. The chronic increase in cardiac afterload results in concentric LVH and altered diastolic function. Hypertension also alters cerebral autoregulation, such that normal cerebral blood flow is maintained in the face of high blood pressures; autoregulation limits may be in the range of mean blood pressures of 110–180 mm Hg.

The mechanisms responsible for the changes observed in hypertensive patients seem to involve vascular hypertrophy, hyperinsulinemia, abnormal increases in intracellular calcium, and increased intracellular sodium concentrations in vascular smooth muscle and renal tubular cells. The increased intracellular calcium presumably results in increased arteriolar tone, whereas the increased sodium concentration impairs renal excretion of sodium. Sympathetic nervous system overactivity and enhanced responses to sympathetic agonists are present in some patients. Hypertensive patients sometimes display an exaggerated response to vasopressors and vasodilators. Overactivity of the renin–angiotensin–aldosterone system seems to play an important role in patients with accelerated hypertension.

Long-Term Treatment

Effective drug therapy reduces the progression of hypertension and the incidence of stroke, congestive heart failure, CAD, and renal damage. Effective treatment can also delay and sometimes reverse concomitant pathophysiological changes, such as LVH and altered cerebral autoregulation.

Some patients with mild hypertension require only single-drug therapy, which may consist of a thiazide diuretic, ACE inhibitor, angiotensin-receptor blocker (ARB), β -adrenergic blocker, or calcium channel blocker, although guidelines and outcome studies favor the first three options. Concomitant illnesses should guide drug selection. All patients with a prior MI should receive a β -adrenergic blocker and an ACE inhibitor (or ARB) to improve

outcomes, irrespective of the presence of hypertension. In many patients, the “guideline specified” agents will also be more than sufficient to control hypertension.

Patients with moderate to severe hypertension often require two or three drugs for control. The combination of a diuretic with a β -adrenergic blocker and an ACE inhibitor is often effective when single-drug therapy is not. As previously noted, ACE inhibitors (or ARBs) prolong survival in patients with congestive heart failure, left ventricular dysfunction, or a prior MI. Familiarity with the names, mechanisms of action, and side effects of commonly used antihypertensive agents is important for anesthesiologists (Table 21–5).

PREOPERATIVE MANAGEMENT

A recurring question in anesthetic practice is the degree of preoperative hypertension that is acceptable for patients scheduled for elective surgery. Except for optimally controlled patients, most hypertensive patients present to the operating room with some degree of hypertension. Although data suggest that even moderate preoperative hypertension (diastolic pressure <90–110 mm Hg) is not clearly statistically associated with *postoperative* complications, other data indicate that the untreated or poorly controlled hypertensive patient is more apt to experience *intraoperative* episodes of myocardial ischemia, arrhythmias, or both hypertension and hypotension. Intraoperative adjustments in anesthetic depth and use of vasoactive drugs should reduce the incidence of postoperative complications referable to poor preoperative control of hypertension.

Although patients should ideally undergo elective surgery only when rendered normotensive, this is not always feasible or necessarily desirable because of altered cerebral autoregulation. Excessive reductions in blood pressure can compromise cerebral perfusion. Moreover, the decision to delay or to proceed with surgery should be individualized, based on the severity of the preoperative blood pressure elevation; the likelihood of coexisting myocardial ischemia, ventricular dysfunction, or cerebrovascular or renal complications; and the surgical procedure (whether major

surgically induced changes in cardiac preload or afterload are anticipated). With rare exceptions, antihypertensive drug therapy should be continued up to the time of surgery. Some clinicians withhold ACE inhibitors and ARBs on the morning of surgery because of their association with an increased incidence of intraoperative hypotension; however, withholding these agents increases the risk of marked perioperative hypertension and the need for parenteral antihypertensive agents. It also requires the surgical team to remember to

restart the medication after surgery. The decision to delay elective surgical procedures in patients with sustained preoperative diastolic blood pressures higher than 110 mm Hg should be made when the perceived benefits of delayed surgery exceed the risks. Unfortunately, there are few appropriate studies to guide the decision-making.

History

The preoperative history should inquire into the severity and duration of the hypertension, the

drug therapy currently prescribed, and the presence or absence of hypertensive complications. Symptoms of myocardial ischemia, ventricular failure, impaired cerebral perfusion, or peripheral vascular disease should be elicited, as well as the patient's record of compliance with the drug regimen. The patient should be questioned regarding chest pain, exercise tolerance, shortness of breath (particularly at night), dependent edema, postural lightheadedness, syncope, episodic visual disturbances or episodic neurologic symptoms, and claudication. Adverse effects of current antihypertensive drug therapy (Table 21-6) should also be identified.

Physical Examination & Laboratory Evaluation

Ophthalmoscopy is useful in hypertensive patients. Visible changes in the retinal vasculature usually parallel the severity and progression of arteriosclerosis and hypertensive damage in other organs. An S_4 cardiac gallop is common in patients with LVH. Other physical findings, such as pulmonary rales and an S_3 cardiac gallop, are late findings and indicate congestive heart failure. Blood pressure can be measured in both the supine and standing positions. Orthostatic changes can be due to volume depletion, excessive vasodilatation, or sympatholytic drug

TABLE 21-6 Adverse effects of long-term antihypertensive therapy.

Class	Adverse Effects
Diuretics	
Thiazide	Hypokalemia, hyponatremia, hyperglycemia, hyperuricemia, hypomagnesemia, hyperlipidemia, hypercalcemia
Loop	Hypokalemia, hyperglycemia, hypocalcemia, hypomagnesemia, metabolic alkalosis

α -Adrenergic blockers	Postural hypertension, tachycardia, fluid retention
Central α_2 -agonists	Postural hypotension, sedation, dry mouth, depression, decreased anesthetic requirements, bradycardia, rebound hypertension, positive Coombs test and hemolytic anemia (methyldopa), hepatitis (methyldopa)
Ganglionic blockers	Postural hypotension, diarrhea, fluid retention, depression (reserpine)
Vasodilators	
Calcium channels blockers	Cardiac depression, bradycardia, conduction blockade (verapamil, diltiazem), peripheral edema (nifedipine), tachycardia (nifedipine), enhanced neuromuscular nondepolarizing blockade
ACE inhibitors ¹	Cardiac depression, bradycardia, conduction blockade (verapamil, diltiazem), peripheral edema (nifedipine), tachycardia (nifedipine), enhanced neuromuscular nondepolarizing blockade
Angiotensin-receptor antagonists	Hypotension, renal failure in bilateral renal artery stenosis, hyperkalemia
Direct vasodilators	Reflex tachycardia, fluid retention, headache, systemic lupus erythematosus-like syndrome (hydralazine), pleural or pericardial effusion (minoxidil)

¹ACE, angiotensin-converting enzyme.

therapy; preoperative fluid administration can prevent severe hypotension after induction of anesthesia in these patients. Although asymptomatic carotid bruits are usually hemodynamically insignificant, they may be reflective of atherosclerotic vascular disease that may affect the coronary circulation. When a bruit is detected, further workup should be guided by the urgency of the scheduled surgery and the likelihood that further investigations, if diagnostic, would result in a change in therapy. Doppler studies of the carotid arteries can be used to define the extent of carotid disease.

The ECG is often normal, but in patients with a long history of hypertension, it may show evidence of ischemia, conduction abnormalities, an old infarction, or LVH or strain. A normal ECG does not exclude CAD or LVH. Similarly, a normal heart size

on a chest radiograph does not exclude ventricular hypertrophy. Echocardiography is a sensitive test of LVH and can be used to evaluate ventricular systolic and diastolic functions in patients with symptoms of heart failure. Chest radiographs are rarely useful in an asymptomatic patient, but may show a boot-shaped heart (suggestive of LVH), frank cardiomegaly, or pulmonary vascular congestion.

Renal function is best evaluated by measurement of serum creatinine and blood urea nitrogen levels. Serum electrolyte levels (K) should be determined in patients taking diuretics or digoxin or those with renal impairment. Mild to moderate hypokalemia (3–3.5 mEq/L) is often seen in patients taking diuretics, but does not have adverse outcome effects. Potassium replacement should be undertaken only in patients who are symptomatic

or who are also taking digoxin. Hypomagnesemia is often present and may be a cause of perioperative arrhythmias. Hyperkalemia may be encountered in patients who are taking potassium-sparing diuretics or ACE inhibitors, particularly those with impaired renal function.

Premedication

Premedication reduces preoperative anxiety and is desirable in hypertensive patients. Mild to moderate preoperative hypertension often resolves following administration of an agent such as midazolam.

INTRAOPERATIVE MANAGEMENT

Objectives

The overall anesthetic plan for a hypertensive patient is to maintain an appropriate stable blood pressure range. Patients with borderline hypertension may be treated as normotensive patients. Those with long-standing or poorly controlled hypertension, however, have altered autoregulation of cerebral blood flow; higher than normal mean blood pressures may be required to maintain adequate cerebral blood flow. Because most patients with long-standing hypertension are assumed to have some element of CAD and cardiac hypertrophy, excessive blood pressure elevations are undesirable. Hypertension, particularly in association with tachycardia, can precipitate or exacerbate myocardial ischemia, ventricular dysfunction, or both. Arterial blood pressure should generally be kept within 20% of preoperative levels. If marked hypertension (>180/120 mm Hg) is present preoperatively, arterial blood pressure should be maintained in the high-normal range (150–140/90–80 mm Hg).

Monitoring

Most hypertensive patients do not require special intraoperative monitors. Direct intraarterial pressure monitoring should be reserved for patients with wide swings in blood pressure and those undergoing major surgical procedures associated with rapid or marked changes in cardiac preload or afterload.

Electrocardiographic monitoring should focus on detecting signs of ischemia. Urinary output should generally be monitored with an indwelling urinary catheter in patients with a preexisting renal impairment who are undergoing procedures expected to last more than 2 hr. When invasive hemodynamic monitoring is used, reduced ventricular compliance (see Chapter 20) is often apparent in patients with ventricular hypertrophy; these patients may require more intravenous fluid to produce a higher filling pressure to maintain adequate left ventricular end-diastolic volume and cardiac output. Volume administration in patients with decreased ventricular compliance can also result in elevated pulmonary arterial pressures and pulmonary congestion.

Induction

Induction of anesthesia and endotracheal intubation are often associated with hemodynamic instability in **2** hypertensive patients. Regardless of the level of preoperative blood pressure control, many patients with hypertension display an accentuated hypotensive response to induction of anesthesia, followed by an exaggerated hypertensive response to intubation. Many, if not most, antihypertensive agents and general anesthetics are vasodilators, cardiac depressants, or both. In addition, many hypertensive patients present for surgery in a volume-depleted state. Sympatholytic agents attenuate the normal protective circulatory reflexes, reducing sympathetic tone and enhancing vagal activity.

Up to 25% of hypertensive patients may exhibit severe hypertension following endotracheal intubation. Prolonged laryngoscopy should be avoided. Moreover, intubation should generally be performed under deep anesthesia (provided hypotension can be avoided). One of several techniques may be used before intubation to attenuate the hypertensive response:

- Deepening anesthesia with a potent volatile agent
- Administering a bolus of an opioid (fentanyl, 2.5–5 mcg/kg; alfentanil, 15–25 mcg/kg; sufentanil, 0.5–1.0 mcg/kg; or remifentanyl, 0.5–1 mcg/kg).

- Administering lidocaine, 1.5 mg/kg intravenously, intratracheally, or topically in the airway
- Achieving β -adrenergic blockade with esmolol, 0.3–1.5 mg/kg; metoprolol 1–5 mg; or labetalol, 5–20 mg.

Choice of Anesthetic Agents

A. Induction Agents

The superiority of any one agent or technique over another has not been established. Propofol, barbiturates, benzodiazepines, and etomidate are equally safe for inducing general anesthesia in most hypertensive patients. Ketamine by itself can precipitate marked hypertension; however, it is almost never used as a single agent. When administered with a small dose of another agent, such as a benzodiazepine or propofol, ketamine's sympathetic stimulating properties can be blunted or eliminated.

B. Maintenance Agents

Anesthesia may be safely continued with volatile agents (alone or with nitrous oxide), a balanced technique (opioid + nitrous oxide + muscle relaxant), or a total intravenous technique. Regardless of the primary maintenance technique, addition of a volatile agent or intravenous vasodilator generally allows convenient intraoperative blood pressure control.

C. Muscle Relaxants

With the possible exception of large bolus doses of pancuronium, any muscle relaxant can be used. Pancuronium-induced vagal blockade and neural release of catecholamines could exacerbate hypertension in poorly controlled patients, but, if given slowly, in small increments, pancuronium is unlikely to cause medically important increases in heart rate or blood pressure. Moreover, pancuronium can be useful in offsetting excessive vagal tone induced by opioids or surgical manipulations. Hypotension following large (intubating) doses of atracurium may be accentuated in hypertensive patients.

D. Vasopressors

Hypertensive patients may display an exaggerated response to both endogenous catecholamines (from intubation or surgical stimulation) and exogenously administered sympathetic agonists. If a vasopressor is necessary to treat excessive hypotension, a small dose of a direct-acting agent, such as phenylephrine (25–50 mcg), may be useful. Patients taking sympatholytics preoperatively may exhibit a decreased response to ephedrine. Vasopressin as a bolus or infusion can also be employed to restore vascular tone in the hypotensive patient.

Intraoperative Hypertension

Intraoperative hypertension not responding to an increase in anesthetic depth (particularly with a volatile agent) can be treated with a variety of parenteral agents (Table 21-7). Readily reversible causes—such as inadequate anesthetic depth, hypoxemia, or hypercapnia—should always be excluded before initiating antihypertensive therapy. Selection of a hypotensive agent depends on the severity, acuteness, and cause of hypertension; the baseline ventricular function; the heart rate; the presence of bronchospastic pulmonary disease; and the anesthesiologist's familiarity with each of the drug options. β -Adrenergic blockade alone or as a supplement is a good choice for a patient with good ventricular function and an elevated heart rate, but is relatively contraindicated in a patient with bronchospastic disease. Metoprolol, esmolol, or labetalol are readily used intraoperatively. Nicardipine or clevidipine may be preferable to β -blockers for patients with bronchospastic disease. Nitroprusside remains the most rapid and effective agent for the intraoperative treatment of moderate to severe hypertension. Nitroglycerin may be less effective, but is also useful in treating or preventing myocardial ischemia. Fenoldopam, a dopamine agonist, is also a useful hypotensive agent; furthermore, it increases renal blood flow. Hydralazine provides sustained blood pressure control, but also has a delayed onset and can cause reflex tachycardia. The latter is not seen with labetalol because of a combined α - and β -adrenergic blockade.

TABLE 21-7 Parenteral agents for the acute treatment of hypertension.

Agent	Dosage Range	Onset	Duration
Nitroprusside	0.5–10 mcg/kg/min	30–60	1–5 min
Nitroglycerin	0.5–10 mcg/kg/min	1 min	3–5 min
Esmolol	0.5 mg/kg over 1 min; 50–300 mcg/kg/min	1 min	12–20 min
Labetalol	5–20 mg	1–2 min	4–8 hr
Metoprolol	2.5–5 mg	1–5 min	5–8 hr
Hydralazine	5–20 mg	5–20 min	4–8 hr
Clevidipine	1–32 mg/hr	1–3 min	5–15 min
Nicardipine	0.25–0.5 mg 5–15 mg/hr	1–5 min	3–4 hr
Enalaprilat	0.625–1.25 mg	6–15 min	4–6 hr
Fenoldopam	0.1–1.6 mg/kg/min	5 min	5 min

POSTOPERATIVE MANAGEMENT

Postoperative hypertension is common and should be anticipated in patients who have poorly controlled hypertension. Close blood pressure monitoring should be continued in both the recovery room and the early postoperative period. In addition to myocardial ischemia and congestive heart failure, marked sustained elevations in blood pressure can contribute to the formation of wound hematomas and the disruption of vascular suture lines.

Hypertension in the recovery period is often multifactorial and enhanced by respiratory abnormalities, anxiety and pain, volume overload, or bladder distention. Contributing causes should be corrected and parenteral antihypertensive agents given if necessary. Intravenous labetalol is particularly useful in controlling hypertension and tachycardia, whereas vasodilators are useful in controlling blood pressure in the setting of a slow heart rate. When the patient resumes oral intake, preoperative medications should be restarted.

ISCHEMIC HEART DISEASE

Preoperative Considerations

Myocardial ischemia is characterized by a metabolic oxygen demand that exceeds the oxygen supply. Ischemia can therefore result from a marked increase in myocardial metabolic demand, a reduction in myocardial oxygen delivery, or a combination of both. Common causes include coronary arterial vasospasm or thrombosis; severe hypertension or tachycardia (particularly in the presence of ventricular hypertrophy); severe hypotension, hypoxemia, or anemia; and severe aortic stenosis or regurgitation.

By far, the most common cause of myocardial ischemia is atherosclerosis of the coronary arteries. CAD is responsible for about 25% of all deaths in Western societies and is a major cause of perioperative morbidity and mortality. The overall incidence of CAD in surgical patients is estimated to be between 5% and 10%. Major risk factors for CAD include hyperlipidemia, hypertension, diabetes, cigarette smoking, increasing age, male sex, and a positive family history. Other risk factors include

obesity, a history of cerebrovascular or peripheral vascular disease, menopause, use of high-estrogen oral contraceptives (in women who smoke), and a sedentary lifestyle.

CAD may be clinically manifested by symptoms of myocardial necrosis (infarction), ischemia (usually angina), arrhythmias (including sudden death), or ventricular dysfunction (congestive heart failure). When symptoms of congestive heart failure predominate, the term “ischemic cardiomyopathy” is often used.

Unstable Angina

Unstable angina is defined as (1) an abrupt increase in severity, frequency (more than three episodes per day), or duration of anginal attacks (crescendo angina); (2) angina at rest; or (3) new onset of angina (within the past 2 months) with severe or frequent episodes (more than three per day). Unstable angina may occur following MI or be precipitated by non-cardiac medical conditions (including severe anemia, fever, infections, thyrotoxicosis, hypoxemia, and emotional distress) in previously stable patients.

Unstable angina, particularly when it is associated with significant ST-segment changes at rest, usually reflects severe underlying coronary disease and frequently precedes MI. Plaque disruption with platelet aggregates or thrombi and vasospasm are frequent pathological correlates. Critical stenosis in one or more major coronary arteries is present in more than 80% of patients with these symptoms. Patients with unstable angina require evaluation and treatment, which may include admission to a coronary care unit and some form of coronary intervention.

Chronic Stable Angina

Anginal chest pains are most often substernal, exertional, radiating to the neck or arm, and relieved by rest or nitroglycerin. Variations are common, including epigastric, back, or neck pain, or transient shortness of breath from ventricular dysfunction (anginal equivalent). Nonexertional ischemia and silent (asymptomatic) ischemia are recognized as fairly common occurrences. Patients with diabetes have an increased incidence of silent ischemia.

Symptoms are generally absent until the atherosclerotic lesions cause 50% to 75% occlusion of

the coronary circulation. When a stenotic segment reaches 70% occlusion, maximum compensatory dilatation is usually present distally: blood flow is generally adequate at rest, but becomes inadequate with increased metabolic demand. An extensive collateral blood supply allows some patients to remain relatively asymptomatic in spite of severe disease. Coronary vasospasm is also a cause of transient transmural ischemia in some patients; 90% of vasospastic episodes occur at preexisting stenotic lesions in epicardial vessels and are often precipitated by a variety of factors, including emotional upset and hyperventilation (Prinzmetal's angina). Coronary spasm is most often observed in patients who have angina with varying levels of activity or emotional stress (variable-threshold); it is least common with classic exertional (fixed-threshold) angina.

The overall prognosis of patients with CAD is related to both the number and severity of coronary obstructions, as well as to the extent of ventricular dysfunction.

Treatment of Ischemic Heart Disease

The general approach in treating patients with ischemic heart disease is five-fold:

- Correction of risk factors, with the hope of slowing disease progression.
- Modification of the patient's lifestyle to reduce stress and improve exercise tolerance.
- Correction of complicating medical conditions that can exacerbate ischemia (ie, hypertension, anemia, hypoxemia, hyperthyroidism, fever, infection, or adverse drug effects).
- Pharmacological manipulation of the myocardial oxygen supply-demand relationship.
- Correction of coronary lesions by percutaneous coronary intervention (angioplasty [with or without stenting] or atherectomy) or coronary artery bypass surgery.

The last three approaches are of direct relevance to anesthesiologists. The same principles should be applied in the care of these patients in both the operating room and the intensive care unit.

¹SA, sinoatrial; AV, atrioventricular; ↑, increases; —, no change; ↓, decreases.

The most commonly used pharmacological agents are nitrates, β-blockers, and calcium channel blockers. These drugs also have potent circulatory effects, which are compared in [Table 21-8](#). Any of these agents can be used for mild angina. Calcium channel blockers are the drugs of choice for patients with predominantly vasospastic angina. β-Blockers improve the long-term outcome of patients with CAD. Nitrates are good agents for both types of angina.

A. Nitrates

Nitrates relax all vascular smooth muscle, but have a much greater effect on venous than on arterial vessels. Decreasing venous and arteriolar tone and reducing the effective circulating blood volume (cardiac preload) reduce wall tension afterload. These effects tend to reduce myocardial oxygen demand. The prominent venodilatation makes nitrates excellent agents when congestive heart failure is also present.

Perhaps equally important, nitrates dilate the coronary arteries. Even minor degrees of dilatation at stenotic sites may be sufficient to increase blood flow, because flow is directly related to the fourth power of the radius. Nitrate-induced coronary vasodilatation preferentially increases subendocardial blood flow in ischemic areas. This favorable redistribution of coronary blood flow to ischemic areas may

be dependent on the presence of collaterals in the coronary circulation.

Nitrates can be used for both the treatment of acute ischemia and prophylaxis against frequent anginal episodes. Unlike β-blockers and calcium channel blockers, nitrates do not have a negative inotropic effect—a desirable feature in the presence of ventricular dysfunction. Intravenous nitroglycerin can also be used for controlled hypotensive anesthesia.

B. Calcium Channel Blockers

The effects and uses of the most commonly used calcium channel blockers are shown in [Table 21-9](#). Calcium channel blockers reduce myocardial oxygen demand by decreasing cardiac afterload and augment oxygen supply by increasing blood flow (coronary vasodilatation). Verapamil and diltiazem also reduce demand by slowing the heart rate.

Nifedipine's potent effects on the systemic blood pressure may precipitate hypotension, reflex tachycardia, or both; its fast-onset preparations (eg, sublingual) have been associated with MI in some patients. Its tendency to decrease afterload generally offsets any negative inotropic effect. The slow-release form of nifedipine is associated with much less reflex tachycardia and is more suitable than other agents for patients with ventricular

TABLE 21-9 Comparison of calcium channel blockers.

Agent	Route	Dosage ¹	Half-life	Clinical Use			
				Angina	Hypertension	Cerebral Vasospasm	Supraventricular Tachycardia
Verapamil	PO	40–240 mg	5 hr	+	+		+

dysfunction. In contrast, verapamil and diltiazem have greater effects on cardiac contractility and atrioventricular (AV) conduction and therefore should be used cautiously, if at all, in patients with ventricular dysfunction, conduction abnormalities, or bradyarrhythmias. Diltiazem seems to be better tolerated than verapamil in patients with impaired ventricular function. Nicardipine, nimodipine, and clevidipine generally have the same effects as nifedipine; nimodipine is primarily used in preventing cerebral vasospasm following subarachnoid hemorrhage, whereas nicardipine is used as an intravenous arterial vasodilator. Clevidipine is an ultrashort-acting arterial vasodilator.

Calcium channel blockers can have significant interactions with anesthetic agents. All calcium channel blockers potentiate both depolarizing and nondepolarizing neuromuscular blocking agents and the circulatory effects of volatile agents. Both

verapamil and diltiazem can potentiate depression of cardiac contractility and conduction in the AV node by volatile anesthetics. Nifedipine and similar agents can potentiate systemic vasodilatation by volatile and intravenous agents.

C. β -Adrenergic Blocking Agents

These drugs decrease myocardial oxygen demand by reducing heart rate and contractility, and, in some cases, afterload (via their antihypertensive effect). Optimal blockade results in a resting heart rate between 50 and 60 beats/min and prevents appreciable increases with exercise (<20 beats/min increase during exercise). Available agents differ in receptor selectivity, intrinsic sympathomimetic (partial agonist) activity, and membrane-stabilizing properties (Table 21-10). Membrane stabilization, often described as a quinidine-like effect, results in antiarrhythmic activity. Agents with

TABLE 21-10 Comparison of β -adrenergic blocking agents.

¹Also possesses unique antiarrhythmic properties.

intrinsic sympathomimetic properties are better tolerated by patients with mild to moderate ventricular dysfunction. Certain β -blockers (carvedilol and extended-duration metoprolol) improve survival in patients with chronic heart failure. This has not been shown to be a drug class effect. Blockade of β_2 -adrenergic receptors also can mask hypoglycemic symptoms in patients with diabetes, delay metabolic recovery from hypoglycemia, and impair the handling of large potassium loads. Cardioselective (β_1 -receptor-specific) agents, although generally better tolerated than nonselective agents in patients with reactive airways, must still be used cautiously in such patients. The selectivity of cardioselective agents tends to be dose dependent. Patients on

long-standing β -blocker therapy should have these agents continued perioperatively. Acute β -blocker withdrawal in the perioperative period places patients at a markedly increased risk of cardiac morbidity and mortality.

Documentation of avoidance of β -blocker withdrawal is a frequent tool by which “quality” of anesthesia services can be assessed by regulatory agencies.

D. Other Agents

ACE inhibitors prolong survival in patients with congestive heart failure or left ventricular dysfunction. Chronic aspirin therapy reduces coronary events in patients with CAD and prevents coronary

and ischemic cerebral events in at-risk patients. Antiarrhythmic therapy in patients with complex ventricular ectopy who have significant CAD and left ventricular dysfunction should be guided by an electrophysiological study. Patients with inducible sustained ventricular tachycardia (VT) or ventricular fibrillation are candidates for an automatic internal cardioverter-defibrillator (ICD). Treatment of ventricular ectopy (with the exception of sustained VT) in patients with good ventricular function does not improve survival and may increase mortality. In contrast, ICDs have been shown to improve survival in patients with advanced cardiomyopathy (ejection fraction <30%), even in the absence of demonstrable arrhythmias.

E. Combination Therapy

Moderate to severe angina frequently requires combination therapy with two or all three classes of agents. Patients with ventricular dysfunction may not tolerate the combined negative inotropic effect of a β -blocker and a calcium channel blocker together; an ACE inhibitor is better tolerated and seems to improve survival. Similarly, the additive effect of a β -blocker and a calcium channel blocker on the AV node may precipitate heart block in susceptible patients.

PREOPERATIVE MANAGEMENT

The importance of ischemic heart disease—particularly a history of MI—as a risk factor for perioperative morbidity and mortality was discussed earlier in the chapter. Most studies confirm that perioperative outcome is related to disease severity, ventricular function, and the type of surgery to be undertaken.

3 Patients with extensive (three-vessel or left main) CAD, a recent history of MI, or ventricular dysfunction are at greatest risk of cardiac complications. As mentioned above, current guidelines recommend revascularization when such treatment would be indicated irrespective of the patient's need for surgery.

Chronic stable (mild to moderate) angina does not seem to increase perioperative risk substantially. Similarly, a history of prior coronary artery bypass

surgery or coronary angioplasty alone does not seem to substantially increase perioperative risk. In some studies, maintenance of chronic β -receptor blockers in the perioperative period has been shown to reduce perioperative mortality and the incidence of postoperative cardiovascular complications; however, other studies have shown an increase in stroke and death following preoperative introduction of β -blockers to “at risk” patients. Consequently, as with all drugs, the risks and benefits of initiating therapy with β -blockers in at risk patients must be considered. Like β -blockers, statins should be continued perioperatively in patients so routinely treated, as acute perioperative withdrawal of statins is associated with adverse outcomes. ACC/AHA guidelines suggest that β -blockers are useful in patients undergoing vascular surgery with evidence of ischemia on their evaluative workup (class I).

History

The history is of prime importance in patients with ischemic heart disease. Questions should encompass symptoms, current and past treatment, complications, and the results of previous evaluations. This information alone is usually enough to provide some estimate of disease severity and ventricular function.

The most important symptoms to elicit include chest pains, dyspnea, poor exercise tolerance, syncope, or near syncope. The relationship between symptoms and activity level should be established. Activity should be described in terms of everyday tasks, such as walking or climbing stairs. Patients may be relatively asymptomatic despite severe CAD if they have a sedentary lifestyle. Patients with diabetes are particularly prone to silent ischemia. The patient's description of chest pains may suggest a major role for vasospasm (variable-threshold angina). Easy fatigability or shortness of breath suggests impaired ventricular function.

A history of unstable angina or MI should include the time of its occurrence and whether it was complicated by arrhythmias, conduction disturbances, or heart failure. Localization of the areas of ischemia is invaluable in deciding which electrocardiographic leads to monitor intraoperatively. Arrhythmias and conduction abnormalities are

more common in patients with previous infarction and in those with poor ventricular function. This latter group of patients will often have ICDs.

Physical Examination & Routine Laboratory Evaluation

Evaluation of patients with CAD is similar to that of patients with hypertension. Laboratory evaluation in patients who have a history compatible with recent unstable angina and are undergoing emergency procedures should include cardiac enzymes. Serum levels of cardiac-specific troponins, creatine kinase (MB isoenzyme), and lactate dehydrogenase (type 1 isoenzyme) are useful in excluding MI.

The baseline ECG is normal in 25% to 50% of patients with CAD but no prior MI. Electrocardiographic evidence of ischemia often becomes apparent only during chest pain. The most common baseline abnormalities are nonspecific ST-segment and T-wave changes. Prior infarction is often manifested by Q waves or loss of R waves in the leads closest to the infarct. First-degree AV block, bundle-branch block, or hemiblock may be present. Persistent ST-segment elevation following MI may be indicative of a left ventricular aneurysm. A long rate-corrected QT interval ($QT_c > 0.44$ s) may reflect the underlying ischemia, drug toxicity (usually class Ia antiarrhythmic agents, antidepressants, or phenothiazines), electrolyte abnormalities (hypokalemia or hypomagnesemia), autonomic dysfunction, mitral valve prolapse, or, less commonly, a congenital abnormality. Patients with a long QT interval are at risk of developing ventricular arrhythmias—particularly polymorphic VT (torsade de pointes), which can lead to ventricular fibrillation. The long QT interval reflects nonuniform prolongation of ventricular repolarization and predisposes patients to reentry phenomena. In contrast to polymorphic ventricular arrhythmias with a normal QT interval, which respond to conventional antiarrhythmics, polymorphic tachyarrhythmias with a long QT interval generally respond best to pacing or magnesium salts. Patients with congenital prolongation generally respond to β -adrenergic blocking agents. Left stellate ganglion blockade is also effective and suggests that autonomic imbalance plays an important role in this group of patients.

The chest film can be used to exclude cardiomegaly or pulmonary vascular congestion secondary to ventricular dysfunction. Rarely, calcification of the coronaries, aorta, or the aortic valve may be seen on the chest radiograph; such is a more common finding on CT.

Specialized Studies

When used as screening tests for the general population, noninvasive stress tests have a low predictability in asymptomatic patients, but are sufficiently reliable in symptomatic patients with suspect lesions.

4 Holter monitoring, exercise electrocardiography, myocardial perfusion scans, and echocardiography are important in determining perioperative risk and the need for coronary angiography; however, these tests are indicated only if their outcome would alter patient care.

Current ACC/AHA guidelines recommend noninvasive stress testing in patients scheduled for noncardiac surgery with active cardiac conditions (class I). The current guidelines also suggest that there may be benefit of such testing in patients with three or more clinical risk factors and poor functional capacity (class IIa). Likewise, they suggest that noninvasive testing can be of some possible benefit in patients with one or two clinical risk factors undergoing intermediate risk or vascular surgery (class IIb). What they do not recommend is the indiscriminate use of noninvasive cardiac testing in patients with no risk factors undergoing intermediate-risk surgery. Consequently, indications for preoperative cardiac screening tests continue to narrow.

A. Holter Monitoring

Continuous ambulatory electrocardiographic (Holter) monitoring is useful in evaluating arrhythmias, antiarrhythmic drug therapy, and severity and frequency of ischemic episodes. Silent (asymptomatic) ischemic episodes are frequently found in patients with CAD. Frequent ischemic episodes on preoperative Holter monitoring correlate well with intraoperative and postoperative ischemia. Holter monitoring has an excellent negative predictive value for postoperative cardiac complications.

B. Exercise Electrocardiography

The usefulness of this test is limited in patients with baseline ST-segment abnormalities and those who are unable to increase their heart rate (>85% of maximal predicted) because of fatigue, dyspnea, or drug therapy. Overall sensitivity is 65%, and specificity is 90%. The test is most sensitive (85%) in patients with three-vessel or left main CAD. Disease that is limited to the left circumflex artery may also be missed because ischemia in its distribution may not be evident on the standard surface ECG. A normal test does not necessarily exclude CAD, but suggests that severe disease is not likely. The degree of ST-segment depression, its severity and configuration, the time of onset in the test, and the time required for resolution are important findings. A myocardial ischemic response at low levels of exercise is associated with a significantly increased risk of perioperative complications and long-term cardiac events. Other significant findings include changes in blood pressure and the occurrence of arrhythmias. Exercise-induced ventricular ectopy frequently indicates severe CAD associated with ventricular dysfunction. The ischemia presumably leads to electrical instability in myocardial cells. Given that risk seems to be associated with the degree of myocardium potentially ischemic, testing often includes perfusion scans or echocardiographic assessments; however, in ambulatory patients, exercise ECG testing is useful because it estimates functional capacity and detects myocardial ischemia.

C. Myocardial Perfusion Scans and Other Imaging Techniques

Myocardial perfusion imaging using thallium-201 or technetium-99m is used in evaluating patients who cannot exercise (eg, peripheral vascular disease) or who have underlying ECG abnormalities that preclude interpretation during exercise (eg, left bundle-branch block). If the patient cannot exercise, images are obtained before and after injection of an intravenous coronary dilator (eg, dipyridamole or adenosine) to produce a hyperemic response similar to exercise. Myocardial perfusion studies following exercise or injection of dipyridamole or adenosine have a high sensitivity, but only fairly good specificity for CAD. They are best for

detecting two- or three-vessel disease. These scans can locate and quantitate areas of ischemia or scarring and differentiate between the two. Perfusion defects that fill in on the redistribution phase represent ischemia, not previous infarction. The negative predictive value of a normal perfusion scan is approximately 99%.

MRI, PET, and CT scans are increasingly being used to define coronary artery anatomy and determine myocardial viability.

D. Echocardiography

This technique provides information about both regional and global ventricular function and may be carried out at rest, following exercise, or with administration of dobutamine. Detectable regional wall motion abnormalities and the derived left ventricular ejection fraction correlate well with angiographic findings. Moreover, dobutamine stress echocardiography seems to be a reliable predictor of adverse cardiac complications in patients who cannot exercise. New or worsening wall motion abnormalities following dobutamine infusion are indicative of significant ischemia. Patients with an ejection fraction of less than 50% tend to have more severe disease and increased perioperative morbidity. Dobutamine stress echocardiography, however, may not be reliable in patients with left bundle-branch block because septal motion may be abnormal, even in the absence of left anterior descending CAD in some patients.

E. Coronary Angiography

Coronary angiography remains the definitive way to evaluate CAD and is associated with a low complication rate (<1%). Nonetheless, coronary angiography should be performed only to determine if the patient may benefit from percutaneous coronary angioplasty or coronary artery bypass grafting prior to noncardiac surgery. The location and severity of occlusions can be defined, and coronary vasospasm may also be observed on angiography. In evaluating fixed stenotic lesions, occlusions greater than 50% to 75% are generally considered significant. The severity of disease is often expressed according to the number of major coronary vessels affected (one-, two-, or three-vessel

disease). Significant stenosis of the left main coronary artery is of great concern because disruption of flow in this vessel will have adverse effects on almost the entire left ventricle.

Ventriculography, measurement of the ejection fraction, and measurement of intracardiac pressures, also provide important information. Indicators of significant ventricular dysfunction include an ejection fraction <50%, a left ventricular end-diastolic pressure >18 mm Hg, a cardiac index <2.2 L/min/m², and marked or multiple wall motion abnormalities.

Guidelines suggest that patients with stable angina and significant left main disease, stable angina and three-vessel disease, stable angina and two-vessel disease with an ejection fraction <50%, unstable angina, non-ST segment elevation MI, and acute ST segment elevation MI benefit from revascularization. This recommendation also applies to patients who are scheduled for noncardiac surgery (class I). Conversely, revascularization is not indicated in patients with stable angina (class III). Moreover, elective noncardiac surgery is not recommended within 4–6 weeks following bare metal stent placement or within 12 months of placement of a drug-eluting stent, if the surgery requires that antiplatelet therapy be discontinued.

Premedication

Allaying fear, anxiety, and pain preoperatively are desirable goals in patients with CAD. Satisfactory premedication prevents sympathetic activation, which adversely affects the myocardial oxygen supply–demand balance. Overmedication is equally detrimental and should be avoided because it may result in hypoxemia, respiratory acidosis, and hypotension. A benzodiazepine, alone or in combination with an opioid, is commonly used. (The concomitant administration of oxygen via nasal cannula helps avoid hypoxemia following premedication.) Patients with poor ventricular function and coexistent lung disease should receive reduced doses. Preoperative medications should generally be continued until the time of surgery. They may be given orally (with a small sip of water), intramuscularly, intravenously, sublingually, or transdermally.

5 The sudden withdrawal of antianginal medication perioperatively—particularly β -blockers—can precipitate a sudden, rebound increase in ischemic episodes. In the past, some clinicians prophylactically administered nitrates intravenously or transdermally to patients with CAD in the perioperative period. Although this practice may be theoretically advantageous, there is no evidence of its efficacy in patients not previously on long-term nitrate therapy and without evidence of ongoing ischemia. Transdermal absorption of nitroglycerin may be erratic in the perioperative period.

INTRAOPERATIVE MANAGEMENT

The intraoperative period is regularly associated with factors and events that can adversely affect the myocardial oxygen demand–supply relationship. Activation of the sympathetic system plays a major role. Hypertension and enhanced contractility increase myocardial oxygen demand, whereas tachycardia increases demand and reduces supply. Although myocardial ischemia is commonly associated with tachycardia, it can occur in the absence of any apparent hemodynamic derangement.

Objectives

6 The overwhelming priority in managing patients with ischemic heart disease is maintaining a favorable myocardial supply–demand relationship. Autonomic-mediated increases in heart rate and blood pressure should be controlled by deep anesthesia or adrenergic blockade. Excessive reductions in coronary perfusion pressure or arterial oxygen content are to be avoided. Although exact limits are not defined or predictable, diastolic arterial pressure should generally be maintained at 50 mm Hg or above. Higher diastolic pressures may be preferable in patients with high-grade coronary occlusions. Excessive increases—such as those caused by fluid overload—in left ventricular end-diastolic pressure should be avoided because they increase ventricular wall tension (afterload) and can reduce subendocardial perfusion (see Chapter 20). Transfusion carries its own risks and consequently there is no set transfusion trigger in patients with

CAD; however, anemia can lead to tachycardia, worsening the balance between myocardial oxygen supply and demand.

MONITORING

Intraarterial pressure monitoring is reasonable for all patients with severe CAD and major or multiple cardiac risk factors who are undergoing any but the most minor procedures. Central venous (or rarely pulmonary artery) pressure can be monitored during prolonged or complicated procedures involving large fluid shifts or blood loss. Less invasive methods of cardiac output determination and volume assessment have been previously discussed in this text. Transesophageal echocardiography (TEE) and transthoracic echocardiography (TTE) can provide valuable information, both qualitative and quantitative, on contractility and ventricular chamber size (preload) perioperatively. Intensive care unit staff increasingly use ultrasound to assist in hemodynamic management. Numerous “basic” courses in TEE and TTE are available to assist practitioners in performing “hemodynamic,” as opposed to cardiac diagnostic TEE.

7 Intraoperative detection of ischemia depends on recognition of electrocardiographic changes, hemodynamic manifestations, or regional wall motion abnormalities on TEE. Doppler TEE also allows detection of the onset of mitral regurgitation caused by ischemic papillary muscle dysfunction.

A. Electrocardiography

Early ischemic changes are subtle and can often be overlooked. They involve changes in T-wave morphology, including inversion, tenting, or both (Figure 21-1). More obvious ischemia may be seen in the form of progressive ST-segment depression. Down-sloping and horizontal ST depressions are of greater specificity for ischemia than is up-sloping depression. New ST-segment elevations are rare during noncardiac surgery and are indicative of severe ischemia, vasospasm, or infarction. However, the increasing number of individuals treated with drug-eluting stents can be problematic perioperatively, especially if surgical concerns necessitate discontinuation of antiplatelet therapy (eg, emergency spine

surgery). Such patients are at very increased risk of thrombosis and perioperative MI. Anesthesia staff should never for nonsurgical reasons (eg, desire to perform a spinal anesthetic) discontinue antiplatelet or anti thrombotic agents perioperatively without first discussing the risks and benefits of the proposed anesthetic requiring suspension of antiplatelet therapy with the patient and his or her cardiologist. ACC/AHA offers recommendations on the approach of bringing patients to surgery following percutaneous coronary interventions and the type of interventions suggested when subsequent surgery is expected (Figures 21-2 and 21-3). It should be noted that an isolated minor ST elevation in the mid-precordial leads (V_3 and V_4) can be a normal variant in young patients. Ischemia may also present as an unexplained intraoperative atrial or ventricular arrhythmia or the onset of a new conduction abnormality. The sensitivity of the ECG in detecting ischemia is related to the number of leads monitored. Studies suggest that the V_5 , V_4 , II, V_2 , and V_3 leads (in decreasing sensitivity) are most useful. Ideally, at least two leads should be monitored simultaneously. Usually, lead II is monitored for inferior wall ischemia and arrhythmias, and V_5 is monitored for anterior wall ischemia. When only one channel can be monitored, a modified V_5 lead provides the highest sensitivity.

B. Hemodynamic Monitoring

The most common hemodynamic abnormalities observed during ischemic episodes are hypertension and tachycardia. They are almost always a cause (rather than the result) of ischemia. Hypotension is a late and ominous manifestation of progressive ventricular dysfunction. TEE readily will demonstrate a dysfunctional ventricle and ventricular wall motion changes associated with myocardial ischemia. Ischemia is frequently, but not always, associated with an abrupt increase in pulmonary capillary wedge pressure. The sudden appearance of a prominent v wave on the wedge waveform is usually indicative of acute mitral regurgitation from ischemic papillary muscle dysfunction or acute left ventricular dilatation.

C. Transesophageal Echocardiography

TEE can be helpful in detecting global and regional cardiac dysfunction, as well as valvular function in selected patients. Moreover, detection of new

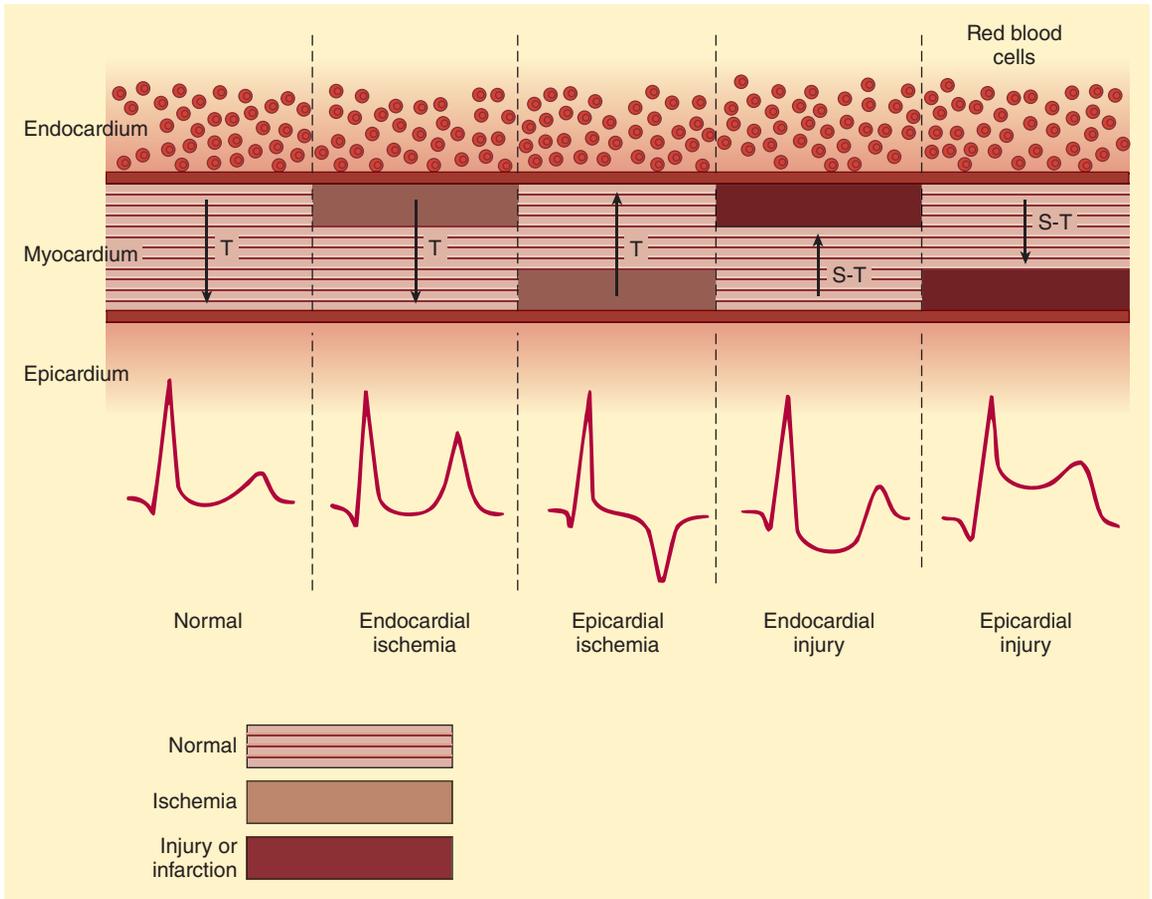

FIGURE 21-1 Electrocardiographic signs of ischemia. Patterns of ischemia and injury. (Information compiled from Schamroth L: *The 12 Lead Electrocardiogram*. Blackwell, 1989.)

regional wall motion abnormalities is a rapid and more sensitive indicator of myocardial ischemia than the ECG. In animal studies in which coronary blood flow is gradually reduced, regional wall motion abnormalities develop before the ECG changes. Although the occurrence of new intraoperative abnormalities correlates with postoperative MIs in some studies, not all such abnormalities are necessarily ischemic. Both regional and global abnormalities can be caused by changes in heart rate, altered conduction, preload, afterload, or drug-induced changes in contractility. Decreased systolic wall thickening may be a more reliable index for ischemia than endocardial wall motion alone.

Arrhythmias, Pacemakers, and Internal Cardioverter-Defibrillator Management

Electrolyte disorders, heart structure defects, inflammation, myocardial ischemia, cardiomyopathies, and conduction abnormalities can all contribute to the development of perioperative arrhythmias and heart block. Consequently, the anesthesia staff must be prepared to manage both chronic and new-onset cardiac rhythm problems.

Supraventricular tachycardias (SVTs) can have hemodynamic consequences secondary to loss of AV synchrony and decreased diastolic filling time.

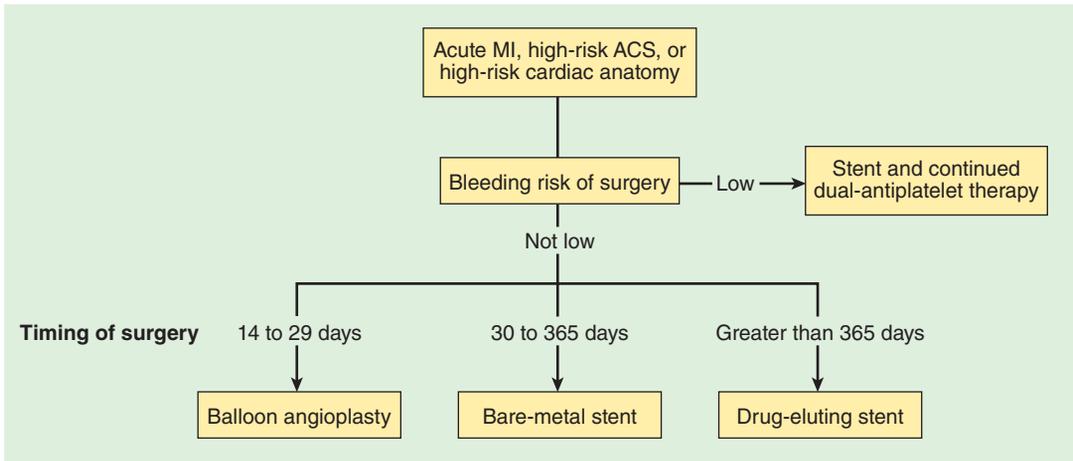

FIGURE 21-2 Proposed treatment for patients requiring percutaneous coronary intervention (PCI) who need subsequent surgery. ACS, acute coronary syndrome; COR, class of recommendation; LOE, level of evidence;

MI, myocardial infarction. (Reproduced, with permission, from Fleisher L, Beckman J, Brown K, et al: ACC/AHA 2007 guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery. *Circulation* 2007;116: e418.)

Loss of the “P” wave on the ECG with a fast ventricular response is consistent with SVTs. Most SVTs occur secondary to a reentrant mechanism. Reentrant arrhythmias occur when conduction tissues in the heart depolarize or repolarize at varying rates. In this manner, a self-perpetuating loop of

repolarization and depolarization can occur in the conduction pathways and/or AV node. SVTs producing hemodynamic collapse are treated perioperatively with synchronized cardioversion. Adenosine can likewise be given to slow AV node conduction and potentially disrupt the reentrant loop. SVTs

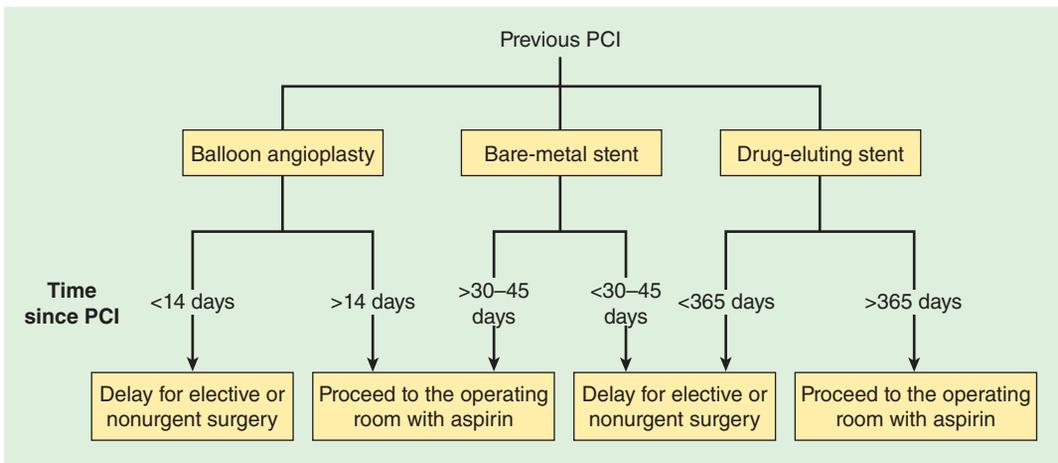

FIGURE 21-3 Proposed approach to the management of patients with previous percutaneous coronary intervention (PCI) who require non-cardiac surgery, based on expert opinion. (Reproduced, with permission, from Fleisher L,

Beckman J, Brown K, et al: ACC/AHA 2007 guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery. *Circulation* 2007;116: e418.)

in patients without accessory conduction bundles (Wolff–Parkinson–White [WPW] syndrome) are treated with β -blockers and calcium channel blockers. In patients with known WPW, procainamide or amiodarone can be used to treat SVTs. At times, SVTs manifest with a broad QRS complex and seem to be similar to VTs. Such rhythms, when they present, should be treated like VT, until proven otherwise.

Atrial fibrillation (AF) can complicate the perioperative period (Figure 21–4). Up to 35% of cardiac surgery patients develop postoperative AF. Moreover, many patients present with AF for anesthesia and noncardiac surgery. The ACC/AHA has issued voluminous guidelines for the outpatient management of AF. The guidelines recommend use of β -blockers or nondihydropyridine calcium antagonists for ventricular rate control in patients without accessory conduction pathways. Amiodarone, procainamide, disopyramide, and ibutilide are suggested for ventricular rate control in patients with accessory pathways. The use of digitalis and nondihydropyridine calcium channel blockers is contraindicated in patients with accessory pathways.

The ACC/AHA guidelines also recommend anti-thrombotic therapy in patients with long-standing AF. Consequently, many patients with AF will present to the operating room on some form of anti-thrombotic therapy—often the vitamin K antagonist warfarin. However, ACC/AHA guidelines suggest that aspirin can be an alternative to vitamin K antagonists in low-risk patients or those with contraindications to oral anticoagulation. Likewise, in patients with AF without mechanical prosthetic heart valves, the guidelines suggest that it is acceptable to discontinue anticoagulation for up to 1 week in advance of surgical procedures, without instituting heparin anticoagulation.

When AF develops perioperatively, rate control with β -blockers can often be instituted. Chemical cardioversion can be attempted with amiodarone or procainamide. Of note, if the duration of AF is greater than 48 hours, or unknown, ACC/AHA guidelines recommend anticoagulation for 3 weeks prior to and 4 weeks following either electrical or chemical cardioversion. Alternatively, TEE can be performed to rule out the presence of left atrial or left atrial appendage thrombus.

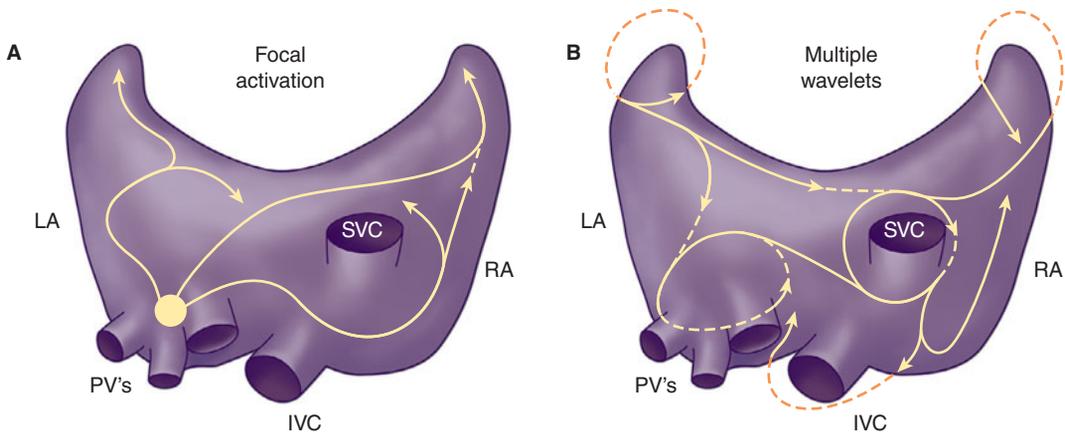

FIGURE 21–4 Posterior view of principal electrophysiological mechanisms of atrial fibrillation. **A:** Focal activation. The initiating focus (indicated by the dot) often lies within the region of the pulmonary veins. The resulting wavelets represent fibrillatory conduction, as in multiple-wavelet reentry. **B:** Multiple-wavelet reentry. Wavelets (indicated by arrows) randomly reenter tissue

previously activated by the same or another wavelet. The routes the wavelets travel vary. LA, left atrium; PV, pulmonary vein; IVC, inferior vena cava; SVC, superior vena cava; RA, right atrium. (Reproduced with permission, from Konings KT, Kirchhof CJ, Smeets JR, et al: High-density mapping of electrically induced atrial fibrillation in humans. *Circulation* 1994 Apr;89(4):1665-1680.)

Should AF develop postoperatively, ventricular rate response can be controlled with AV nodal blocking agents, unless contraindicated. Should AF result in hemodynamic instability, synchronized cardioversion can be attempted. Patients at high risk of AF following cardiac surgery can be treated with prophylactic amiodarone.

AF is most frequently associated with loss of atrial muscle and the development of fibrosis. Fibrosis may contribute to reentrant mechanisms of AF as depolarization/repolarization becomes nonhomogeneous. AF may also develop from a focal source often located in the pulmonary veins. In patients with an accessory bundle, AF can produce rapid ventricular responses and hemodynamic collapse. Drugs that slow conduction across the AV node (eg, digitalis, verapamil, diltiazem) do not slow conduction across the accessory pathway, potentially leading to hemodynamic collapse. The ACC/AHA guidelines likewise recommend caution in the use of β -blockers for AF in patients with preexcitation syndromes.

Ventricular arrhythmias have been the subject of much review by the AHA (**Table 21-11**). Ventricular premature contractions (VPCs) can appear perioperatively secondary to electrolyte abnormalities (hypokalemia, hypomagnesium, hypocalcemia), acidosis, ischemia, embolic phenomenon, mechanical irritation of the heart from central lines, cardiac manipulation, and drug effects. Correction of the underlying source of any arrhythmia should be addressed. Patients can likewise present with VPCs secondary to various cardiomyopathies (dilated, hypertrophic, and arrhythmogenic right ventricular).

The incidence of sudden cardiac death (SCD) is estimated at 1-2/1000 per year. Consequently, some patients will experience an unexpected death in the perioperative period. All anesthesia providers must be prepared to resuscitate and manage patients with ventricular arrhythmias, including VT (nonsustained and sustained) and ventricular fibrillation.

Nonsustained ventricular tachycardia is a short run of ventricular ectopy that lasts <30 sec and spontaneously terminates, whereas sustained VT persists longer than 30 seconds. VT is either monomorphic or polymorphic, depending on the QRS complex. If

the QRS complex morphology changes, it is designated as polymorphic VT. Torsades de pointes is a form of VT associated with a prolonged QT interval, producing a sine wave-like VT pattern on the ECG. Ventricular fibrillation requires immediate resuscitative efforts and defibrillation.

Patients presenting with ventricular ectopy and nonsustained runs of VT should undergo investigation prior to surgery. Supraventricular and ventricular arrhythmias constitute active cardiac conditions that warrant evaluation and treatment prior to elective, noncardiac surgery. Exercise testing, echocardiography, and nuclear perfusion studies are all recommended by the ACC/AHA in patients with ventricular arrhythmias as part of their workup and management. Electrophysiologic studies are undertaken to determine the possibility for catheter-mediated ablation of ventricular tachycardias.

Should VT present perioperatively, cardioversion is recommended at any point where hemodynamic compromise occurs. Otherwise, treatment with amiodarone or procainamide can be attempted. At all times, therapy should also be directed at identifying any causative sources of the arrhythmia. β -Blockers are useful in the treatment of VT, especially if ischemia is a suspected causative factor in the development of rhythm. The use of β -blockers following myocardial infarction has reduced the incidence of post-MI ventricular fibrillation.

Torsades de pointes is associated with conditions that lengthen the QT interval. If the arrhythmia develops in association with pauses, pacing can be effective. Likewise, some patients may benefit from isoproterenol infusions, if they develop pause-dependent torsades de pointes. Magnesium sulfate may be useful in patients with long QT syndrome and episodes of torsades.

The development of perioperative ventricular fibrillation (VF) requires defibrillation and the use of resuscitation algorithms. Amiodarone can be used to stabilize the rhythm following successful defibrillation.

Following VF, patients can present to surgery for both ICD placement and other surgical procedures. ICDs are recommended in patients with a history of survived sudden cardiac death (SCD), decreased ventricular function following

TABLE 21–11 Classification of ventricular arrhythmias.

Classification by Clinical Presentation		
Hemodynamically stable	Asymptomatic	The absence of symptoms that could result from an arrhythmia.
	Minimal symptoms, e.g., palpitations	Patient reports palpitations felt in either the chest, throat, or neck as described by the following: <ul style="list-style-type: none"> • Heartbeat sensations that feel like pounding or racing • An unpleasant awareness of heartbeat • Feeling skipped beats or a pause
Hemodynamically unstable	Presyncope	Patient reports presyncope as described by the following: <ul style="list-style-type: none"> • Dizziness • Lightheadedness • Feeling faint • “Graying out”
	Syncope	Sudden loss of consciousness with loss of postural tone, not related to anesthesia, with spontaneous recovery as reported by the patient or observer. Patient may experience syncope when supine.
	Sudden cardiac death	Death from an unexpected circulatory arrest, usually due to a cardiac arrhythmia occurring within an hour of the onset of symptoms.
	Sudden cardiac arrest	Death from an unexpected circulatory arrest, usually due to a cardiac arrhythmia occurring within an hour of the onset of symptoms, in whom medical intervention (e.g., defibrillation) reverses the event.
Classification by Electrocardiography		
Nonsustained VT		Three or more beats in duration, terminating spontaneously in less than 30 s.
		VT is a cardiac arrhythmia of three or more consecutive complexes in duration emanating from the ventricles at a rate of greater than 100 bpm (cycle length less than 600 ms)
	Monomorphic Polymorphic	Nonsustained VT with a single QRS morphology. Nonsustained VT with a changing QRS morphology at cycle length between 600 and 180 ms.
Sustained VT		VT greater than 30 s in duration and/or requiring termination due to hemodynamic compromise in less than 30 s.
	Monomorphic	Sustained VT with a stable single QRS morphology.
	Polymorphic	Sustained VT with a changing or multiform QRS morphology at cycle length between 600 and 180 ms.
Bundle-branch reentrant tachycardia		VT due to reentry involving the His-Purkinje system, usually with LBBB morphology; this usually occurs in the setting of cardiomyopathy.
Bidirectional VT		VT with a beat-to-beat alternans in the QRS frontal plane axis, often associated with digitalis toxicity.
Torsades de pointes		Characterized by VT associated with a long QT or QTc, and electrocardiographically characterized by twisting of the peaks of the QRS complexes around the isoelectric line during the arrhythmia: <ul style="list-style-type: none"> • “Typical,” initiated following “short-long-short” coupling intervals. • Short coupled variant initiated by normal-short coupling.

(continued)

TABLE 21-11 Classification of ventricular arrhythmias. (continued)

Classification by Electrocardiography	
Ventricular flutter	A regular (cycle length variability 30 ms or less) ventricular arrhythmia approximately 300 bpm (cycle length—200 ms) with a monomorphic appearance; no isoelectric interval between successive QRS complexes.
Ventricular fibrillation	Rapid, usually more than 300 bpm/200 ms (cycle length 180 ms or less), grossly irregular ventricular rhythm with marked variability in QRS cycle length, morphology, and amplitude.
Classification by Disease Entity	
Chronic coronary heart disease Heart failure Congenital heart disease Neurological disorders Structurally normal hearts Sudden infant death syndrome Cardiomyopathies: Dilated cardiomyopathy Hypertrophic cardiomyopathy Arrhythmogenic right ventricular cardiomyopathy	

LBBB, left bundle-branch block; VT, ventricular tachycardia.

Reproduced, with permission, from Zipes DP, Camm AJ, Borggrefe M, et al: ACC/AHA/ESC 2006 guidelines for management of patients with ventricular arrhythmias and the prevention of sudden cardiac death—executive summary. *Circulation* 2006;114:1088.

MI, and left ventricular ejection fractions <35%. Additionally, ICDs are used to treat potential sudden cardiac death in patients with dilated, hypertrophic, arrhythmogenic right ventricular, and genetic cardiomyopathies.

ICDs usually have a biventricular pacing function that improves the effectiveness of left ventricular contraction. Patients with heart failure frequently have a widened QRS complex >120 msec. In such patients, ventricular systole is less efficient, as the lateral and septal left ventricular walls do not effectively contract because of the conduction delay. Cardiac resynchronization therapy (CRT) has been shown to improve functional status in patients with heart failure (Table 21-12).

Anesthetic management for the placement of ICDs and other electrophysiologic procedures (eg, catheter ablation) depends on the patient's underlying conditions. Many patients present with systolic and diastolic heart failure, and, as such, are dependent on sympathetic tone to maintain blood pressure. Many patients tolerate ICD placement

using deep sedation rather than general anesthesia. However, catheter-based electrophysiologic studies can be quite time consuming, and patients can develop atelectasis and airway obstruction. Should the patient's blood pressure suddenly decline during electrophysiologic studies, development of pericardial tamponade should be ruled out. Emergent drainage of tamponade may be necessary.

Many patients present to surgery with ICDs in place. Published guidelines of the American Society of Anesthesiologists can provide assistance in the management of such patients.

Management is a three-step process, as follows:

- *Preoperative.* Identify the type of device and determine if it is used for antibradycardia functions. Consult with the patient's cardiologist preoperatively as to the device's function and use history.
- *Intraoperative.* Determine what electromagnetic interference is likely to present intraoperatively and advise the use of bipolar electrocautery where possible. Assure the availability of temporary pacing and defibrillation equipment and apply pads as necessary. Patients who are pacer dependent can be programmed to an asynchronous mode to mitigate electrical interference. Magnet application to ICDs may disable the antitachycardia function, but not convert to an asynchronous pacemaker. Consultation with the patient's cardiologist and interrogation of the device is advised.
- *Postoperative.* The device must be interrogated to ensure that therapeutic functions have been restored. Patients should be continuously monitored until the antitachycardia functions of the device are restored and its function has been confirmed.

ICDs are particularly problematic intraoperatively when electrocautery is used because the device may (1) interpret cautery as ventricular fibrillation; (2) inhibit pacemaker function due to cautery artifact; (3) increase the pacing rate due to activation of a rate-responsive sensor; or (4) temporarily or permanently reset to a backup or reset mode. Use of bipolar cautery, placement of the grounding pad far from the ICD device, and limiting use of the cautery to only short bursts help to reduce the likelihood of problems, but will not eliminate them.

ICD devices should have the defibrillator function programmed off immediately before surgery and reprogrammed back on immediately afterward. External defibrillation pads should be applied and attached to a defibrillator machine intraoperatively.

Careful monitoring of the arterial pulse with pulse oximetry or an arterial waveform is necessary to ensure that the pacemaker is not inhibited and that there is arterial perfusion during episodes of ECG artifact from surgical cautery. The manufacturer should be contacted to determine the best method for managing the device (eg, reprogramming or applying a magnet) prior to surgery. A large number of ICD models are in use; however, most suspend their antitachycardia function in response to a magnet.

HEART FAILURE

An increasing number of patients present for surgery with either systolic and/or diastolic heart failure. Congestive heart failure affects more than 5 million Americans. Heart failure may be secondary to ischemia, valvular heart disease, infectious agents, and many types of cardiomyopathy. Most patients seek medical attention secondary to heart failure because of complaints of dyspnea and fatigue. Heart failure develops over time, as symptoms worsen (Figure 21–5). Patients generally undergo echocardiography to diagnose structural heart defects, to detect signs of cardiac “remodeling”, to determine the left ventricular ejection fraction, and to assess the heart's diastolic function. Laboratory evaluations of concentration of brain natriuretic peptide (BNP) are likewise obtained to distinguish heart failure from other causes of dyspnea. BNP is released from the heart, and its elevation is associated with impaired ventricular function.

In response to ventricular failure, the body attempts to compensate for LV systolic function through the sympathetic and renin–angiotensin–aldosterone system. Consequently, patients experience salt retention, volume expansion, sympathetic stimulation, and vasoconstriction. The heart dilates to maintain the stroke volume in spite of decreased contractility. Over time, compensatory mechanisms fail and contribute to the symptoms associated with heart failure (eg, edema, tachycardia, decreased tissue perfusion). Patients with systolic heart failure are likely to present to surgery having been previously treated with diuretics, ACE inhibitors, angiotensin receptor blockers, and

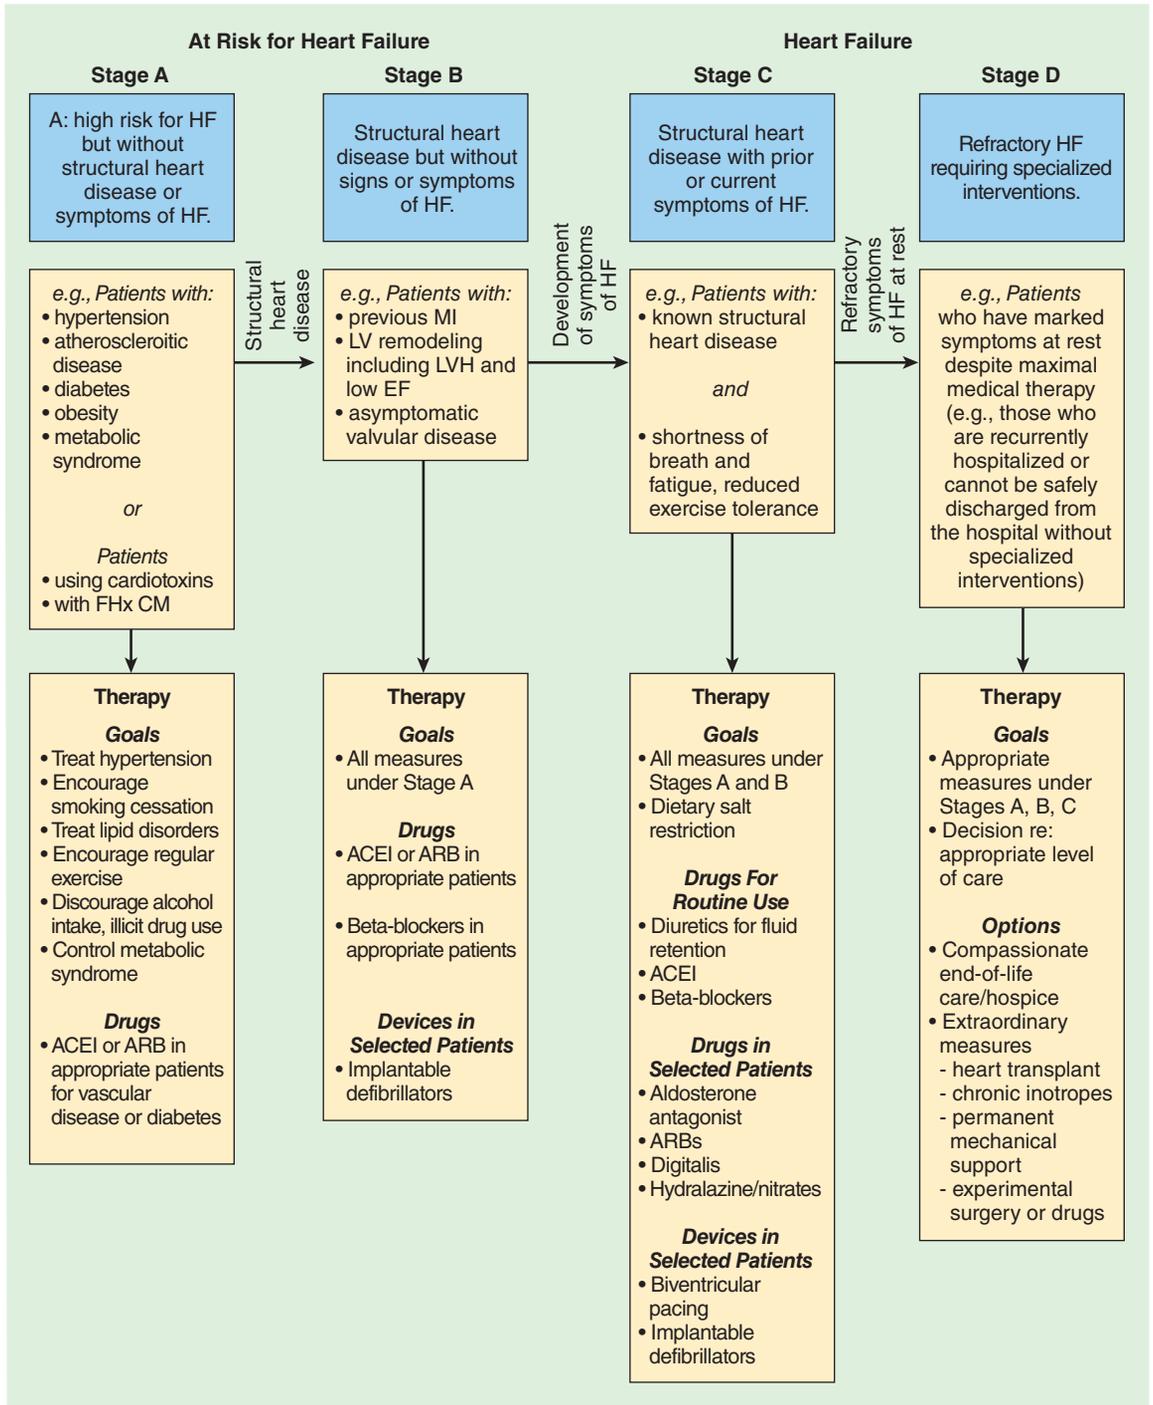

FIGURE 21-5 Stages in the development of heart failure/recommended therapy by stage. ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin II receptor blocker; EF, ejection fraction; FHx CM, family history of cardiomyopathy; HF, heart failure; LVH, left ventricular hypertrophy; MI, myocardial infarction. (Reproduced, with

permission, from Jessup M, Abraham W, Casey D, et al: 2009 Focused update: ACCF/AHA guidelines for the diagnosis and management of heart failure in adults: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *Circulation* 2009;119:1977.)

possibly aldosterone antagonists. Electrolytes must be measured, as heart failure therapies frequently lead to changes in serum potassium concentration. Angiotensin receptor blocker or ACE inhibitor use may contribute to periinduction hypotension in the patient with heart failure. ACE inhibitors are rarely associated with angioedema requiring emergent airway management.

Diastolic ventricular dysfunction produces symptoms of congestion and heart failure. Myocardial relaxation is a dynamic, not passive, process. The heart with preserved diastolic function accommodates volume during diastole, with minimal increases in left ventricular end-diastolic pressure. Conversely, the heart with diastolic dysfunction relaxes poorly and produces increased left ventricular end-diastolic pressure. The left ventricular end-diastolic pressure is transmitted to the left atrium and pulmonary vasculature resulting in symptoms of congestion.

Anesthetic management of the patient with heart failure requires careful assessment and optimization of intravascular fluid volume—especially if positive inotropic agents, vasoconstrictors, or vasodilators are used. In particular, patients with diastolic dysfunction may tolerate increases in volume poorly, leading to pulmonary congestion.

HYPERTROPHIC CARDIOMYOPATHY

Hypertrophic cardiomyopathy (HCM) is an autosomal dominant trait that affects 1 in 500 adults. Many patients are unaware of the condition, and some will present with SCD as an initial manifestation. Symptoms include dyspnea, exercise intolerance, palpitations, and chest pain. Clinically, HCM is detected by the murmur of dynamic left ventricular outflow tract (LVOT) obstruction in late systole. Symptomatic patients frequently have a thickened intraventricular septum of 20 to 30 mm. Mutations in the genes that code for the cardiac sarcomeres and their supporting proteins are implicated. The myocardium of the intraventricular septum is abnormal, and many patients can develop diastolic dysfunction and SCD without pronounced dynamic obstructive gradients. During systole, the anterior leaflet of

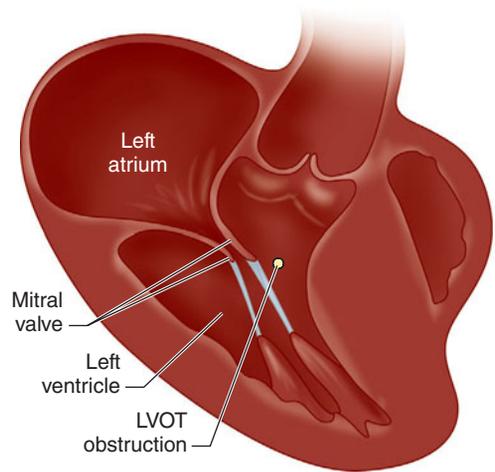

FIGURE 21-6 The midesophageal long axis view is shown. As a consequence of the hypertrophied interventricular septum, flow patterns within the heart are altered so that the anterior leaflet of the mitral valve is drawn during ventricular systole into the left ventricular outflow tract (LVOT), producing obstruction. This is known as systolic anterior motion of the mitral valve (SAM). (Reproduced, with permission, from Wasnick J, Hillel Z, Kramer D, et al: *Cardiac Anesthesia & Transesophageal Echocardiography*, McGraw-Hill, 2011.)

the mitral valve abuts the intraventricular septum (**Figure 21-6**), producing obstruction and a late systolic murmur.

Perioperative management is aimed at minimizing the degree of LVOT obstruction. This is accomplished by maintaining adequate intravascular volume, avoiding vasodilatation, and reducing myocardial contractility through the use of β -blockers.

Valvular Heart Disease

1. General Evaluation of Patients

Regardless of the lesion or its cause, preoperative evaluation should be primarily concerned with determining the identity and severity of the lesion and its hemodynamic significance, residual ventricular function, and the presence of any secondary effects on pulmonary, renal, and hepatic function.

Concomitant CAD should not be overlooked, particularly in older patients and those with known risk factors (see above). Myocardial ischemia may also occur in the absence of significant coronary occlusion in patients with severe aortic stenosis or regurgitation.

History

The preanesthesia history should focus on symptoms related to decreased ventricular function. Symptoms and signs should be correlated with laboratory data. Questions should evaluate exercise tolerance, fatigability, and pedal edema and shortness of breath in general (dyspnea), when lying flat (orthopnea), or at night (paroxysmal nocturnal dyspnea). The New York Heart Association functional classification of heart disease (Table 21-13) is useful for grading the severity of heart failure symptoms and estimating prognosis. Patients should also be questioned about chest pains and neurological symptoms. Some valvular lesions are associated with thromboembolic phenomena. Prior procedures, such as valvotomy or valve replacement and their effects, should also be well documented.

A review of medications should evaluate efficacy and exclude serious side effects. Commonly used agents include diuretics, vasodilators, ACE inhibitors, β -blockers, antiarrhythmics, and anticoagulants. Preoperative vasodilator therapy may be used to decrease preload, afterload, or both. Excessive vasodilatation worsens exercise tolerance and is often first manifested as postural (orthostatic) hypotension.

TABLE 21-13 Modified New York Association functional classification of heart disease.

Class	Description
I	Asymptomatic except during severe exertion
II	Symptomatic with moderate activity
III	Symptomatic with minimal activity
IV	Symptomatic at rest

Physical Examination

The most important signs to identify on physical examination are those of congestive heart failure. Left-sided (S_3 gallop or pulmonary rales) and right-sided (jugular venous distention, hepatojugular reflux, hepatosplenomegaly, or pedal edema) signs may be present. Auscultatory findings may confirm the valvular dysfunction (Figure 21-7), but echocardiographic studies are more reliable. Neurological deficits, usually secondary to embolic phenomena, should be documented.

Laboratory Evaluation

In addition to the laboratory studies discussed for patients with hypertension and CAD, liver function tests may be useful in assessing hepatic dysfunction caused by passive hepatic congestion in patients with severe or chronic right-sided failure. Arterial blood gases can be measured in patients with significant pulmonary symptoms. Reversal of warfarin or heparin should be documented with a prothrombin time and international normalized ratio (INR) or partial thromboplastin time, respectively, prior to surgery.

Electrocardiographic findings are generally nonspecific. The chest radiograph is useful to assess cardiac size and pulmonary vascular congestion.

Special Studies

Echocardiography, imaging studies, and cardiac catheterization provide important diagnostic and prognostic information about valvular lesions, but should only be obtained if the results will change therapy or outcomes. More than one valvular lesion is often found. In many instances, noninvasive studies obviate the need for cardiac catheterization, unless there are concerns about CAD. Information from these studies is best reviewed with a cardiologist. The following questions must be answered:

- Which valvular abnormality is most important hemodynamically?
- What is the severity of an identified lesion?
- What degree of ventricular impairment is present?
- What is the hemodynamic significance of other identified abnormalities?
- Is there any evidence of CAD?

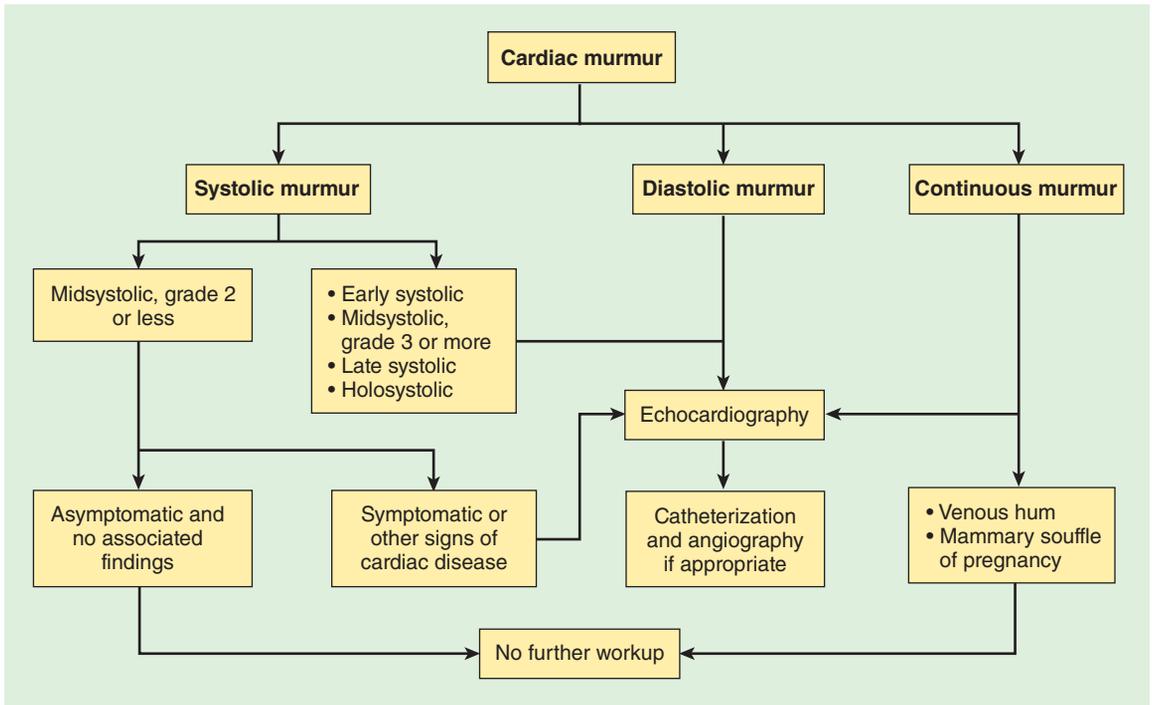

FIGURE 21-7 Strategy for evaluating heart murmurs. (Reproduced, with permission, from Bonow RO, Carabello BA, Chatterjee K, et al: 2008 focused update incorporated in the ACC/AHA 2006 guidelines for the management of patients with valvular heart disease: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (writing committee

to revise the 1998 guidelines for the management of patients with valvular heart disease): endorsed by the Society of Cardiovascular Anesthesiologists, Society for Cardiovascular Angiography and Interventions, and Society of Thoracic Surgeons. *Circulation* 2008;118:e523.)

The ACC/AHA have prepared detailed guidelines to assist in the management of the patient with valvular heart disease. Although the evaluation of the patient with a heart murmur generally rests with the cardiologist, anesthesia providers will on occasion discover the presence of a previously undetected murmur on preanesthetic examination. In particular, anesthesiologists are concerned that undiagnosed, critical aortic stenosis might be present, which could potentially lead to hemodynamic collapse with either regional or general anesthesia. In the past, most valvular heart diseases were a consequence of rheumatic heart disease; however, with an aging surgical population, increasing numbers of patients have degenerative valve problems. More than one in eight patients older than age 75 years may manifest at least one form of moderate to severe valvular heart disease.

A study conducted in the Netherlands reported that the prevalence of aortic stenosis was 2.4% in patients older than age 60 years who were scheduled for elective surgery. Underdiagnosed valvular disease is particularly prevalent in elderly females.

According to the ACC/AHA guidelines, auscultation of the heart is the most widely used method to detect valvular heart disease. Murmurs occur as a consequence of the accelerated blood flow through narrowed openings in stenotic and regurgitant lesions. Although systolic murmurs may be related to increased blood flow velocity, the ACC/AHA guidelines note that all diastolic and continuous murmurs reflect pathology. Other than murmurs that are thought to be innocent, such as mid-systolic flow murmurs (grade 2 or softer), the ACC/AHA guidelines recommend echocardiographic evaluation.

When new murmurs are detected in a preoperative evaluation, consultation with the patient's personal physician is helpful to determine the need for echocardiographic evaluation. In many centers, immediate echocardiographic evaluation can be performed in the preoperative area.

2. Specific Valvular Disorders

MITRAL STENOSIS

Preoperative Considerations

Mitral stenosis almost always occurs as a delayed complication of rheumatic fever. However, mitral stenosis can also occur in dialysis-dependent patients. Two-thirds of patients with mitral stenosis are female. The stenotic process is estimated to begin after a minimum of 2 years following rheumatic heart disease and results from progressive fusion and calcification of the valve leaflets. Symptoms generally develop after 20–30 years, when the mitral valve orifice is reduced from its normal 4–6 cm² opening to less than 1.5 cm². Less than 50% of patients have isolated mitral stenosis; the remaining patients also have mitral regurgitation, and up to 25% of patients also have rheumatic involvement of the aortic valve (stenosis or regurgitation).

Pathophysiology

The rheumatic process causes the valve leaflets to thicken, calcify, and become funnel shaped; annular calcification may also be present. The mitral commissures fuse, the chordae tendinae fuse and shorten, and the valve cusps become rigid; as a result, the valve leaflets typically display bowing or doming during diastole on echocardiography.

Significant restriction of blood flow through the mitral valve results in a transvalvular pressure gradient that depends on cardiac output, heart rate (diastolic time), and cardiac rhythm. Increases in either cardiac output or heart rate (decreased diastolic time) necessitate higher flows across the valve and result in higher transvalvular pressure gradients. The left atrium is often markedly dilated, promoting SVTs, particularly AF. Blood flow stasis in the atrium promotes the formation of thrombi, usually in the left atrial appendage. Loss of normal atrial systole with

AF (which is usually responsible for 20% to 30% of ventricular filling) necessitates even higher diastolic flow across the valve to maintain the same cardiac output and increases the transvalvular gradient.

Acute elevations in left atrial pressure are rapidly transmitted back to the pulmonary capillaries. If mean pulmonary capillary pressure acutely and significantly rises transudation of capillary fluid may result in pulmonary edema. Chronic elevations in pulmonary capillary pressure are partially compensated by increases in pulmonary lymph flow, but eventually result in pulmonary vascular changes, leading to irreversible increases in pulmonary vascular resistance (PVR) and pulmonary hypertension. Reduced lung compliance and a secondary increase in the work of breathing contribute to chronic dyspnea. Right ventricular failure is frequently precipitated by acute or chronic elevations in right ventricular afterload. Marked dilatation of the right ventricle can result in tricuspid or pulmonary valve regurgitation.

Embolic events are common in patients with mitral stenosis and AF. Dislodgment of clots from the left atrium results in systemic emboli, most commonly to the cerebral circulation. Patients also have an increased incidence of pulmonary emboli, pulmonary infarction, hemoptysis, and recurrent bronchitis. Hemoptysis most commonly results from rupture of pulmonary–bronchial venous communications. Chest pain occurs in 10% to 15% of patients with mitral stenosis, even in the absence of CAD; its etiology often remains unexplained, but may be emboli in the coronary circulation or acute right ventricular pressure overload. Patients may develop hoarseness as a result of compression of the left recurrent laryngeal nerve by the enlarged left atrium.

Left ventricular function is normal in the majority of patients with pure mitral stenosis (Figure 21–8), but impaired left ventricular function may be encountered in up to 25% of patients and presumably represents residual damage from rheumatic myocarditis or coexistent hypertensive or ischemic heart disease.

The left ventricle is chronically underloaded in the patient with mitral stenosis. At the same time, the left atrium, right ventricle, and right atrium are frequently dilated and dysfunctional. Vasodilatation that occurs following both neuraxial and general

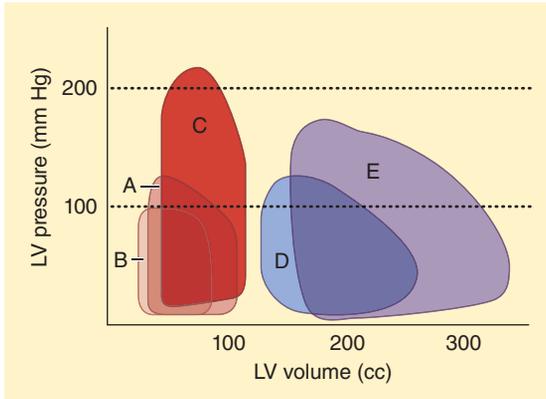

FIGURE 21-8 Pressure–volume loops in patients with valvular heart disease. A, normal; B, mitral stenosis; C, aortic stenosis; D, mitral regurgitation (chronic); E, aortic regurgitation (chronic). LV, left ventricular. (Reproduced, with permission, from Jackson JM, Thomas SJ, Lowenstein E: Anesthetic management of patients with valvular heart disease. *Semin Anesth* 1982;1:239.)

anesthesia can lead to peripheral venous blood pooling and inadequate volume delivery to the left ventricle. This can precipitate hemodynamic collapse.

Calculating Mitral Valve Area & Transvalvular Gradient

Two-dimensional and Doppler echocardiography can be used to estimate both the pressure drop across a stenotic valve and the valve area. Based on the assumption that the velocity of blood flow is much greater distal than proximal to an obstruction, the Bernoulli equation can be simplified:

$$\Delta P = 4V^2$$

where ΔP is the pressure gradient (mm Hg) and V is blood flow velocity (m/s) distal to the obstruction. Valve orifice can be estimated from the time it takes for the initial peak pressure gradient to fall to one-half of its original value, the pressure half-time ($T_{1/2}$). This relationship is approximated by

$$A = \frac{220}{T_{1/2}}$$

where A is valve orifice (cm^2) and $T_{1/2}$ is the time from peak flow velocity (V_{max}) to $V_{\text{max}}/1.4$. This relationship

is based on the observation that $T_{1/2}$ remains relatively constant for a given orifice over a wide range of flows. A pressure half-time of 220 msec corresponds to a mitral valve area of 1 cm^2 .

Mitral valve areas less than 1 cm^2 are typically associated with transvalvular gradients of 20 mm Hg at rest and dyspnea with minimal exertion; a mitral valve area less than 1 cm^2 is often referred to as critical mitral stenosis. Patients with valve areas between 1.5 and 2.0 cm^2 are generally asymptomatic or have only mild symptoms with exertion. When the mitral valve area is between 1 and 1.5 cm^2 , most patients are symptomatic with mild to moderate exertion. Although cardiac output may be normal at rest, it fails to increase appropriately during exertion because of decreased left ventricular preload.

Treatment

The time from onset of symptoms to incapacitation averages 5–10 years. At that stage, most patients die within 2–5 years. Surgical correction is therefore usually undertaken once significant symptoms develop. Percutaneous transseptal balloon valvuloplasty may be used in selected young or pregnant patients, as well as older patients who are poor surgical candidates. Medical management is primarily supportive and includes limitation of physical activity, sodium restriction, and diuretics. Small doses of a β -adrenergic blocking drug may also be useful in controlling heart rate in patients with mild to moderate symptoms. Patients with a history of emboli and those at high risk (age older than 40 years; a large atrium with chronic atrial fibrillation) are usually anticoagulated.

Anesthetic Management

A. Objectives

8 The principal hemodynamic goals are to maintain a sinus rhythm (if present preoperatively) and to avoid tachycardia, large increases in cardiac output, and both hypovolemia and fluid overload by judicious administration of intravenous fluids.

B. Monitoring

Invasive hemodynamic monitoring is often used for major surgical procedures, particularly those associated with large fluid shifts. TEE can also be used to

help guide perioperative management. Overzealous fluid replacement readily precipitates pulmonary edema in patients with severe disease. Pulmonary capillary wedge pressure measurements in the presence of mitral stenosis reflect the transvalvular gradient and not necessarily left ventricular end-diastolic pressure. Prominent *a* waves and a decreased *y* descent are typically present on the pulmonary capillary wedge pressure waveform in patients who are in sinus rhythm. A prominent *cv* wave on the central venous pressure waveform is usually indicative of secondary tricuspid regurgitation. The ECG typically shows a notched P wave in patients who are in sinus rhythm.

C. Choice of Agents

Patients may be very sensitive to the vasodilating effects of spinal and epidural anesthesia. Epidural anesthesia may be easier to manage than spinal anesthesia because of the more gradual onset of sympathetic blockade. There is no “ideal” general anesthetic, and agents should be employed to achieve the desired effects of permitting sufficient diastolic time to adequately load the left ventricle. Vasopressors are often needed to maintain vascular tone following anesthetic induction.

Intraoperative tachycardia may be controlled by deepening anesthesia with an opioid (excluding meperidine) or β -blocker (esmolol or metoprolol). In the presence of atrial fibrillation, ventricular rate should be controlled. **Marked hemodynamic deterioration from sudden SVT necessitates cardioversion.** Phenylephrine is preferred over ephedrine as a vasopressor because the former lacks β -adrenergic agonist activity. Vasopressin can also be employed to restore vascular tone should hypotension develop secondary to anesthetic induction.

MITRAL REGURGITATION

Preoperative Considerations

Mitral regurgitation can develop acutely or insidiously as a result of a large number of disorders. Chronic mitral regurgitation is usually the result of rheumatic fever (often with concomitant mitral stenosis); congenital or developmental abnormalities of the valve apparatus; or dilatation, destruction, or calcification of the mitral annulus. Acute mitral regurgitation is

usually due to myocardial ischemia or infarction (papillary muscle dysfunction or rupture of a chorda tendinea), infective endocarditis, or chest trauma.

Pathophysiology

The principal derangement is a reduction in forward stroke volume due to backward flow of blood into the left atrium during systole. The left ventricle compensates by dilating and increasing end-diastolic volume (Figure 21–8). Regurgitation through the mitral valve initially maintains a normal end systolic volume in spite of an increased end diastolic volume. However, as the disease progresses the end systolic volume increases. By increasing end-diastolic volume, the volume-overloaded left ventricle can maintain a normal cardiac output despite blood being ejected retrograde into the atrium. With time, patients with chronic mitral regurgitation eventually develop eccentric left ventricular hypertrophy and progressive impairment in contractility. In patients with severe mitral regurgitation, the regurgitant volume may exceed the forward stroke volume. In time, wall stress increases, resulting in an increased demand for myocardial oxygen supply.

The regurgitant volume passing through the mitral valve is dependent on the size of the mitral valve orifice (which can vary with ventricular cavity size), the heart rate (systolic time), and the left ventricular–left atrial pressure gradient during systole. The last factor is affected by the relative resistances of the two outflow paths from the left ventricle, namely, SVR and left atrial compliance. Thus, a decrease in SVR or an increase in mean left atrial pressure will reduce the regurgitant volume. Atrial compliance also determines the predominant clinical manifestations. Patients with normal or reduced atrial compliance (acute mitral regurgitation) have primarily pulmonary vascular congestion and edema. Patients with increased atrial compliance (long-standing mitral regurgitation resulting in a large dilated left atrium) primarily show signs of a reduced cardiac output. Most patients are between the two extremes and exhibit symptoms of both pulmonary congestion and low cardiac output. Patients with a regurgitant fraction of less than 30% of the total stroke volume generally have mild symptoms. Regurgitant fractions of 30% to 60% generally cause

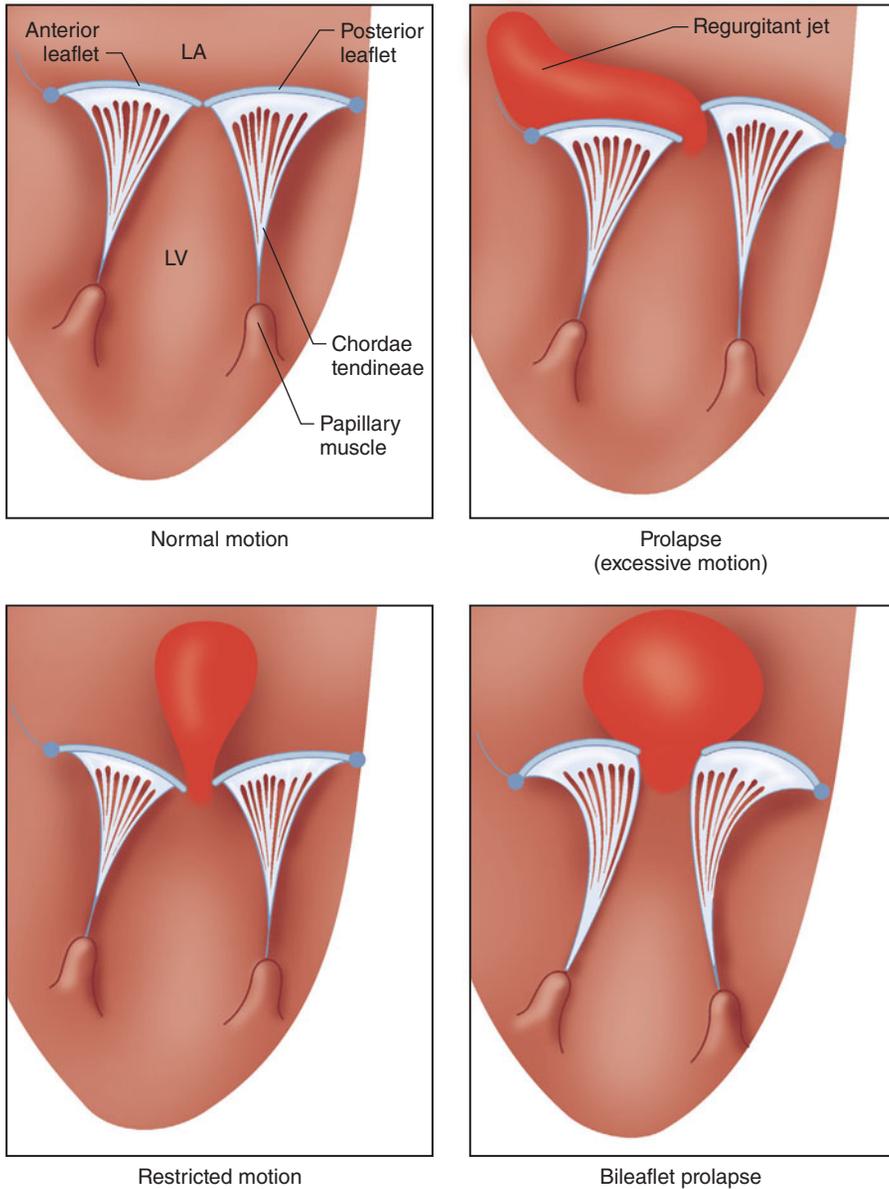

FIGURE 21-9 Classification of mitral valve leaflet motion (as seen from transesophageal echocardiography). Note that with prolapse, the free edge of the leaflet(s)

extends beyond the plane of the mitral annulus producing an eccentric jet. With restricted motion, the leaflets fail to coapt, resulting in a central jet.

moderate symptoms, whereas fractions greater than 60% are associated with severe disease.

Echocardiography, particularly TEE, is useful in delineating the underlying pathophysiology of mitral regurgitation and guiding treatment. Mitral valve

leaflet motion is often described as normal, prolapsing, or restrictive (Figure 21-9). Excessive motion or prolapse is defined by systolic movement of a leaflet beyond the plane of the mitral valve and into the left atrium (see the section below on mitral valve prolapse).

Calculating Regurgitant Fraction

To calculate regurgitant fraction (RF), forward stroke volume (SV) and the regurgitant stroke volume (RSV) must be measured. Although they can both be estimated by catheterization data, pulsed Doppler echocardiography provides reasonably accurate calculations. Stroke volume is measured at the left ventricular outflow tract (LVOT) and at the mitral valve (MV), where

Stroke volume = cross-sectional area (A) \times (TVI)

and cross-sectional area (A) can be approximated as,

$$A = 0.785 \times (\text{diameter})^2$$

The time-velocity integral (TVI) is the integral of the velocity versus the time signal obtained with pulsed Doppler. The TVI reflects the distance the blood has traveled during a heart beat. By knowing the area through which the blood travels and the distance traveled, it is possible to estimate the stroke volume. This is the case because the area is expressed in centimeters squared, and the distance is expressed in centimeters. The product of these measures is cubic centimeters or milliliters—hence, the stroke volume for each heartbeat.

Thus, the volume of blood that enters through the mitral valve must be the same as that passing through the left ventricular outflow track. Any difference between the two represents the amount of the volume that initially entered the left ventricle, but that did not pass the LVOT. This is the volume that regurgitated into the left atrium.

$$\text{RSV}_{\text{mitral regurgitation}} = (A_{\text{MV}} \times \text{VTI}_{\text{MV}}) - (A_{\text{LVOT}} \times \text{TVI}_{\text{LVOT}}),$$

and

$$\text{RF} = \text{RSV}/\text{SV}$$

An RSV greater than 65 mL usually correlates with severe mitral regurgitation.

Treatment

Afterload reduction is beneficial in most patients and may even be lifesaving in patients with acute mitral regurgitation. Reduction of SVR increases forward SV and decreases the regurgitant volume. Surgical treatment is usually reserved for patients

with moderate to severe symptoms. Valvuloplasty or valve repair are performed whenever possible to avoid the problems associated with valve replacement (eg, thromboembolism, hemorrhage, and prosthetic failure). Catheter-mediated valve repairs are continually being refined, potentially reducing the need for “open” surgery. Anesthesiologists skilled in advanced perioperative echocardiography assist in correctly identifying the leaflet(s) to be repaired and determining the repair’s success. Three-dimensional echocardiography is increasingly employed to assist in the assessment of the mitral valve (see Figure 5-29).

Anesthetic Management

A. Objectives

9 Anesthetic management should be tailored to the severity of mitral regurgitation as well as the underlying left ventricular function. Factors that exacerbate the regurgitation, such as slow heart rates and acute increases in afterload, should be avoided. Bradycardia can increase the regurgitant volume by increasing left ventricular end-diastolic volume and acutely dilating the mitral annulus. The heart rate should ideally be kept between 80 and 100 beats/min. Acute increases in left ventricular afterload, such as with endotracheal intubation and surgical stimulation under “light” anesthesia, should be treated rapidly but without excessive myocardial depression. Excessive volume expansion can also worsen the regurgitation by dilating the left ventricle.

B. Monitoring

Monitors are based on the severity of ventricular dysfunction, as well as the procedure. Mitral regurgitation may be recognized on the pulmonary artery wedge waveform as a large v wave and a rapid y descent (Figure 21-10). The height of the v wave is inversely related to atrial and pulmonary vascular compliance, but is directly proportional to pulmonary blood flow and the regurgitant volume; thus, the v wave may not be prominent in patients with chronic mitral regurgitation, except during acute deterioration. Very large v waves are often apparent on the pulmonary artery pressure waveform, even without wedging the catheter. Color-flow Doppler TEE can be invaluable in quantitating the severity of

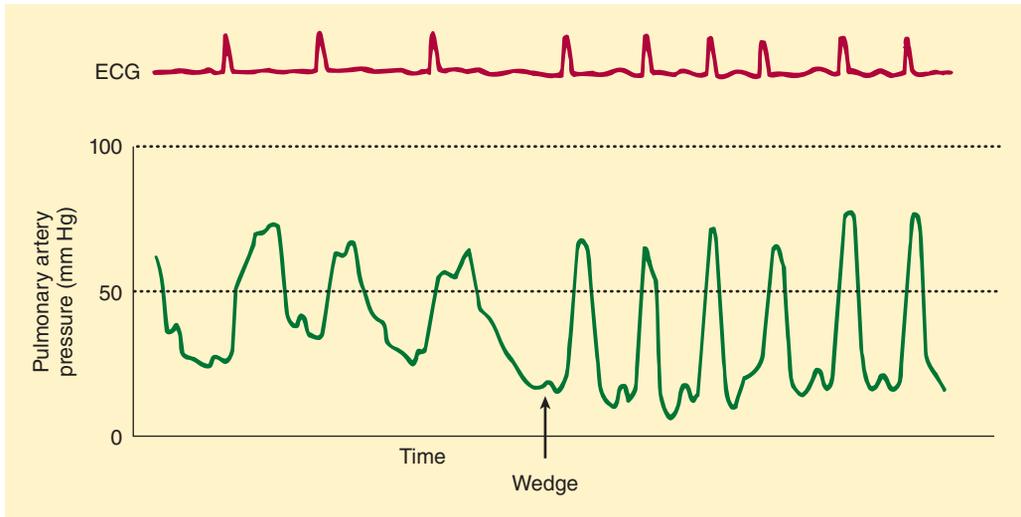

FIGURE 21-10 The pulmonary capillary wedge waveform in mitral regurgitation, demonstrating a large v wave.

the regurgitation and guiding therapeutic interventions in patients with severe mitral regurgitation. By definition, blood flow reverses in the pulmonary veins during systole with severe mitral regurgitation.

C. Choice of Agents

Patients with relatively well-preserved ventricular function tend to do well with most anesthetic techniques. Spinal and epidural anesthesia are well tolerated, provided bradycardia is avoided. Patients with moderate to severe ventricular impairment may be sensitive to depression from high concentrations of volatile agents. An opioid-based anesthetic may be more suitable for those patients—again, provided bradycardia is avoided.

MITRAL VALVE PROLAPSE

Preoperative Considerations

Mitral valve prolapse is classically characterized by a mid-systolic click, with or without a late apical systolic murmur on auscultation. It is a relatively common abnormality that is present in up to 1% to 2.5% of the general population. The diagnosis is based on auscultatory findings and is confirmed by echocardiography, which shows systolic prolapse of mitral valve leaflets into the left atrium. Patients with the

murmur often have some element of mitral regurgitation. The posterior mitral leaflet is more commonly affected than the anterior leaflet. The mitral annulus may also be dilated. Pathologically, most patients have redundancy or some myxomatous degeneration of the valve leaflets. Most cases of mitral valve prolapse are sporadic or familial, affecting otherwise normal persons. A high incidence of mitral valve prolapse is found in patients with connective tissue disorders (particularly Marfan syndrome).

The overwhelming majority of patients with mitral valve prolapse are asymptomatic, but in a small percentage of patients, the myxomatous degeneration is progressive. Manifestations, when they occur, can include chest pains, arrhythmias, embolic events, florid mitral regurgitation, infective endocarditis, and, rarely, sudden death. The diagnosis can be made preoperatively by auscultation of the characteristic click, but must be confirmed by echocardiography. The prolapse is accentuated by maneuvers that decrease ventricular volume (preload). Both atrial and ventricular arrhythmias are common. Although bradyarrhythmias have been reported, paroxysmal supraventricular tachycardia is the most commonly encountered sustained arrhythmia. An increased incidence of abnormal AV bypass tracts is reported in patients with mitral valve prolapse.

Most patients have a normal life span. About 15% develop progressive mitral regurgitation. A smaller percentage develops embolic phenomena or infective endocarditis. Patients with both a click and a systolic murmur seem to be at greater risk of developing complications. Anticoagulation or antiplatelet agents may be used for patients with a history of emboli, whereas β -adrenergic blocking drugs are commonly used for arrhythmias.

Anesthetic Management

The management of these patients is based on their clinical course. Most patients are asymptomatic and do not require special care. Ventricular arrhythmias may occur intraoperatively, particularly following sympathetic stimulation, and will generally respond to lidocaine or β -adrenergic blocking agents. Mitral regurgitation caused by prolapse is generally exacerbated by decreases in ventricular size. Hypovolemia and factors that increase ventricular emptying or decrease afterload should be avoided. Vasopressors with pure α -adrenergic agonist activity (such as phenylephrine) may be preferable to those that are primarily β -adrenergic agonists (ephedrine).

AORTIC STENOSIS

Preoperative Considerations

Valvular aortic stenosis is the most common cause of obstruction to left ventricular outflow. Left ventricular outflow obstruction is less commonly due to hypertrophic cardiomyopathy, discrete congenital subvalvular stenosis, or, rarely, supra-valvular stenosis. Valvular aortic stenosis is nearly always congenital, rheumatic, or degenerative. Abnormalities in the number of cusps (most commonly a bicuspid valve) or their architecture produce turbulence that traumatizes the valve and eventually leads to stenosis. Rheumatic aortic stenosis is rarely isolated; it is more commonly associated with aortic regurgitation or mitral valve disease. In the most common degenerative form, calcific aortic stenosis, wear and tear results in the buildup of calcium deposits on normal cusps, preventing them from opening completely (Figure 21-11).

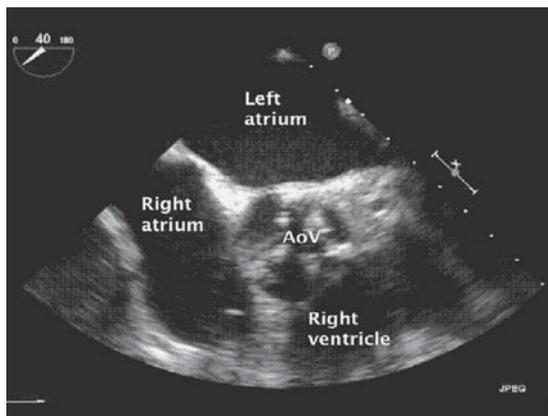

FIGURE 21-11 A stenotic aortic valve is clearly seen in this midesophageal short axis aortic valve view. Calcification of the aortic valve is usually associated with senile degeneration. However, congenitally abnormal (bicuspid) and rheumatic presentations also occur. (Reproduced, with permission, from Wasnick J, Hillel Z, Kramer D, et al: *Cardiac Anesthesia & Transesophageal Echocardiography*, McGraw-Hill, 2011.)

Pathophysiology

Left ventricular outflow obstruction caused by valvular aortic stenosis is almost always gradual, allowing the ventricle, at least initially, to compensate and maintain SV. Concentric left ventricular hypertrophy enables the ventricle to maintain SV by generating the needed transvalvular pressure gradient and to reduce ventricular wall stress.

Critical aortic stenosis is said to exist when the aortic valve orifice is reduced to 0.5–0.7 cm² (normal is 2.5–3.5 cm²). With this degree of stenosis, patients generally have a transvalvular gradient of approximately 50 mm Hg at rest (with a normal cardiac output) and are unable to increase cardiac output in response to exertion. Moreover, further increases in the transvalvular gradient do not significantly increase SV. With long-standing aortic stenosis, myocardial contractility progressively deteriorates and compromises left ventricular function.

Classically, patients with advanced aortic stenosis have the triad of dyspnea on exertion, angina, and orthostatic or exertional syncope. A prominent feature of aortic stenosis is a decrease in left ventricular compliance as a result of hypertrophy.

Diastolic dysfunction is the result of an increase in ventricular muscle mass, fibrosis, or myocardial ischemia. In contrast to left ventricular end-diastolic volume, which remains normal until very late in the disease, left ventricular end-diastolic pressure is elevated early in the disease. The decreased diastolic pressure gradient between the left atrium and left ventricle impairs ventricular filling, which becomes quite dependent on a normal atrial contraction. Loss of atrial systole can precipitate congestive heart failure or hypotension in patients with aortic stenosis. Cardiac output may be normal in symptomatic patients at rest, but characteristically, it does not appropriately increase with exertion. Patients may experience angina even in the absence of CAD. Myocardial oxygen demand increases because of ventricular hypertrophy, whereas myocardial oxygen supply decreases as a result of the marked compression of intramyocardial coronary vessels caused by high intracavitary systolic pressures (up to 300 mm Hg). Exertional syncope or near-syncope is thought to be due to an inability to tolerate the vasodilatation in muscle tissue during exertion. Arrhythmias leading to severe hypoperfusion may also account for syncope and sudden death in some patients.

CALCULATING AORTIC VALVE AREA & TRANSVALVULAR GRADIENT

As with mitral stenosis, the pressure gradient across the aortic valve can be determined noninvasively using continuous wave Doppler echocardiography:

$$\Delta P = 4V^2$$

where ΔP is the peak pressure gradient (mm Hg) and V is peak blood flow velocity (m/s) distal to the obstruction. Peak velocities greater than 4.5 m/sec are usually indicative of severe stenosis. Moreover, if the area proximal to the stenosis (LVOT) can be measured, the continuity equation can then be applied to estimate valve area. Either TVIs or maximum velocities can be used:

$$A_2 = \frac{A_1 V_1}{V_2}$$

where A_2 is valve area, A_1 is the cross-sectional area of the LVOT, V_1 is maximum blood flow velocity in LVOT, and V_2 is maximum flow velocity through the aortic valve.

Treatment

Once symptoms develop, most patients, without surgical treatment, will die within 2–5 years. Percutaneous balloon valvuloplasty is generally used in younger patients with congenital aortic stenosis; it can also be used in elderly patients with calcific aortic stenosis who are poor candidates for aortic valve replacement. Its efficacy for the latter group is short-lived, however, and restenosis usually occurs within 6–12 months. Catheter-delivered aortic valves are increasingly being perfected and deployed in the treatment of aortic valve disease. Surgical replacement of the stenotic aortic valve remains the mainstay of therapy.

Anesthetic Management

A. Objectives

10 Maintenance of normal sinus rhythm, heart rate, vascular resistance, and intravascular volume is critical in patients with aortic stenosis. Loss of a normally timed atrial systole often leads to rapid deterioration, particularly when associated with tachycardia. The combination of the two (AF with rapid ventricular response) seriously impairs ventricular filling and necessitates immediate cardioversion. The reduced ventricular compliance also makes the patient very sensitive to abrupt changes in intravascular volume. Many patients behave as though they have a fixed SV in spite of adequate hydration; under these conditions, cardiac output becomes very rate dependent. Extreme bradycardia (<50 beats/min) is therefore poorly tolerated. Heart rates between 60 and 90 beats/min are optimal in most patients.

B. Monitoring

Close monitoring of the ECG and blood pressure is crucial. Monitoring for ischemia is complicated by baseline ST-segment and T-wave abnormalities. Intraarterial pressure monitoring is desirable in patients with severe aortic stenosis, as

many of these patients do not tolerate even brief episodes of hypotension. Pulmonary artery catheterization data should be interpreted carefully; a higher than normal pulmonary capillary wedge pressure is often required to maintain adequate left ventricular end-diastolic volume and cardiac output. Prominent *a* waves are often visible on the pulmonary artery wedge pressure waveform. Vasodilators should generally be used cautiously because patients are often very sensitive to these agents. TEE can be useful in these patients for monitoring ischemia, ventricular preload, contractility, valvular function, and the effects of therapeutic interventions.

C. Choice of Agents

Patients with mild to moderate aortic stenosis (generally asymptomatic) may tolerate spinal or epidural anesthesia. These techniques should be employed very cautiously, however, because hypotension readily occurs as a result of reductions in preload, afterload, or both. Epidural anesthesia may be preferable to single-shot spinal anesthesia in many situations because of its slower onset of hypotension, which allows more timely correction. Continuous spinal catheters can similarly be used to gradually increase the level of regional anesthesia and limit the possibility of blood pressure collapse. Spinal and epidural anesthesia are relatively contraindicated in patients with severe aortic stenosis.

In the patient with severe aortic stenosis the choice of general anesthetic agents is less important than managing their hemodynamic effects. Most general anesthetics can produce both vasodilation and hypotension, which require treatment post induction. If a volatile agent is used, the concentration should be controlled to avoid excessive vasodilatation, myocardial depression, or loss of normal atrial systole. Significant tachycardia and severe hypertension, which can precipitate ischemia, should be treated immediately by increasing anesthetic depth or administration of a β -adrenergic blocking agent. Most patients with aortic stenosis tolerate moderate hypertension and are sensitive to vasodilators. Moreover, because of an already precarious myocardial oxygen demand–supply balance, they tolerate even mild degrees of hypotension

poorly. Hypotension should generally be promptly treated with escalating doses (25–100 mcg) of phenylephrine. Intraoperative supraventricular tachycardias with hemodynamic compromise should be treated with immediate synchronized cardioversion. Frequent ventricular ectopy (which often reflects ischemia) is usually poorly tolerated hemodynamically and should be treated. Amiodarone is generally effective for both supraventricular and ventricular arrhythmias.

AORTIC REGURGITATION

Preoperative Considerations

Aortic regurgitation usually develops slowly and is progressive (chronic), but it can also develop quickly (acute). Chronic aortic regurgitation may be caused by abnormalities of the aortic valve, the aortic root, or both. Abnormalities in the valve are usually congenital (bicuspid valve) or due to rheumatic fever. Diseases affecting the ascending aorta cause regurgitation by dilating the aortic annulus; they include syphilis, annuloaortic ectasia, cystic medial necrosis (with or without Marfan syndrome), ankylosing spondylitis, rheumatoid and psoriatic arthritis, and a variety of other connective tissue disorders. Acute aortic insufficiency most commonly follows infective endocarditis, trauma, or aortic dissection.

Pathophysiology

Regardless of the cause, aortic regurgitation produces volume overload of the left ventricle. The effective forward SV is reduced because of backward (regurgitant) flow of blood into the left ventricle during diastole. Systemic arterial diastolic pressure and SVR are typically low. The decrease in cardiac afterload helps facilitate ventricular ejection. Total SV is the sum of the effective stroke volume and the regurgitant volume. The regurgitant volume depends on the heart rate (diastolic time) and the diastolic pressure gradient across the aortic valve (diastolic aortic pressure minus left ventricular end-diastolic pressure). Slow heart rates increase regurgitation because of the associated disproportionate increase in diastolic time, whereas increases in diastolic arterial pressure favor regurgitant volume by increasing the pressure gradient for backward flow.

With chronic aortic regurgitation, the left ventricle progressively dilates and undergoes eccentric hypertrophy. Patients with severe aortic regurgitation have the largest end-diastolic volumes of any heart disease. The resulting increase in end-diastolic volume maintains an effective SV. Any increase in the regurgitant volume is compensated by an increase in end-diastolic volume. Left ventricular end-diastolic pressure is usually normal or only slightly elevated, because ventricular compliance initially increases. Eventually, as ventricular function deteriorates, the ejection fraction declines, and impaired ventricular emptying is manifested as gradual increases in left ventricular end-diastolic pressure and end-systolic volume.

Sudden incompetence of the aortic valve does not allow compensatory dilatation or hypertrophy of the left ventricle. Effective SV rapidly declines because the normal-sized ventricle is unable to accommodate a sudden large regurgitant volume. The sudden rise in left ventricular end-diastolic pressure is transmitted back to the pulmonary circulation and causes acute pulmonary venous congestion.

Acute aortic regurgitation typically presents as the sudden onset of pulmonary edema and hypotension, whereas chronic regurgitation usually presents insidiously as congestive heart failure. Symptoms are generally minimal (in the chronic form) when the regurgitant volume remains under 40% of SV, but become severe when it exceeds 60%. Angina can occur even in the absence of coronary disease. The myocardial oxygen demand is increased from muscle hypertrophy and dilatation, whereas the myocardial blood supply is reduced by low diastolic pressures in the aorta as a result of the regurgitation.

Calculating Regurgitant Fraction & Other Measurements of Severity

As with mitral regurgitation, RSV and RF for aortic regurgitation can be estimated by pulsed Doppler echocardiography. Stroke volume is measured at the left ventricular outflow tract (LVOT) and at the mitral valve (MV). The stroke volume ejected at the LVOT includes both the stroke volume that entered the left ventricle through the mitral valve and the volume of blood that entered the left ventricle through the leaky aortic valve.

Thus,

$$\text{RSV}_{\text{aortic regurgitation}} = (A_{\text{LVOT}} \times \text{TVI}_{\text{LVOT}}) - (A_{\text{MV}} \times \text{TVI}_{\text{MV}})$$

and

$$\text{RF} = \text{RSV}/\text{SV}$$

Pressure half-time ($T_{1/2}$, see the section on mitral stenosis above) of the regurgitant jet is another useful echocardiographic parameter for clinically assessing the severity of aortic regurgitation. The shorter the half-time, the more severe the regurgitation; severe regurgitation rapidly raises left ventricular diastolic pressure and results in more rapid pressure equilibration. Unfortunately, $T_{1/2}$ is affected not only by the regurgitant orifice area, but also by aortic and ventricular pressure. An aortic regurgitation jet with a $T_{1/2}$ less than 240 msec is associated with severe regurgitation.

Treatment

Most patients with chronic aortic regurgitation remain asymptomatic for 10–20 years. Once significant symptoms develop, the expected survival time is about 5 years without valve replacement. Diuretics and afterload reduction, particularly with ACE inhibitors, generally benefit patients with advanced chronic aortic regurgitation. The decrease in arterial blood pressure reduces the diastolic gradient for regurgitation. Patients with chronic aortic regurgitation should receive valve replacement before irreversible ventricular dysfunction occurs.

Patients with acute aortic regurgitation typically require intravenous inotropic and vasodilator therapy. Early intervention is indicated in patients with acute aortic regurgitation: medical management alone is associated with a high mortality rate.

Anesthetic Management

A. Objectives

The heart rate should be maintained toward the upper limits of normal (80–100 beats/min).

11 Bradycardia and increases in SVR increase the regurgitant volume in patients with aortic regurgitation, whereas tachycardia can contribute to myocardial ischemia. Excessive myocardial depression should also be avoided. The compensatory

increase in cardiac preload should be maintained, but overzealous fluid replacement can readily result in pulmonary edema.

B. Monitoring

Invasive hemodynamic monitoring should be employed in patients with acute aortic regurgitation and in those with severe chronic regurgitation. Premature closure of the mitral valve often occurs during acute aortic regurgitation and may cause pulmonary capillary wedge pressure to give a falsely high estimate of left ventricular end-diastolic pressure. The appearance of a large *v* wave suggests mitral regurgitation secondary to dilatation of the left ventricle. The arterial pressure wave in patients with aortic regurgitation characteristically has a very wide pulse pressure. *Pulsus bisferiens* may also be present in patients with moderate to severe aortic insufficiency and is thought to result from the rapid ejection of a large SV. Color-flow Doppler TEE can be invaluable in quantitating the severity of the regurgitation and guiding therapeutic interventions. By definition, some reversal of blood flow is present in the aorta during all of diastole (holodiastolic) with severe aortic regurgitation; moreover, the more distal the detection of holodiastolic flow reversal is in the aorta, the more severe the regurgitation.

C. Choice of Agents

Most aortic insufficiency patients tolerate spinal and epidural anesthesia well, provided intravascular volume is maintained. When general anesthesia is required, inhalational agents may be ideal because of the associated vasodilatation. Phenylephrine (25–50 mcg) can be used to treat hypotension secondary to anesthetic-induced vasodilatation. Large doses of phenylephrine increase SVR (and arterial diastolic pressure) and may exacerbate the regurgitation.

TRICUSPID REGURGITATION

Preoperative Considerations

Up to 70% to 90% of patients have trace to mild tricuspid regurgitation on echocardiography; the regurgitant volume in these cases is almost always insignificant. Clinically significant tricuspid regurgitation, however, is most commonly due to dilatation of the right ventricle from pulmonary hypertension

that is associated with chronic left ventricular failure. Tricuspid regurgitation can also follow infective endocarditis (usually in injecting drug abusers), rheumatic fever, carcinoid syndrome, or chest trauma or may be due to Ebstein's anomaly (downward displacement of the valve because of abnormal attachment of the valve leaflets).

Pathophysiology

Chronic left ventricular failure often leads to sustained increases in pulmonary vascular pressures. The chronic increase in afterload causes progressive dilatation of the thin-walled right ventricle, and excessive dilatation of the tricuspid annulus eventually results in regurgitation. An increase in end-diastolic volume allows the right ventricle to compensate for the regurgitant volume and maintain an effective forward flow. Because the right atrium and the vena cava are compliant and can usually accommodate the volume overload, mean right atrial and central venous pressures are generally only slightly elevated. Acute or marked elevations in pulmonary artery pressures increase the regurgitant volume and are reflected by an increase in central venous pressure. Moreover, sudden marked increases in right ventricular afterload sharply reduce the effective right ventricular output, reduce left ventricular preload, and can precipitate systemic hypotension.

Chronic venous hypertension leads to passive congestion of the liver and progressive hepatic dysfunction. Severe right ventricular failure with underloading of the left heart may also produce right-to-left shunting through a patent foramen ovale, which can result in marked hypoxemia.

The normal right ventricle does not extend to the apex of the heart when visualized using echocardiography. As the right heart dilates, it acquires a more spherical shape, the right ventricle extends to the apex of the heart, and the interventricular septum is flattened. These changes can impair left heart function.

Calculating Pulmonary Artery Pressure

With severe tricuspid regurgitation, the normal systolic inflow into the right atrium is reversed, and the reversal of flow is also observed in the hepatic veins.

Systolic pulmonary artery pressure (PAS) can be estimated from the peak velocity of the regurgitant jet:

$$\Delta P = 4 \times V^2$$

where ΔP is the systolic pressure gradient (mm Hg) between the right ventricle and right atrium, and V is peak blood flow velocity (m/s) of the regurgitant jet. If the central venous pressure (CVP) is known or assumed, then

$$PAS = CVP + \Delta P$$

Treatment

Tricuspid regurgitation is generally well tolerated by most patients. Because the underlying disorder is generally more important than the tricuspid regurgitation itself, treatment is aimed at the underlying disease process. With moderate to severe regurgitation, tricuspid annuloplasty may be performed in conjunction with replacement of another valve. Recent studies suggest that correction of significant tricuspid regurgitation is beneficial when patients are brought to surgery for replacement of another valve.

Anesthetic Management

A. Objectives

Hemodynamic goals should be directed primarily toward the underlying disorder. Hypovolemia and factors that increase right ventricular afterload, such as hypoxia and acidosis, should be avoided to maintain effective right ventricular SV and left ventricular preload. Positive end-expiratory pressure and high mean airway pressures may also be undesirable during mechanical ventilation because they reduce venous return and increase right ventricular afterload.

B. Monitoring

In these patients, invasive monitoring may be useful. Pulmonary artery catheterization is not always possible; rarely a large regurgitant flow may make passage of a pulmonary artery catheter across the tricuspid valve difficult. Increasing CVP implies worsening right ventricular dysfunction. The x descent is absent, and a prominent cv wave is usually present on the CVP waveform. Thermodilution cardiac output measurements are falsely elevated because of the tricuspid regurgitation. Color-flow Doppler TEE is useful in evaluating the severity of the regurgitation and other associated abnormalities.

C. Choice of Agents

The selection of anesthetic agents should be based on the underlying disorder. Most patients tolerate spinal

and epidural anesthesia well. Coagulopathy secondary to hepatic dysfunction should be excluded prior to any regional technique. During general anesthesia, nitrous oxide may exacerbate pulmonary hypertension and should be administered cautiously, if at all.

ENDOCARDITIS PROPHYLAXIS

The ACC/AHA guidelines regarding prophylactic antibiotic regimens in patients with prosthetic heart valves and other structural heart abnormalities have dramatically changed in recent years, decreasing the number of indications for antibiotic administration. The risk of antibiotic administration is often considered greater than the potential for developing perioperative endocarditis. At present, the ACC/AHA guidelines suggest the use of endocarditis prophylaxis in the highest risk patients undergoing dental procedures involving gingival manipulation or perforation of the oral mucosa (class IIa); see [Tables 21–14](#) and [21–15](#). Such conditions include:

- Patients with prosthetic cardiac valves or prosthetic heart materials
- Patients with a past history of endocarditis

TABLE 21–14 Endocarditis prophylaxis for dental procedures (UPDATED)¹.

Reasonable	Not Recommended
Endocarditis prophylaxis is reasonable for patients with the highest risk of adverse outcomes who undergo dental procedures that involve manipulation of either gingival tissue or the periapical region of teeth or perforation of the oral mucosa.	Endocarditis prophylaxis is not recommended for: <ul style="list-style-type: none"> • Routine anesthetic injections through noninfected tissue • Dental radiographs • Placement or removal of prosthodontic or orthodontic appliances • Adjustment of orthodontic appliances • Placement of orthodontic brackets • Shedding of deciduous teeth • Bleeding from trauma to the lips or oral mucosa

- Patients with congenital heart disease that is either partially repaired or unrepaired
- Patients with congenital heart disease with residual defects following repair
- Patients with congenital heart disease within 6 months of a complete repair, whether catheter-based or surgical
- Cardiac transplant patients with structurally abnormal valves

Class III recommendations indicate that prophylaxis is not necessary for nondental procedures, including TEE and esophagogastroduodenoscopy, except in the presence of an active infection.

Endocarditis is believed to occur in areas of cardiac endothelial damage, where in cases of

bacteremia, bacteria can be deposited and multiply. Areas of increased myocardial blood flow velocity lead to damaged endothelium, providing a template for bacterial adherence and growth. Indeed, the latest ACC/AHA guidelines do not suggest prophylaxis for genitourinary or gastrointestinal procedures; however, the AHA does note that it is reasonable to administer antibiotics to prevent wound infection. Moreover, they note that although prophylaxis is not suggested for respiratory tract procedures, it is a reasonable strategy in high-risk patients in whom an incision has been made in the respiratory tract (eg, in tonsillectomy).

In spite of these much reduced indications, the ACC/AHA notes that many patients and physicians expect the administration of endocarditis

prophylaxis in patients with valvular heart disease, aortic coarctation, and hypertrophic cardiomyopathy. As always, the risk of antibiotic administration must be considered in offering prophylaxis to patients outside of the ACC/AHA high-risk category. Guidelines are ever changing, and although not considered to be “standard of care,” they are increasingly present in medical practice; furthermore, deviation from guidelines often requires explanation as being outside of “evidenced-based” practice. Review of ACC/AHA guidelines, which are now available online, are recommended when high-risk patients are encountered.

ANTICOAGULATION

Patients with mechanical prosthetic heart valves require anticoagulation, which is currently accomplished with warfarin. Aspirin is also indicated in this population, as well as in patients with bioprosthetic valves, to prevent thrombus formation. Warfarin is sometimes also used initially for mitral bioprosthetic valves (Table 21–16).

Patients with prosthetic valves often present for noncardiac surgery that will require temporary discontinuation of anticoagulation. The ACC/AHA guidelines indicate that patients at low risk of thrombosis, such as those with bileaflet mechanical valves

TABLE 21–16 Recommendations for antithrombotic therapy in patients with prosthetic heart valves.

	Aspirin (75–100 mg)	Warfarin (INR 2.0–3.0)	Warfarin (INR 2.5–3.5)	No Warfarin
Mechanical prosthetic valves

Greater than 3 months	Class I			Class IIa
MVR–high risk	Class I	Class I		

Depending on patients' clinical status, antithrombotic therapy must be individualized (see special situations in text). In patients receiving warfarin, aspirin is recommended in virtually all situations. Risk factors: atrial fibrillation, left ventricular dysfunction, previous thromboembolism, and hypercoagulable condition. International normalized ratio (INR) should be maintained between 2.5 and 3.5 for aortic disc valves and Starr-Edwards valves.

AVR indicates aortic valve replacement; and MVR, mitral valve replacement.

Data from McAnuty JH, Rahimtoola SH. Antithrombotic therapy in valvular heart disease. In: Schlant R, Alexander RW, editors. *Hurst's The Heart*. New York, McGraw-Hill, 1998:1867-1874.

in the aortic position with no additional problems (eg, no AF or no hypercoagulable state) can discontinue warfarin 48–72 hours preoperatively so that the INR falls below 1.5. In patients at greater risk of thrombosis, warfarin should be discontinued and heparin, either unfractionated or low molecular weight, started when the INR falls below 2.0. Heparin can be discontinued 4–6 hours prior to surgery and then restarted as soon as surgical bleeding permits, until the patient can be restarted on warfarin therapy. Fresh frozen plasma may be given, if needed, in an emergency situation to interrupt warfarin therapy. Vitamin K should not be administered, as it could potentially lead to a hypercoagulable state. Anesthesia staff should always consult with the patient's surgeon and the physician responsible for prescribing the anticoagulation before adjusting anticoagulation or antiplatelet regimens preoperatively.

Congenital Heart Disease

Preoperative Considerations

Congenital heart disease encompasses a seemingly endless list of abnormalities that may be detected in infancy, early childhood, or, less commonly, adulthood. The incidence of congenital heart disease in all live births approaches 1%. The natural history of some defects is such that patients often survive to adulthood (Table 21-17). Moreover, the number of surviving adults with congenital heart disease is steadily increasing, possibly as a result of advances in surgical and medical treatment. An increasing number of patients with congenital heart disease may therefore be encountered during noncardiac surgery and obstetric deliveries. Knowledge of the

anatomy of the original heart structure defect and of any corrective repairs is essential prior to anesthetizing the patient with congenital heart disease (CHD).

The complex nature and varying pathophysiology of congenital heart defects make classification difficult. A commonly used scheme is presented in Table 21-18. Most patients present with cyanosis, congestive heart failure, or an asymptomatic abnormality. Cyanosis is typically the result of an abnormal intracardiac communication that allows unoxygenated blood to reach the systemic arterial circulation (right-to-left shunting). Congestive heart failure is most prominent with defects that either obstruct left ventricular outflow or markedly increase pulmonary blood flow. The latter is usually due to an abnormal intracardiac communication that returns oxygenated blood to the right heart (left-to-right shunting). Whereas right-to-left shunts generally decrease pulmonary blood flow, some complex lesions increase pulmonary blood flow—even in the presence of right-to-left shunting. In many cases, more than one lesion is present.

In fact, survival (prior to surgical correction) with some anomalies (eg, transposition, total anomalous venous return, pulmonary atresia) depends on the simultaneous presence of another shunting lesion (eg, patent ductus arteriosus, patent foramen ovale, ventricular septal defect). Chronic hypoxemia in patients with cyanotic heart disease typically results in erythrocytosis. This increase in red cell mass, which is due to enhanced erythropoietin secretion from the kidneys, serves to restore tissue oxygen concentration to normal. Unfortunately, blood viscosity can also rise to the point at which it may interfere with oxygen delivery. When tissue oxygenation is restored to normal, the hematocrit is stable (usually <65%), and symptoms of the hyperviscosity syndrome are absent, the patient is said to have compensated erythrocytosis. Patients with uncompensated erythrocytosis do not establish this equilibrium; they have symptoms of hyperviscosity and may be at risk of thrombotic complications, particularly stroke. The last is aggravated by dehydration. Children younger than age 4 years seem to be at greatest risk of stroke. Phlebotomy is generally not recommended if symptoms of hyperviscosity are absent and the hematocrit is <65%.

Coagulation abnormalities are common in patients with cyanotic heart disease. Platelet counts tend to be low-normal, and many patients have subtle or overt defects in the coagulation cascade. Phlebotomy may improve hemostasis in some patients. Hyperuricemia often occurs because of increased urate reabsorption secondary to renal hypoperfusion. Gouty arthritis is uncommon, but the hyperuricemia can result in progressive renal impairment.

Preoperative Doppler echocardiography is invaluable in helping to define the anatomy of the defect(s) and to confirm or exclude the existence of other lesions or complications, their physiological significance, and the effects of any therapeutic interventions.

Anesthetic Management

This population of patients includes four groups: those who have undergone corrective cardiac surgery and require no further operations, those who have had only palliative surgery, those who have not yet undergone any cardiac surgery, and those whose

TABLE 21–19 Common problems in survivors of surgery for congenital heart defects.

<ul style="list-style-type: none"> Arrhythmias Hypoxemia Pulmonary hypertension Existing shunts Paradoxical embolism Bacterial endocarditis

conditions are inoperable and may be awaiting cardiac transplantation. Although the management of the first group of patients may be the same as that of normal patients (except for consideration of prophylactic antibiotic therapy), the care of others requires familiarity with the complex pathophysiology of these defects. Even patients who have had corrective surgery may be prone to the development of perioperative problems (Tables 21–19 and 21–20). Some surgical procedures eliminate the risk of endocarditis, whereas others increase the risk through the use of prosthetic valves or conduits or the creation of new shunts.

For the purpose of anesthetic management, congenital heart defects may be divided into obstructive lesions, predominantly left-to-right shunts, or predominantly right-to-left shunts. In reality, shunts can also be bidirectional and may reverse under certain conditions.

1. Obstructive Lesions

Pulmonic Stenosis

Pulmonary valve stenosis obstructs right ventricular outflow and causes concentric right ventricular hypertrophy. Severe obstruction presents in the neonatal period, whereas lesser degrees of obstruction may go undetected until adulthood. The valve is usually deformed and is either bicuspid or tricuspid. Valve leaflets are often partially fused and display systolic doming on echocardiography. The right ventricle undergoes hypertrophy, and poststenotic dilatation of the pulmonary artery is often present. Symptoms are those of right ventricular heart failure. Symptomatic patients readily develop fatigue, dyspnea, and peripheral cyanosis with exertion as a result of the limited pulmonary blood flow and increased oxygen extraction by tissues. With severe stenosis, the pulmonic valve gradient exceeds 60–80 mm Hg, depending on the age of the patient. Right-to-left shunting may also occur in the presence of a patent foramen ovale or atrial septal defect. Cardiac output is very dependent on an elevated heart rate, but excessive increases in the latter can compromise ventricular filling. Percutaneous balloon valvuloplasty is generally considered the initial treatment of choice in most patients with symptomatic pulmonic stenosis. Anesthetic management for patients undergoing surgery should maintain a normal or slightly high heart rate, augment preload, and avoid factors that increase PVR.

2. Predominantly Left-to-Right (Simple) Shunts

Simple shunts are isolated abnormal communications between the right and left sides of the heart. Because pressures are normally higher on the left side of the heart, blood usually flows across from left to right, and blood flow through the right heart and the lungs increases. Depending on the size and location of the communication, the right ventricle may also be subjected to the higher left-sided pressures, resulting in both pressure and volume overload. Right ventricular afterload is normally 5% that of the left ventricle, so even small left-to-right pressure gradients can produce large increases in

pulmonary blood flow. The ratio of pulmonary (Q_p) to systemic (Q_s) blood flow is useful to determine the directionality of the shunt.

A ratio greater than 1 usually indicates a left-to-right shunt, whereas a ratio less than 1 indicates a right-to-left shunt. A ratio of 1 indicates either no shunting or a bidirectional shunt of opposing magnitudes.

Large increases in pulmonary blood flow produce pulmonary vascular congestion and increase extravascular lung water. The latter interferes with gas exchange, decreases lung compliance, and increases the work of breathing. Left atrial distention also compresses the left bronchus, whereas distention of pulmonary vessels compresses smaller bronchi.

Over the course of several years, chronic increases in pulmonary blood flow produce vascular changes that irreversibly increase PVR. Elevation of right ventricular afterload produces hypertrophy and progressively raises right-sided cardiac pressures. With advanced disease, the pressures within the right heart can exceed those within the left heart. Under these conditions, the intracardiac shunt reverses and becomes a right-to-left shunt (Eisenmenger syndrome).

When a communication is small, shunt flow depends primarily on the size of the communication (restrictive shunt). When the communication is large (nonrestrictive shunt), shunt flow depends on the relative balance between PVR and SVR.

12 An increase in SVR relative to PVR favors left-to-right shunting, whereas an increase in PVR relative to SVR favors right-to-left shunting. Common chamber lesions (eg, single atrium, single ventricle, truncus arteriosus) represent the extreme form of nonrestrictive shunts; shunt flow with these lesions is bidirectional and totally dependent on relative changes in the ventricular afterload.

13 The presence of shunt flow between the right and left hearts, regardless of the direction of blood flow, mandates the meticulous exclusion of air bubbles and particulate material from intravenous fluids to prevent paradoxical embolism into the cerebral or coronary circulations.

Atrial Septal Defects

Ostium secundum atrial septal defects (ASDs) are the most common type and usually occur as isolated

lesions in the area of the fossa ovalis. The defect is sometimes associated with partial anomalous pulmonary venous return, most commonly of the right upper pulmonary vein. A secundum ASD may result in single or multiple (fenestrated) openings between the atria. The less common sinus venosus and ostium primum ASDs are typically associated with other cardiac abnormalities. Sinus venosus defects are located in the upper interatrial septum close to the superior vena cava; one or more of the right pulmonary veins often abnormally drains into the superior vena cava. In contrast, ostium primum ASDs are located in the lower interatrial septum and overlie the mitral and tricuspid valves; most patients also have a cleft in the anterior leaflet of the mitral valve and some have an abnormal septal leaflet in the tricuspid valve.

Most children with ASDs are minimally symptomatic; some have recurrent pulmonary infections. Congestive heart failure and pulmonary hypertension are more commonly encountered in adults with ASDs. Patients with ostium primum defects often have large shunts and may also develop significant mitral regurgitation. In the absence of heart failure, anesthetic responses to inhalation and intravenous agents are generally not significantly altered in patients with ASDs. **Large increases in SVR should be avoided because they may worsen the left-to-right shunting.**

Ventricular Septal Defects

Ventricular septal defect (VSD) is a common congenital heart defect, accounting for up to 25% to 35% of congenital heart disease. The defect is most frequently found in the membranous part of the interventricular septum (membranous or infracristal VSD) in a posterior position and anterior to the septal leaflet of the tricuspid valve. Muscular VSDs are the next most frequent type and are located in the mid or apical portion of the interventricular septum, where there may be a single defect or multiple openings (resembling Swiss cheese). Defects in the subpulmonary (supracristal) septum are often associated with aortic regurgitation because the right coronary cusp can prolapse into the VSD. Septal defects at the ventricular inlet are usually similar in development and location to AV septal defects (see the following section).

The resulting functional abnormality of a VSD is dependent on the size of the defect, PVR, and the presence or absence of other abnormalities. Small VSDs, particularly of the muscular type, often close during childhood. Restrictive defects are associated with only small left-to-right shunts (pulmonary–systemic blood flow ratios less than 1.75:1). Large defects produce large left-to-right shunts (shunts larger than 2:1) that vary directly with SVR and indirectly with PVR. Recurrent pulmonary infections and congestive heart failure are common with pulmonary–systemic flow ratios of 3–5:1. Patients with small VSDs are treated medically and followed by electrocardiography (for signs of right ventricular hypertrophy) and echocardiography. Surgical closure is usually undertaken in patients with large VSDs before pulmonary vascular disease and Eisenmenger physiology develop. As with atrial defects, in the absence of heart failure, anesthetic responses to inhalation and intravenous agents are generally not significantly altered. Similarly, increases in SVR worsen the left-to-right shunting. **When right-to-left shunting is present, abrupt increases in PVR or decreases in SVR are poorly tolerated.**

Atrioventricular Septal Defects

Endocardial cushion (AV canal) defects produce contiguous atrial and ventricular septal defects, often with very abnormal AV valves. This is a common lesion in patients with Down syndrome. The defect can produce large shunts both at the atrial and ventricular levels. Mitral and tricuspid regurgitation exacerbate the volume overload on the ventricles. Initially, shunting is predominately left to right; however, with increasing pulmonary hypertension, Eisenmenger syndrome with obvious cyanosis develops.

Patent Ductus Arteriosus

Persistence of the communication between the main pulmonary artery and the aorta can produce restrictive or nonrestrictive left-to-right shunts. This abnormality is commonly responsible for the cardiopulmonary deterioration of premature infants and occasionally presents later in life when it can be

corrected thoracoscopically. Anesthetic goals should be similar to atrial and ventricular septal defects.

Partial Anomalous Venous Return

This defect is present when one or more pulmonary veins drains into the right side of the heart; the anomalous veins are usually from the right lung. Possible anomalous entry sites include the right atrium, the superior or inferior vena cava, and the coronary sinus. The resulting abnormality produces a variable amount of left-to-right shunting. The clinical course and prognosis are usually excellent and similar to that of a secundum ASD. A very large coronary sinus on TEE suggests anomalous drainage into the coronary sinus, which may complicate the management of cardioplegia during cardiac surgery. Total anomalous venous return is corrected immediately after birth.

3. Predominantly Right-to-Left (Complex) Shunts

Lesions within this group (some also called **mixing lesions**) often produce both ventricular outflow obstruction and shunting. The obstruction favors shunt flow toward the unobstructed side. When the obstruction is relatively mild, the amount of shunting is affected by the ratio of SVR to PVR, but increasing degrees of obstruction fix the direction and magnitude of the shunt. Atresia of any one of the cardiac valves represents the extreme form of obstruction. Shunting occurs proximal to the atretic valve and is completely fixed; survival depends on another distal shunt (usually a patent ductus arteriosus [PDA], patent foramen ovale, ASD, or VSD), where blood flows in the opposite direction. This group of defects may also be divided according to whether they increase or decrease pulmonary blood flow.

Tetralogy of Fallot

This anomaly classically includes right ventricular outflow obstruction, right ventricular hypertrophy, and a VSD with an overriding aorta. Right ventricular obstruction in most patients is due to infundibular stenosis, which is due to hypertrophy of the subpulmonic muscle (crista ventricularis).

At least 20% to 25% of patients also have pulmonic stenosis, and a small percentage of patients has some element of supra-valvular obstruction. The pulmonic valve is often bicuspid, or, less commonly, atretic. Infundibular obstruction may be increased by sympathetic tone and is therefore dynamic; this obstruction is likely responsible for the hypercyanotic spells observed in very young patients. **The combination of right ventricular outflow obstruction and a VSD results in ejection of unoxygenated right ventricular blood, as well as oxygenated left ventricular blood into the aorta.** The right-to-left shunting across the VSD has both fixed and variable components. The fixed component is determined by the severity of the right ventricular obstruction, whereas the variable component depends on SVR and PVR.

Neonates with severe right ventricular obstruction may deteriorate quickly, as pulmonary blood flow decreases when a PDA starts to close. Intravenous prostaglandin E_1 (0.05–0.2 mcg/kg/min) is used to prevent ductal closure in such instances. Surgical palliation with a left-to-right systemic shunt or complete correction is then usually undertaken. For the former, a modified Blalock-Taussig (systemic–pulmonary artery) shunt is most often used to increase pulmonary blood flow. In this procedure, a synthetic graft is anastomosed between a subclavian artery and an ipsilateral pulmonary artery. Complete correction involves closure of the VSD, removal of obstructing infundibular muscle, and pulmonic valvulotomy or valvuloplasty, when necessary.

14 The goals of anesthetic management in patients with tetralogy of Fallot should be to maintain intravascular volume and SVR. Increases in PVR, such as might occur from acidosis or excessive airway pressures, should be avoided. **Ketamine (intramuscular or intravenous) is a commonly used induction agent because it maintains or increases SVR and therefore does not aggravate the right-to-left shunting.** Patients with milder degrees of shunting generally tolerate inhalation induction. The right-to-left shunting tends to slow the uptake of inhalation anesthetics; in contrast, it may accelerate the onset of intravenous agents. Oxygenation often improves following induction of anesthesia. Muscle relaxants that release histamine should be

avoided. Hypercyanotic spells may be treated with intravenous fluid and phenylephrine (5 mcg/kg). Beta blockers (eg, propranolol) may also be effective in relieving infundibular spasm. Sodium bicarbonate to correct the resulting metabolic acidosis, may also be helpful when the hypoxemia is severe and prolonged.

Tricuspid Atresia

With tricuspid atresia, blood can flow out of the right atrium only via a patent foramen ovale (or an ASD). Moreover, a PDA (or VSD) is necessary for blood to flow from the left ventricle into the pulmonary circulation. Cyanosis is usually evident at birth, and its severity depends on the amount of pulmonary blood flow that is achieved. Early survival is dependent on prostaglandin E_1 infusion, with or without a percutaneous Rashkind balloon atrial septostomy. Severe cyanosis requires a modified Blalock–Taussig shunt early in life. The preferred surgical management is a modified Fontan procedure, in which the venous drainage is directed to the pulmonary circulation. In some centers, a superior vena cava to the main pulmonary artery (bidirectional Glenn) shunt may be employed before or instead of a Fontan procedure. With both procedures, blood from the systemic veins flows to the left atrium without the assistance of the right ventricle. Success of the procedure depends on a high systemic venous pressure and maintaining both low PVR and a low left atrial pressure. Heart transplantation may be necessary for a failed Fontan procedure.

Transposition of the Great Arteries

In patients with transposition of the great arteries, pulmonary and systemic venous return flows normally back to the right and left atrium, respectively, but the aorta arises from the right ventricle, and the pulmonary artery arises from the left ventricle. Thus, deoxygenated blood returns back into the systemic circulation, and oxygenated blood returns back to the lungs. Survival is possible only through mixing of oxygenated and deoxygenated blood across the foramen ovale and a PDA. The presence of a VSD increases mixing and reduces the level of hypoxemia. Prostaglandin E_1 infusion is usually necessary. Rashkind septostomy may be necessary

if surgical correction is delayed. Corrective surgical treatment involves an arterial switch procedure in which the aorta is divided and reanastomosed to the left ventricle, and the pulmonary artery is divided and reanastomosed to the right ventricle. The coronary arteries must also be reimplanted into the old pulmonary artery root. A VSD, if present, is closed. Less commonly, an atrial switch (Senning) procedure may be carried out if an arterial switch is not possible. In this latter procedure, an intraatrial baffle is created from the atrial wall, and blood from the pulmonary veins flows across an ASD to the right ventricle, from which it is ejected into the systemic circulation.

Transposition of the great vessels may occur with a VSD and pulmonic stenosis. This combination of defects mimics tetralogy of Fallot; however, the obstruction affects the left ventricle, not the right ventricle. Corrective surgery involves patch closure of the VSD, directing left ventricular outflow into the aorta, ligation of the proximal pulmonary artery, and connecting the right ventricular outflow to the pulmonary artery with a valved conduit (Rastelli procedure).

Truncus Arteriosus

With a truncus arteriosus defect, a single arterial trunk supplies the pulmonary and systemic circulation. The truncus always overrides a VSD, allowing both ventricles to eject into it. As PVR gradually decreases after birth, pulmonary blood flow increases greatly, resulting in heart failure. If left untreated, PVR increases, and cyanosis develops again, along with Eisenmenger physiology. Surgical correction closes the VSD, separates the pulmonary artery from the truncus, and connects the right ventricle to the pulmonary artery with a conduit (Rastelli repair).

Hypoplastic Left Heart Syndrome

This syndrome describes a group of defects characterized by aortic valve atresia and marked underdevelopment of the left ventricle. The right ventricle is the main pumping chamber for both systemic and pulmonary circulations. It ejects normally into the pulmonary artery, and all (or nearly all) blood flow entering the aorta is usually derived

from a PDA. Surgical treatment includes both the Norwood repair and a hybrid approach to palliation. In the Norwood repair, a new aorta is created from the hypoplastic aorta and the main pulmonary artery. Pulmonary blood flow is delivered via a Blalock–Taussig shunt. The right ventricle becomes the heart's systemic pumping ventricle. A hybrid approach has also been advocated for the treatment of hypoplastic left heart syndrome. In this approach, the pulmonary arteries are banded to reduce pulmonary blood flow, and the PDA is stented to provide for systemic blood flow.

The Patient with a Transplanted Heart

Preoperative Considerations

The number of patients with cardiac transplants is increasing because of both the increasing frequency of transplantation and improved post-transplant survival rates. These patients may present to the operating room early in the postoperative period for mediastinal exploration or retransplantation, or they may appear later for incision and drainage of infections, orthopedic surgery, or unrelated procedures.

15 The transplanted heart is totally denervated, so direct autonomic influences are absent. Cardiac impulse formation and conduction are normal, but the absence of vagal influences causes a relatively high resting heart rate (100–120 beats/min). Although sympathetic fibers are similarly interrupted, the response to circulating catecholamines is normal or even enhanced because of denervation sensitivity (increased receptor density). Cardiac output tends to be low-normal and increases relatively slowly in response to exercise because the response is dependent on an increase in circulating catecholamines. Because the Starling relationship between end-diastolic volume and cardiac output is normal, the transplanted heart is also often said to be preload dependent. Coronary autoregulation is preserved.

Preoperative evaluation should focus on evaluating the functional status of the transplanted organ and detecting complications of immunosuppression.

Rejection may be heralded by arrhythmias (in the first 6 months) or decreased exercise tolerance from a progressive deterioration of myocardial performance. Periodic echocardiographic evaluations are commonly used to monitor for rejection, but the most reliable technique is endomyocardial biopsy. Accelerated atherosclerosis in the graft is a very common and serious problem that limits the life of the transplant. Moreover, myocardial ischemia and infarction are almost always silent because of the denervation. Because of this, patients must undergo periodic evaluations, including angiography, for assessment of coronary atherosclerosis.

Immunosuppressive therapy usually includes cyclosporine, azathioprine, and prednisone. Important side effects include nephrotoxicity, bone marrow suppression, hepatotoxicity, opportunistic infections, and osteoporosis. Hypertension and fluid retention are common and typically require treatment with a diuretic and an ACE inhibitor. Stress doses of corticosteroids are needed when patients undergo major procedures.

Anesthetic Management

Almost all anesthetic techniques, including regional anesthesia, have been used successfully for transplanted patients. The preload-dependent function of the graft makes maintenance of a normal or high cardiac preload desirable. Moreover, the absence of reflex increases in heart rate can make patients particularly sensitive to rapid vasodilatation. Indirect vasopressors, such as ephedrine, are less effective than direct-acting agents because of the absence of catecholamine stores in myocardial neurons. Isoproterenol or epinephrine infusions should be readily available to increase the heart rate if necessary.

Careful electrocardiographic monitoring for ischemia is necessary. The ECG usually demonstrates two sets of P waves, one representing the recipient's own sinoatrial node (SA) (which is left intact), and the other representing the donor's SA node. The recipient's SA node may still be affected by autonomic influences, but it does not affect cardiac function. Direct arterial pressure monitoring should be used for major operations; strict asepsis should be observed during placement.

In a recently transplanted patient, the right ventricle of the transplanted heart may not be able to overcome the resistance of the pulmonary vasculature. Right ventricular failure can occur perioperatively, requiring the use of inhaled nitric oxide, inotropes, and, at times, right ventricular assist devices.

CASE DISCUSSION

Hip Fracture in an Elderly Woman who Fell

A 71-year-old woman presents for open reduction and internal fixation of a left hip fracture. She gives a history of two episodes of lightheadedness several days prior to her fall today. When questioned about her fall, she can only recall standing in her bathroom while brushing her teeth and then awakening on the floor with hip pain. The preoperative ECG shows a sinus rhythm with a P–R interval of 220 msec and a right bundle-branch block (RBBB) pattern.

Why should the anesthesiologist be concerned about a history of syncope?

A history of syncope in elderly patients should always raise the possibility of arrhythmias and underlying organic heart disease. Although arrhythmias can occur in the absence of organic heart disease, the two are commonly related. Cardiac syncope usually results from an abrupt arrhythmia that suddenly compromises cardiac output and impairs cerebral perfusion. Lightheadedness and presyncope, may reflect lesser degrees of cerebral impairment. Both bradyarrhythmias and tachyarrhythmias (see Chapter 20) can produce syncope. **Table 21–21** lists other cardiac and noncardiac causes of syncope.

How do bradyarrhythmias commonly arise?

Bradyarrhythmias may arise from either SA node dysfunction or abnormal AV conduction of the cardiac impulse. A delay or block of the impulse can occur anywhere between the SA node and the distal His-Purkinje system). Reversible abnormalities may be due to abnormal vagal tone, electrolyte

TABLE 21–21 Causes of syncope.

Cardiac

- Arrhythmias
 - Tachyarrhythmias (usually >180 beats/min)
 - Bradyarrhythmias (usually <40 beats/min)
- Impairment of left ventricular ejection
 - Aortic stenosis
 - Hypertrophic cardiomyopathy
 - Massive myocardial infarction
 - Atrial myxoma
- Impairment of right ventricular output
 - Tetralogy of Fallot
 - Primary pulmonary hypertension
 - Pulmonary embolism
 - Pulmonic valve stenosis
- Biventricular impairment
 - Cardiac tamponade
 - Massive myocardial infarction

Noncardiac

- Accentuated reflexes
 - Vasodepressor reflex (ie, vasovagal syncope)
 - Carotid sinus hypersensitivity
 - Neuralgias

- Sustained Valsalva maneuver
- Cerebrovascular disease
- Seizures
- Metabolic
 - Hypoxia
 - Marked hypocapnia
 - Hypoglycemia

abnormalities, drug toxicity, hypothermia, or myocardial ischemia. Irreversible abnormalities, which initially may be only intermittent before they become permanent, reflect either isolated conduction system abnormalities or underlying heart disease (most commonly hypertensive, coronary artery, or valvular heart disease).

What is the pathophysiology of sinus node dysfunction?

Patients with sinus node dysfunction may have a normal baseline 12-lead ECG but abrupt pauses in SA node activity (sinus arrest) or intermittent block of conduction of the SA impulse to the surrounding tissue (exit block). Symptoms are usually present when pauses are prolonged

(>3 s) or the effective ventricular rate is less than 40 beats/min. Patients may experience intermittent dizziness, syncope, confusion, fatigue, or shortness of breath. Symptomatic SA node dysfunction, or sick sinus syndrome, is often unmasked by β -adrenergic blocking agents, calcium channel blockers, digoxin, or quinidine. The term tachycardia–bradycardia syndrome is often used when patients experience paroxysmal tachyarrhythmias (usually atrial flutter or fibrillation) followed by sinus pauses or bradycardia. The latter, bradycardia, probably represents failure of the SA node to recover normal automaticity following suppression by the tachyarrhythmia. The diagnosis must be based on electrocardiographic recordings made during symptoms (Holter monitoring) or after provocative tests (carotid baroreceptor stimulation or rapid atrial pacing).

How are AV conduction abnormalities manifested on the surface 12-lead ECG?

AV conduction abnormalities are usually manifested by abnormal ventricular depolarization (bundle-branch block), prolongation of the P–R interval (first-degree AV block), failure of some atrial impulses to depolarize the ventricles (second-degree AV block), or AV dissociation (third-degree AV block; also called complete heart block).

What determines the significance of these conduction abnormalities?

The significance of a conduction system abnormality depends on its location, its likelihood for progression to complete heart block, and the likelihood that a more distal pacemaker site will be able to maintain a stable and adequate escape rhythm (>40 beats/min). The His bundle is normally the lowest area in the conduction system that can maintain a stable rhythm (usually 40–60 beats/min). When conduction fails anywhere above it, a normal His bundle can take over the pacemaker function of the heart and maintain a normal QRS complex, unless a distal intraventricular conduction defect is present. When the escape rhythm arises farther down the His-Purkinje system, the rhythm is usually slower

(<40 beats/min) and is often unstable; it results in a wide QRS complex.

What is the significance of isolated bundle-branch block with a normal P–R interval?

A conduction delay or block in the right bundle-branch results in a typical RBBB QRS pattern on the surface ECG (M-shape or rSR' in V_1) and may represent a congenital abnormality or underlying organic heart disease. In contrast, a delay or block in the main left bundle-branch results in a left bundle-branch block (LBBB) QRS pattern (wide R with a delayed upstroke in V_5) and nearly always represents underlying heart disease. The term hemiblock is often used if only one of the two fascicles of the left bundle-branch is blocked (left anterior or left posterior hemiblock). When the P–R interval is normal—and in the absence of an acute MI—a conduction block in either the left or right bundle rarely leads to complete heart block.

Can the site of an AV block always be determined from a 12-lead ECG?

No. A first-degree AV block (P–R interval >200 ms) can reflect abnormal conduction anywhere between the atria and the distal His-Purkinje system. Mobitz type I second-degree AV block, which is characterized by progressive lengthening of the P–R interval before a P wave is not conducted (a QRS does not follow the P wave), is usually due to a block in the AV node itself, and can be caused by digitalis toxicity or myocardial ischemia; progression to a third-degree AV block is uncommon.

In patients with Mobitz type II second-degree AV block, atrial impulses are periodically not conducted into the ventricle without progressive prolongation of the P–R interval. The conduction block is nearly always in or below the His bundle and frequently progresses to complete (third-degree) AV block, particularly following an acute anteroseptal MI. The QRS is typically wide.

In patients with a third-degree AV block, the atrial rate and ventricular depolarization rates are independent (AV dissociation) because atrial impulses completely fail to reach the ventricles. If the site of the block is in the AV node, a stable His

bundle rhythm will result in a normal QRS complex, and the ventricular rate will often increase following administration of atropine. If the block involves the His bundle, the origin of the ventricular rhythm is more distal, resulting in wide QRS complexes. A wide QRS complex does not necessarily exclude a normal His bundle, as it may represent a more distal block in one of the bundle branches.

Can AV dissociation occur in the absence of AV block?

Yes. AV dissociation may occur during anesthesia with volatile agents in the absence of AV block and results from sinus bradycardia or an accelerated AV junctional rhythm. During isorhythmic dissociation, the atria and ventricles beat independently at nearly the same rate. The P wave often just precedes or follows the QRS complex, and their relationship is generally maintained. In contrast, interference AV dissociation results from a junctional rhythm that is faster than the sinus rate—such that sinus impulses always find the AV node refractory.

How do bifascicular and trifascicular blocks present?

A bifascicular block exists when two of the three major His bundle-branches (right, left anterior, or left posterior) are partially or completely blocked. If one fascicle is completely blocked and the others are only partially blocked, a bundle-branch block pattern will be associated with either first-degree or second-degree AV block. If all three are affected, a trifascicular block is said to exist. A delay or partial block in all three fascicles results in either a prolonged P–R interval (first-degree AV block) or alternating LBBB and RBBB. Complete block in all three fascicles results in third-degree AV block.

What is the significance of the electrocardiographic findings in this patient?

The electrocardiographic findings (first-degree AV block plus RBBB) suggest a bifascicular block. Extensive disease of the conduction system is likely. Moreover, the patient's syncopal and near-syncopal episodes suggest that she may be at risk

of life-threatening bradyarrhythmias (third-degree AV block). Intracardiac electrocardiographic recordings would be necessary to confirm the site of the conduction delay.

What is appropriate management for this patient?

Cardiological evaluation is required because of the symptomatic bifascicular block. One of two approaches can be recommended, depending on the urgency of the surgery. If the surgery is truly emergent, a temporary transvenous pacing catheter or a transcutaneous pacemaker is indicated prior to induction of general or regional anesthesia. If the surgery can be postponed 24–48 hr (as in this case), continuous electrocardiographic monitoring, serial 12-lead ECGs, and measurements of cardiac isoenzymes are required to exclude myocardial ischemia or infarction and to try to record findings during symptoms.

What are general perioperative indications for temporary pacing?

Suggested indications include the following: any documented symptomatic bradyarrhythmia; second-degree (type II) AV block, or third-degree AV block and refractory supraventricular tachyarrhythmias.

The first three indications generally require ventricular pacing, whereas the fourth requires atrial pacing electrodes and a programmable rapid atrial pulse generator.

How can temporary cardiac pacing be established?

Pacing can be established by transvenous, transcutaneous, epicardial, or transesophageal electrodes. The most reliable method is generally via a transvenous pacing electrode in the form of a pacing wire or a balloon-tipped pacing catheter. A pacing wire should always be positioned fluoroscopically, but a flow-directed pacing catheter can also be placed in the right ventricle under pressure monitoring. A pacing wire must be used when blood flow has ceased. If the patient has a rhythm, intracardiac electrocardiographic recording showing ST-segment elevation when the

electrode comes in contact with the right ventricular endocardium confirms placement of either type of electrode. Specially designed pulmonary artery catheters have an extra port for passage of a right ventricular pacing wire. These catheters are particularly useful in patients with LBBB, who can theoretically develop complete heart block during catheter placement. Transcutaneous ventricular pacing is also possible via large stimulating adhesive pads placed on the chest and should be used whenever transvenous pacing is not readily available. Epicardial electrodes are usually used during cardiac surgery. Pacing the left atrium via an esophageal electrode is a simple, relatively noninvasive technique, but it is useful only for symptomatic sinus bradycardias and for terminating some supraventricular tachyarrhythmias.

Once positioned, the pacing electrodes are attached to an electrical pulse generator that periodically delivers an impulse at a set rate and magnitude. Most pacemaker generators can also sense the heart's spontaneous (usually ventricular) electrical activity: when activity is detected, the generator suppresses its next impulse. By altering the generator's sensing threshold, the pacemaker generator can function in a fixed (asynchronous) mode or in a demand mode (by increasing sensitivity). The lowest current through the electrode that can depolarize the myocardium is called the threshold current (usually <2 mA for transvenous electrodes).

What is AV sequential pacing?

Ventricular pacing often reduces cardiac output because the atrial contribution to ventricular

filling is lost. When the AV conducting system is diseased, atrial contraction can still be maintained by sequential stimulation by separate atrial and ventricular electrodes. The P–R interval can be varied by adjusting the delay between the atrial and ventricular impulses (usually set at 150–200 ms).

How are pacemakers classified?

Pacemakers are categorized by a five-letter code, according to the chambers paced, chambers sensed, response to sensing, programmability, and arrhythmia function (Table 21–22). The two most commonly used pacing modes are VVI and DDD (the last two letters are frequently omitted).

If a pacemaker is placed in this patient, how can its function be evaluated?

If the patient's underlying rhythm is slower than the rate of a demand pacemaker, pacing spikes should be seen on the ECG. The spike rate should be identical to the programmed (permanent pacemaker—usually 72/min) or set (temporary) pacemaker rate; a slower rate may indicate a low battery. Every pacing spike should be followed by a QRS complex (100% capture). Moreover, every impulse should be followed by a palpable arterial pulse. If the patient has a temporary pacemaker, the escape rhythm can be established by temporarily slowing the pacing rate or decreasing the current output.

When the patient's heart rate is faster than the set pacemaker rate, pacing spikes should not be observed if the generator is sensing properly. In this instance, ventricular capture cannot be evaluated

TABLE 21–22 Classification of pacemakers.

Chamber-Paced	Chamber-Sensed	Response to Sensing	Programmability	Antitacharrhythmia Function
O = none	O = none	O = none	O = none	O = none
A = atrium	A = atrium	T = triggered	P = simple	P = pacing
V = ventricle	V = ventricle	I = inhibited	M = multi-programmable	S = shock
D = dual (atrium and ventricle)	D = dual (atrium and ventricle)	D = dual (triggered and inhibited)	C = communicating R = rate modulation	D = dual (pacing and shock)

unless the pacemaker rate increases or the spontaneous heart rate decreases. Fortunately, when the battery is low, sensing is generally affected before pacing output decreases. A chest radiograph is useful in excluding fracture or displacement of pacing leads. If pacemaker malfunction is suspected, cardiologic consultation is essential.

What intraoperative conditions may cause the pacemaker to malfunction?

Electrical interference from surgical electrocautery units can be interpreted as myocardial electrical activity and can suppress the pacemaker generator. Problems with electrocautery may be minimized by limiting its use to short bursts, limiting its power output, placing its grounding plate as far from the pacemaker generator as possible, and using bipolar cautery. Moreover, continuous monitoring of an arterial pulse wave (pressure, plethysmogram, or oximetry signal) is mandatory to ensure continuous perfusion during electrocautery.

Both hypokalemia and hyperkalemia can alter the pacing electrodes' threshold for depolarizing the myocardium and can result in failure of the pacing impulse to depolarize the ventricle. Myocardial ischemia, infarction, or scarring can also increase the electrodes' threshold and cause failure of ventricular capture.

What are appropriate measures if a pacemaker fails intraoperatively?

If a temporary pacemaker fails intraoperatively, the inspired oxygen concentration should be increased to 100%. All connections and the generator battery should be checked. Most units have a battery-level indicator and a light that flashes with every impulse. The generator should be set into the asynchronous mode, and the ventricular output should be set on maximum. Failure of a temporary transvenous electrode to capture the ventricle is usually due to displacement of the electrode away from the ventricular endocardium; careful slow advancement of the catheter or wire while pacing often results in capture. Pharmacological management (atropine, isoproterenol, or epinephrine)

may be useful until the problem is resolved. If an adequate arterial blood pressure cannot be maintained with adrenergic agonists, cardiopulmonary resuscitation should be instituted until another pacing electrode is placed or a new generator box is obtained. Transcutaneous pacing can be employed.

If a permanent pacemaker malfunctions (as with electrocautery), it should generally be converted to an asynchronous mode. Some units will automatically reprogram themselves to the asynchronous mode if malfunction is detected. Other pacemaker units must be reprogrammed by placing either an external magnet, or, preferably, a programming device over the generator. The effect of an external magnet on some pacemakers—particularly during electrocautery—may be unpredictable and should generally be determined prior to surgery.

Which anesthetic agents are appropriate for patients with pacemakers?

All anesthetic agents have been safely used in patients who already have pacemakers. Even volatile agents seem to have no effect on pacing electrode thresholds. Local anesthesia with moderate to deep intravenous sedation is usually used for placement of permanent pacemakers.

Anesthesia for Cardiovascular Surgery

KEY CONCEPTS

- 1 Cardiopulmonary bypass (CPB) is a technique that diverts venous blood away from the heart (most often from one or more cannulas in the right atrium), adds oxygen, removes CO₂, and returns the blood through a cannula in a large artery (usually the ascending aorta or a femoral artery). As a result, nearly all blood bypasses the heart and lungs.
- 2 The fluid level in the reservoir is critical. If a “roller” pump is used and the reservoir is allowed to empty, air can enter the main pump and be embolized into the patient where it may cause organ damage or fatality.
- 3 Initiation of CPB is associated with a variable increase in stress hormones and systemic inflammatory response.
- 4 Establishing the adequacy of the patient’s preoperative cardiac function should be based on exercise (activity) tolerance, measurements of myocardial contractility such as ejection fraction, the severity and location of coronary stenoses, ventricular wall motion abnormalities, cardiac end-diastolic pressures, cardiac output, and valvular areas and gradients.
- 5 Blood should be immediately available for transfusion if the patient has already had a midline sternotomy (a “redo”); in these cases, the right ventricle or coronary grafts may be adherent to the sternum and may be accidentally entered during the repeat sternotomy.
- 6 In general, pulmonary artery catheterization has been most often used in patients with compromised ventricular function (ejection fraction <40–50%) or pulmonary hypertension and in those undergoing complicated procedures.
- 7 Transesophageal echocardiography (TEE) provides valuable information about cardiac anatomy and function during surgery. Two-dimensional, multiplane TEE can detect regional and global ventricular abnormalities, chamber dimensions, valvular anatomy, and the presence of intracardiac air. Three-dimensional TEE provides a more complete description of valvular anatomy and pathology.
- 8 Anesthetic dose requirements are variable and patient tolerance of inhaled anesthetics generally declines with declining ventricular function. Severely compromised patients should be given anesthetic agents in incremental, small doses.
- 9 Anticoagulation must be established before CPB to prevent acute disseminated intravascular coagulation and formation of clots in the CPB pump.

—Continued next page

Continued—

- 10 Antifibrinolytic therapy may be particularly useful for patients who are undergoing a repeat operation; who refuse blood products, such as Jehovah's Witnesses; who are at high risk for postoperative bleeding because of recent administration of glycoprotein IIb/IIIa inhibitors (abciximab, eptifibatid, or tirofiban); who have preexisting coagulopathy; and who are undergoing long and complicated procedures involving the heart or aorta.
- 11 Hypotension from impaired ventricular filling may occur during manipulation of the venae cavae and the heart.
- 12 Hypothermia (<34°C) potentiates general anesthetic potency, but failure to give anesthetic agents, particularly during rewarming on CPB, may result in awareness and recall.
- 13 Protamine administration can result in a number of adverse hemodynamic effects, some of which are immunological in origin. Protamine given slowly (5–10 min) usually has few effects; when given more rapidly it produces a fairly consistent vasodilation that is easily treated with blood from the pump oxygenator and small doses of phenylephrine. Catastrophic protamine reactions often include myocardial depression and marked pulmonary hypertension. Diabetic patients previously maintained on protamine-containing insulin (such as NPH) may be at increased risk for adverse reactions to protamine.
- 14 Persistent bleeding often follows prolonged durations of bypass (>2 h) and in most instances has multiple causes. Inadequate surgical control of bleeding sites, incomplete reversal of heparin, thrombocytopenia, platelet dysfunction, hypothermia-induced coagulation defects, undiagnosed preoperative hemostatic defects, or newly acquired factor deficiency or hypofibrinogenemia may be responsible.
- 15 Chest tube drainage in the first 2 h of more than 250–300 mL/h (10 mL/kg/h)—in the absence of a hemostatic defect—is excessive and may require surgical reexploration. Intrathoracic bleeding at a site not adequately drained may cause cardiac tamponade, requiring immediate reopening of the chest.
- 16 Factors known to increase pulmonary vascular resistance (PVR) such as acidosis, hypercapnia, hypoxia, enhanced sympathetic tone, and high mean airway pressures are to be avoided for patients with right-to-left shunting; hyperventilation (hypocapnia) with 100% oxygen is usually effective in lowering PVR. Conversely, patients with left-to-right shunting benefit from systemic vasodilation and increases in PVR, although specific hemodynamic manipulation is generally not attempted.
- 17 Induction of general anesthesia in patients with cardiac tamponade can precipitate severe hypotension and cardiac arrest.
- 18 The sudden increase in left ventricular afterload after application of the aortic cross-clamp during aortic surgery may precipitate acute left ventricular failure and myocardial ischemia, particularly in patients with underlying ventricular dysfunction or coronary disease. The period of greatest hemodynamic instability follows the release of the aortic cross-clamp; the abrupt decrease in afterload together with bleeding and the release of vasodilating acid metabolites from the ischemic lower body can precipitate severe systemic hypotension.
- 19 The emphasis of anesthetic management during carotid surgery is on maintaining adequate perfusion to the brain and heart.

Anesthesia for cardiovascular surgery requires an understanding of circulatory physiology, pharmacology, and pathophysiology as well as a familiarity with cardiopulmonary bypass (CPB) pumps, filters, and circuitry; transesophageal echocardiography (TEE); and techniques of myocardial preservation. Because surgical manipulations often have a profound impact on circulatory function, the anesthesiologist must understand the rationale behind the surgical techniques, follow the progress of the surgery, and anticipate the potential problems associated with each step.

This chapter presents an overview of anesthesia for cardiovascular surgery and of the principles, techniques, and physiology of CPB. Surgery on the aorta, the carotid arteries, and the pericardium presents problems that require special anesthetic considerations, which are also discussed herein.

Cardiopulmonary Bypass

1 CPB is a technique that diverts venous blood away from the heart (most often from one or more cannulas in the right atrium), adds oxygen, removes CO₂, and returns the blood through a cannula in a large artery (usually the ascending aorta or a femoral artery). As a result, nearly all blood bypasses the heart and lungs. When CPB is fully

established, the extracorporeal circuit is in series with the systemic circulation and provides both artificial ventilation and perfusion. This technique provides distinctly nonphysiological conditions, because arterial pressure is usually less than normal and blood flow is usually nonpulsatile. To minimize organ damage during this stressful period, various degrees of systemic hypothermia may be employed. Topical hypothermia (an ice-slush solution) and cardioplegia (a chemical solution for arresting myocardial electrical activity) may also be used to protect the heart.

The operation of the CPB machine is a complex task requiring the attention of a perfusionist—a specialized (and certified) technician. Optimal results with CPB require close cooperation and communication between the surgeon, anesthesiologist, and perfusionist.

BASIC CIRCUIT

The typical CPB machine has six basic components: a venous reservoir, an oxygenator, a heat exchanger, a main pump, an arterial filter, tubing that conducts venous blood to the venous reservoir, and tubing that conducts oxygenated blood back to the patient (**Figure 22-1**). Modern machines use a single disposable unit that includes the reservoir, oxygenator, and heat exchanger. Most machines also have

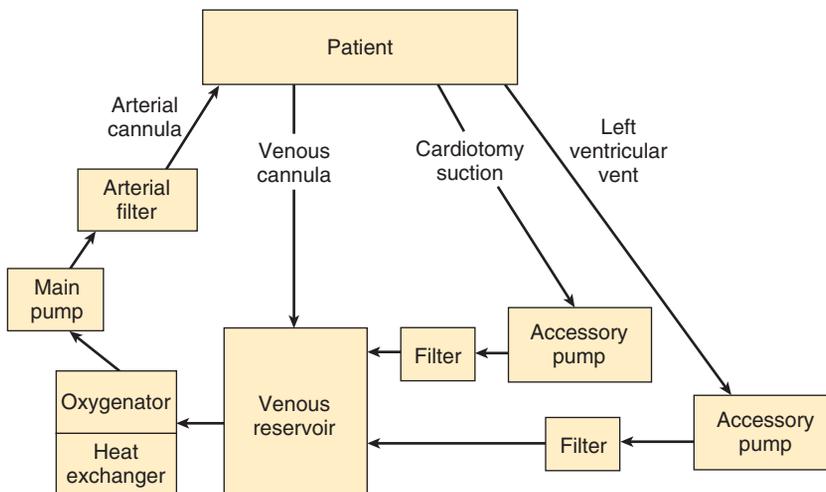

FIGURE 22-1 The basic design of cardiopulmonary bypass machines.

separate accessory pumps that can be used for blood salvage (cardiotomy suction), venting (draining) the left ventricle, and administration of cardioplegia solutions. A number of other filters, alarms, and in-line pressure, oxygen-saturation, and temperature monitors are also typically used.

Prior to use, the CPB circuit must be primed with fluid (typically 1200–1800 mL for adults) that is devoid of bubbles. A balanced salt solution, such as lactated Ringer's solution, is generally used, but other components are frequently added, including colloid (albumin or starch), mannitol (to promote diuresis), heparin (500–5000 units), and bicarbonate. At the onset of bypass, hemodilution decreases the hematocrit to about 22–27% in most patients. Blood is included in priming solutions for smaller children and severely anemic adults to prevent severe hemodilution.

Reservoir

The reservoir of the CPB machine receives blood from the patient via one or two venous cannulas placed in the right atrium, the superior and inferior vena cava, or a femoral vein. With most circuits blood returns to the reservoir by gravity drainage. During extracorporeal circulation the patient's venous pressure is normally low. Thus, the driving force for flow into the pump is directly related to the difference in height between the patient and the reservoir and inversely proportional to the resistance of the cannulas and tubing. An appropriately primed CPB machine draws in blood like a siphon. Entrainment of air in the venous line can produce an air lock that may prevent blood flow. With some circuits (eg, use of an unusually small venous cannula) assisted venous drainage may be required; a regulated vacuum together with a hard shell venous reservoir or centrifugal pump (see below) is used in **2** such instances. The fluid level in the reservoir is critical. If a "roller" pump is used and the reservoir is allowed to empty, air can enter the main pump and be embolized into the patient where it may cause organ damage or fatality. A low reservoir level alarm is typically present. Centrifugal pumps will not pump air but have the disadvantage of not impelling a well-defined volume with each turn of the head (unlike roller pumps).

Oxygenator

Blood is drained by gravity from the bottom of the venous reservoir into the oxygenator, which contains a blood–gas interface that allows blood to equilibrate with the gas mixture (primarily oxygen). A volatile anesthetic is frequently added to the oxygenator gas mixture. The blood–gas interface in a modern, membrane-type oxygenator is a very thin, gas-permeable silicone membrane. Arterial CO_2 tension during CPB is dependent on total gas flow past the oxygenator. By varying the inspired oxygen concentration, a membrane oxygenator allows independent control of PaO_2 and PaCO_2 .

Heat Exchanger

Blood from the oxygenator enters the heat exchanger and can either be cooled or warmed, depending on the temperature of the water flowing through the exchanger; heat transfer occurs by conduction. Because gas solubility decreases as blood temperature rises, a filter is built into the unit to catch any bubbles that may form during rewarming.

Main Pump

Modern CPB machines use either an electrically driven double-arm roller (positive displacement) or a centrifugal pump to propel blood through the CPB circuit.

A. Roller Pumps

Roller pumps produce flow by compressing large-bore tubing in the main pumping chamber as the roller heads turn. Subtotal occlusion of the tubing prevents excessive red cell trauma. The rollers pump blood regardless of the resistance encountered, and produce a nearly continuous nonpulsatile flow. Flow is directly proportional to the number of revolutions per minute. In some pumps, an emergency back-up battery provides power in case of an electrical power failure. All roller pumps have a hand crank to allow manual pumping, but those who have hand cranked a roller pump head will confirm that this is not a good long-term solution.

B. Centrifugal Pumps

Centrifugal pumps consist of a series of cones in a plastic housing. As the cones spin, the centrifugal forces created propel the blood from the centrally

located inlet to the periphery. In contrast to roller pumps, blood flow with centrifugal pumps is pressure sensitive and must be monitored by an electromagnetic flowmeter. Increases in distal pressure will decrease flow and must be compensated for by increasing the pump speed. Because these pumps are nonocclusive, they are less traumatic to blood than roller pumps. Unlike roller pumps, which are placed after the oxygenator (Figure 22–1), centrifugal pumps are normally located between the venous reservoir and the oxygenator. Centrifugal (unlike roller) pumps have the advantage of not being able to pump air.

C. Pulsatile Flow

Pulsatile blood flow is possible with some roller pumps. Pulsations can be produced by instantaneous variations in the rate of rotation of the roller heads; they can also be added after flow is generated. Pulsatile flow is not available with centrifugal pumps. Although there is no consensus and the data are contradictory, some clinicians believe that pulsatile flow improves tissue perfusion, enhances oxygen extraction, attenuates the release of stress hormones, and results in lower systemic vascular resistances (SVRs) during CPB.

Arterial Filter

Particulate matter (eg, thrombi, fat globules, tissue debris) may enter the CPB circuit via the cardiomy suction line. Although filters are often used at other locations, a final, in-line, arterial filter (27–40 μm) helps to reduce systemic embolism. Once filtered, the propelled blood returns to the patient, usually via a cannula in the ascending aorta, or less commonly in the femoral artery. A normally functioning aortic valve prevents blood from regurgitating into the left ventricle.

The filter is always in parallel with a (normally clamped) bypass limb in case the filter becomes clogged or develops increased resistance. For the same reason, arterial inflow pressure is measured before the filter. The filter is also designed to trap air, which can be bled out through a built-in stopcock.

Accessory Pumps & Devices

A. Cardiomy Suction

The cardiomy suction pump aspirates blood from the surgical field during CPB and returns it directly

to the main pump reservoir. This is a potential port of entry for fat and other debris to the pump that could embolize to organs. A so-called cell-saver suction device may also be used to aspirate blood from the surgical field, in which case blood is returned to a separate reservoir on a separate device. When sufficient blood has accumulated (or at the end of the procedure), the cell-saver blood is centrifuged, washed, and returned to the patient. Excessive suction pressure can theoretically contribute to red cell trauma. Use of cell-saver suction (instead of cardiomy suction) during bypass will deplete CPB circuit volume if blood loss is brisk. The high negative pressure of ordinary wall suction devices produces excessive red cell trauma precluding blood salvage from that source.

B. Left Ventricular Vent

With time, even with “total” CPB, blood reaccumulates in the left ventricle as a result of residual pulmonary flow from the bronchial arteries (which arise directly from the aorta or the intercostal arteries) or thebesian vessels (see Chapter 20), or sometimes as a result of aortic valvular regurgitation. Aortic regurgitation can occur as a result of either (structural) valvular abnormalities or surgical manipulation of the heart (functional). Distention by blood of the left ventricle compromises myocardial preservation (see below) and requires decompression (venting). Most surgeons accomplish this by inserting a catheter via the right superior pulmonary vein and left atrium into the left ventricle. Venting may also be accomplished using a catheter placed in the left ventricular apex or across the aortic valve. The blood aspirated by the vent pump normally passes through a filter before being returned to the venous reservoir.

C. Cardioplegia Pump

Cardioplegic solutions are most often administered via an accessory pump on the CPB machine. This technique allows optimal control over the infusion pressure, rate, and temperature. A separate heat exchanger ensures control of the temperature of the cardioplegia solution. Less commonly, cardioplegic solutions may be infused from a cold intravenous fluid bag given under pressure or by gravity.

D. Ultrafiltration

Ultrafiltration can be used during CPB to increase the patient's hematocrit without transfusion. Ultrafilters consist of hollow capillary fibers that can function as membranes, allowing separation of the aqueous phase of blood from its cellular and proteinaceous elements. Blood can be diverted to pass through the fibers either from the arterial side of the main pump or from the venous reservoir using an accessory pump. Hydrostatic pressure forces water and electrolytes across the fiber membrane. Effluents of up to 40 mL/min may be removed.

SYSTEMIC HYPOTHERMIA

Intentional hypothermia is often used following the initiation of CPB. Core body temperature may be reduced to 20–32°C. In recent years, so-called tepid bypass has been used; this may be accomplished by allowing the patient's temperature to “drift” downward to 30–35°C. Metabolic oxygen requirements are generally halved with each reduction of 10°C in body temperature. At the end of the surgical procedure, rewarming via the heat exchanger restores normal body temperature.

For complex repairs, profound hypothermia to temperatures of 15–18°C allows total circulatory arrest for durations of as long as 60 min. During that time, both the heart and the CPB machine are stopped.

The adverse effects of hypothermia include platelet dysfunction; reversible coagulopathy; and depression of myocardial contractility.

MYOCARDIAL PRESERVATION

Optimal results in cardiac surgery require an expeditious and complete surgical repair with minimal physical trauma to the heart. Meanwhile, several techniques are used to prevent myocardial damage and maintain normal cellular integrity and function during CPB. Nearly all patients sustain at least minimal myocardial injury during cardiac surgery. With good preservation techniques, however, most of the injury is reversible. Although myocardial injury can be related to the hemodynamic instability or surgical technique, it most commonly appears to be

related to incomplete myocardial preservation during CPB. Injury related to hemodynamic instability results from an imbalance between oxygen demand and supply, producing cell ischemia. After ischemia, reperfusion injury may also play a role. Reperfusion following a period of ischemia may produce excess oxygen-derived free radicals, intracellular calcium overload, abnormal endothelial–leukocyte interactions, and myocardial cellular edema. Patients at greatest risk are those with poor ventricular function (as measured preoperatively) (see Table 21–13) those with ventricular hypertrophy, and those with diffuse severe coronary artery disease. Inadequate myocardial preservation is usually manifested at the end of bypass as a persistently reduced cardiac output, worsened ventricular function by TEE, or cardiac arrhythmias. Electrocardiographic signs of myocardial ischemia are often difficult to detect due to frequent use of electrical pacing. Myocardial “stunning,” resulting from ischemia and reperfusion, produces systolic and diastolic dysfunction that is reversible with time. The stunned myocardium usually responds to positive inotropic drugs. Myocardial necrosis, on the other hand, produces irreversible injury.

Aortic cross-clamping during CPB completely excludes the coronary arteries from the generalized bypass machine flow to the body, reducing coronary blood flow to 0. Although it is difficult to estimate a safe period for cross-clamping because of differing vulnerabilities among patients and differing techniques for myocardial preservation, CPB times longer than 120 min (while often unavoidable) increase risk relative to shorter bypass times. Myocardial ischemia during bypass may occur not only during aortic clamping, but also after release of the cross-clamp. Low arterial pressures, coronary embolism (from thrombi, platelets, air, fat, or atheromatous debris), reperfusion injury, coronary artery or bypass graft vasospasm, and contortion of the heart—causing compression or distortion of the coronary vessels—are all possible causes. Areas of the myocardium distal to a high-grade coronary obstruction are at greatest risk.

Ischemia causes depletion of high-energy phosphate compounds and an accumulation of intracellular calcium. When coronary blood flow ceases,

creatine phosphate and anaerobic metabolism become the principal sources of cellular energy; fatty acid oxidation is impaired. Unfortunately, these energy stores rapidly become depleted, and the progressive acidosis that develops limits glycolysis.

Cardioplegic solutions maintain normal cellular integrity and function during CPB by reducing energy expenditure and preserving the availability of high-energy phosphate compounds. Although measures directed at increasing or replenishing energy substrates in the form of glucose or glutamate/aspartate infusions are used, the emphasis of myocardial preservation has been on reducing cellular energy requirements to minimal levels. This is accomplished initially by the use of potassium cardioplegia (below). The initial dose of cardioplegic solution may be hypothermic or may start warm (“hot shot”) and progress to cold. Maintenance of myocardial protection may be facilitated by systemic and topical cardiac hypothermia (ice slush). Myocardial hypothermia reduces basal metabolic oxygen consumption, and potassium cardioplegia minimizes energy expenditure by arresting both electrical and mechanical activity. Myocardial temperature is often monitored directly; 10–15°C is usually considered desirable. Cardioplegic solutions can be administered either antegrade through a catheter placed in the proximal aorta between the aortic clamp and the aortic valve, or retrograde through a catheter placed through the right atrium into the coronary sinus.

Ventricular fibrillation and distention (previously discussed) are important causes of myocardial damage. Ventricular fibrillation can dangerously increase myocardial oxygen demand, whereas distention not only increases oxygen demand but also reduces oxygen supply by interfering with subendocardial blood flow. The combination of the two is particularly bad. Other factors that might contribute to perioperative myocardial damage include the use of excessive doses of positive inotropes or calcium salts. In open heart procedures, de-airing of cardiac chambers and venting before and during initial cardiac ejection are critically important in preventing cerebral or coronary air embolism (and strokes—see below). Removing air from coronary grafts during bypass procedures is similarly important.

Depending on the amount and the location of coronary emboli, even small air bubbles can cause varying degrees of ventricular dysfunction at the end of CPB. To some extent, air emboli may preferentially find their way into the right (versus left) coronary ostium because of its superior location on the aortic root in the supine patient.

Potassium Cardioplegia

The most widely used method of arresting myocardial electrical activity is the administration of potassium-rich crystalloid or blood–crystalloid solutions. Following initiation of CPB and aortic cross-clamping, the coronary circulation is perfused intermittently with (usually cold) cardioplegic solutions. The resulting increase in extracellular potassium concentration reduces the transmembrane potential. Eventually, the heart is arrested in diastole. Usually, cold cardioplegia must be repeated at intervals (about every 30 min) because of gradual washout and rewarming of the myocardium. The heart is subject to warming by contact with blood in the adjacent descending aorta and by contact with warmer ambient air in the surgical theater. Moreover, multiple doses of cardioplegia solutions may improve myocardial preservation by preventing an excessive accumulation of metabolites that inhibit anaerobic metabolism.

Although the exact recipe varies from center to center, the essential ingredient of the induction dose of cardioplegic solution is the same: an elevated potassium (10–40 mEq/L) concentration. Potassium concentration is kept below 40 mEq/L, because higher levels can be associated with an excessive potassium load and excessive potassium concentrations at the end of termination of bypass perfusion. Sodium concentration in cardioplegic solutions is usually less than in plasma (<140 mEq/L) because ischemia tends to increase intracellular sodium content. A small amount of calcium (0.7–1.2 mmol/L) is needed to maintain cellular integrity, whereas magnesium (1.5–15 mmol/L) is usually added to control excessive intracellular influxes of calcium. A buffer—most commonly bicarbonate—is necessary to prevent excessive buildup of acid metabolites; in fact, alkalotic perfusates are reported to produce better myocardial preservation. Alternative buffers

include histidine and tromethamine (also known as THAM). Other components may include hypertonic agents to control cellular edema (mannitol) and agents thought to have membrane-stabilizing effects (lidocaine or glucocorticoids). Energy substrates are provided as glucose, glutamate, or aspartate. The question of whether to use crystalloid or blood as a vehicle for achieving cardioplegia remains controversial, although blood cardioplegia has become very common in North America. Evidence suggests that at least some groups of high-risk patients may do better with blood cardioplegia. Certainly, oxygenated blood cardioplegia may contain more oxygen than crystalloid cardioplegia.

Because cardioplegia may not reach areas distal to high-grade coronary obstructions (the areas that need it most), many surgeons administer retrograde cardioplegia through a coronary sinus catheter. Some centers have reported that the combination of antegrade plus retrograde cardioplegia is superior to either technique alone. Others have suggested that continuous warm blood cardioplegia is superior to intermittent hypothermic cardioplegia for myocardial preservation, but many surgeons avoid continuous cardioplegia so that they can operate in a “bloodless” surgical field. Moreover, warm cardiac surgery raises additional concerns about loss of the potentially protective effects of systemic hypothermia against cerebral injury, when true normothermia (rather than tepid bypass) is maintained.

As discussed previously, with prolonged myocardial ischemic times (cross-clamp time), reperfusion of the myocardium can lead to extensive cell injury, rapid accumulation of intracellular calcium, and potentially irreversible cellular necrosis. This process has long been attributed to depletion of endogenous free radical scavengers during CPB and accumulation of deleterious oxygen-derived free radicals. Free radical scavengers, such as mannitol, may help decrease reperfusion injury and are typical constituents of cardioplegic solutions and bypass “priming” solutions. Several steps may help limit reperfusion injury before unclamping of the aorta. Just prior to reperfusion, the heart may be perfused by a reduced potassium cardioplegic solution that serves to wash out accumulated metabolic byproducts. Alternatively, a “hot shot” or warm blood cardioplegic solution may

be administered to wash out byproducts and replenish metabolic substrates. Hypercalcemia should be avoided in the immediate reperfusion period. Reperfusion pressures should be controlled closely because of altered coronary autoregulation. Systemic perfusion pressure is reduced just prior to clamp release; it is then brought up initially to about 40 mm Hg before gradually being increased and maintained at about 70 mm Hg. To further minimize metabolic requirement, the heart should have the opportunity to recover and resume contracting in an empty state for some additional time (5–10 min), and acidosis and hypoxia should be corrected before attempting to wean the patient from bypass perfusion.

Inadequate myocardial protection or inadequate washout and recovery from cardioplegia can result in asystole, atrioventricular conduction block, or a poorly contracting heart at the end of bypass. Excessive volumes of hyperkalemic cardioplegic solutions may produce persisting systemic hyperkalemia. Although calcium salt administration partially offsets hyperkalemia, excessive calcium can promote and enhance myocardial damage. In the usual patient myocardial performance improves with time as the contents of the cardioplegia are cleared from the heart.

PHYSIOLOGICAL EFFECTS OF CARDIOPULMONARY BYPASS

Hormonal, Humoral, & Immunological Responses

3 Initiation of CPB is associated with a variable increase in stress hormones and systemic inflammatory response. Elevated levels of catecholamines, cortisol, arginine vasopressin, and angiotensin are observed. These neurohormonal responses are variously influenced by depth of anesthesia, blood pressure, type of surgical repair, or presence of pulsatile CPB.

Multiple humoral systems are also activated, including complement, coagulation, fibrinolysis, and the kallikrein system. Contact of blood with the internal surfaces of the CPB system activates complement via the alternate pathway (C3) as well as the classic pathway; the latter also activates the

coagulation cascade, platelets, plasminogen, and kallikrein. Mechanical trauma from blood contact with the bypass apparatus also activates platelets and leukocytes. Increased amounts of oxygen-derived free radicals are generated. A systemic inflammatory response syndrome similar to that seen with sepsis and trauma can develop. When this response is intense or prolonged, patients can develop the same complications, including generalized edema, the acute respiratory distress syndrome, coagulopathy, and acute kidney failure.

CPB alters and depletes glycoprotein receptors on the surface of platelets. The resulting platelet dysfunction likely increases perioperative bleeding and potentiates other coagulation abnormalities (activation of plasminogen and the inflammatory response described above).

Animal and clinical research has demonstrated that the inflammatory response to CPB can be modulated by various therapies. Leukocyte depletion reduces inflammation and may similarly reduce complications. Leukocyte-depleted blood cardioplegia has been shown to improve myocardial preservation in some studies. Hemofiltration (ultrafiltration) during CPB, which presumably removes inflammatory cytokines, appears beneficial in pediatric patients. Administration of free radical scavengers such as high-dose vitamins C and E and mannitol has improved outcome in some studies. Systemic corticosteroids before and during CPB can modulate the inflammatory response during CPB but improved outcome is not well established. Two large randomized clinical trials are underway to test whether there is an outcome benefit to the routine use of systemic corticosteroids with CPB.

One once-promising agent, aprotinin, reduced inflammation and surgical bleeding following CPB. Unfortunately, it increased mortality and is no longer available in North America.

CPB Effects on Pharmacokinetics

Plasma and serum concentrations of most water-soluble drugs (eg, nondepolarizing muscle relaxants) acutely decrease at the onset of CPB, but the change can be minimal and inconsequential for most lipid-soluble drugs (eg, fentanyl and sufentanil). The effects of CPB are complex because of

the sudden increase in volume of distribution with hemodilution, decreased protein binding, and changes in perfusion and redistribution between peripheral and central compartments. Some drugs, such as opioids, also bind CPB components (but this is also minimal and inconsequential). Heparin potentially alters protein binding of drugs and ions by releasing and activating lipoprotein lipase, which hydrolyzes plasma triglycerides into free fatty acids; the latter can competitively inhibit drug binding to plasma proteins and bind free calcium ions. With the possible exception of propofol, constant infusion of a drug during CPB (even when adjusted to maintain a constant “effect site” concentration using data from patients *not* undergoing CPB) generally causes progressively increasing blood levels as a result of reduced hepatic and renal perfusion (reduced elimination) and hypothermia (reduced metabolism).

Anesthetic Management of Cardiac Surgery

ADULTS

The preoperative evaluation and anesthetic management of common cardiovascular diseases are discussed in Chapter 21. The same principles apply whether these patients are undergoing cardiac or noncardiac surgery. An important distinction is that patients undergoing cardiac procedures will by definition have advanced disease. Establishing the adequacy of the patient’s preoperative cardiac function should be based on exercise (activity) tolerance, measurements of myocardial contractility such as ejection fraction, the severity and location of coronary stenoses, ventricular wall motion abnormalities, cardiac end-diastolic pressures, cardiac output, and valvular areas and gradients. Fortunately, unlike noncardiac surgery, cardiac surgery improves cardiac function in the majority of patients, and these patients have usually been extensively evaluated before being offered surgical repair. The anesthetic preoperative evaluation should also include a focus on pulmonary, neurological, and renal function, as preoperative impairment of these organ systems predisposes patients to myriad postoperative complications.

1. Preinduction Period

Premedication

The prospect of heart surgery is frightening, and relatively “heavy” oral or intramuscular premedication was often given in the past, particularly when patients had coronary artery disease with good left ventricular function (see Chapter 21). However, in current practice, most patients receive no sedative-hypnotic premedication until their arrival on the surgical unit, at which time most will receive small doses of intravenous midazolam.

Benzodiazepine sedative-hypnotics (diazepam, 5–10 mg orally), alone or in combination with an opioid (morphine, 5–10 mg intramuscularly or hydromorphone, 1–2 mg intramuscularly), were often used in the past. Longer acting premedicant agents (eg, lorazepam) are avoided by most practitioners to permit “fast tracking” of patients through their recovery.

Preparation

The best practitioners of cardiac anesthesia formulate a simple anesthetic plan that includes adequate preparations for contingencies. Many patients are critically ill, and there is little time intraoperatively to have an assistant search for drugs and equipment. At the same time, the anesthetic plan should not be excessively rigid; when problems are encountered with one technique, one should be ready to change to another without delay. Preparation, organization, and attention to detail permit one to more efficiently deal with unexpected intraoperative problems. The anesthesia machine, monitors, infusion pumps, and blood warmer should all be checked before the patient arrives. Drugs—including anesthetic and vasoactive agents—should be immediately available. Many clinicians prepare one vasoconstrictor and one vasodilator infusion before the start of the procedure.

Venous Access

Cardiac surgery is sometimes associated with large and rapid blood loss, and with the need for multiple drug infusions. Ideally, two large-bore (16-gauge or larger) intravenous catheters should be placed. One

of these should be in a large central vein, usually an internal or external jugular or subclavian vein. Central venous cannulations may be accomplished while the patient is awake but sedated or after induction of anesthesia. Studies show no benefit from placing either central venous or pulmonary arterial catheters in awake (versus anesthetized) patients undergoing cardiovascular surgery.

Drug infusions should ideally be given into a central catheter, preferably directly into the catheter or into the injection port closest to the catheter (to minimize dead space). Multilumen central venous catheters and multilumen pulmonary artery catheter introducer sheaths allow for multiple drug infusions with simultaneous measurement of vascular pressures. One intravenous port should be dedicated for drug infusions and nothing else; drug and fluid boluses should be administered through another site. The side port of the introducer sheath used for a pulmonary catheter can be used for drug infusions but serves better as a fluid bolus line when a large-bore introducer (9F) is used.

5 Blood should be immediately available for transfusion if the patient has already had a midline sternotomy (a “redo”); in these cases, the right ventricle or coronary grafts may be adherent to the sternum and may be accidentally entered during the repeat sternotomy.

Monitoring

A. Electrocardiography

The electrocardiogram (ECG) is continuously monitored with two leads, usually leads II and V₅. Baseline tracings of all leads may be recorded on paper for further reference. The advent of monitors with computerized ST-segment analysis and the use of additional monitoring leads (V₄, aVF, and V_{4R}) have greatly improved detection of ischemic episodes, as has the frequent intraoperative use of TEE.

B. Arterial Blood Pressure

In addition to all basic monitoring, arterial cannulation is always performed either prior to or immediately after induction of anesthesia, as the induction period represents a time when major hemodynamic alterations may occur. Radial arterial catheters may

occasionally give falsely low readings following sternal retraction as a result of compression of the subclavian artery between the clavicle and the first rib. They may also provide falsely low values early after CPB due to the opening of atrioventricular shunts in the hand during rewarming. The radial artery on the side of a previous brachial artery cutdown should be avoided, because its use is associated with a greater incidence of arterial thrombosis and wave distortion. Obviously, if a radial artery will be harvested for a coronary bypass conduit, it cannot be used as a site for arterial pressure monitoring. Other useful catheterization sites include the ulnar, axillary, and especially brachial and femoral arteries. A backup manual or automatic blood pressure cuff should also be placed on the opposite side for comparison with direct measurements.

C. Central Venous and Pulmonary Artery Pressure

Central venous pressure is not terribly useful for diagnosis of hypovolemia but has been customarily monitored in nearly all patients undergoing cardiac surgery. The decision about whether to use a pulmonary artery catheter is based on the patient, the procedure, and the preferences of the surgical team. Routine use of a pulmonary artery catheter, once nearly universal in adult cardiovascular practice, is controversial. Pulmonary artery catheterization has declined precipitously in nearly all circumstances except adult cardiac surgery due to lack of evidence of a positive effect on patient outcomes. Left ventricular filling pressures can be measured with a left atrial pressure line inserted by the surgeon during

6 bypass. In general, pulmonary artery catheterization has been most often used in patients with compromised ventricular function (ejection fraction <40–50%) or pulmonary hypertension and in those undergoing complicated procedures. The most useful data are pulmonary artery pressures, the pulmonary artery occlusion (“wedge”) pressure, and thermodilution cardiac outputs. Specialized catheters provide extra infusion ports, continuous measurements of mixed venous oxygen saturation and cardiac output, and the capability for right ventricular or atrioventricular sequential pacing. Given the risk associated with placing any pulmonary artery

catheter, some clinicians opine that it makes sense to restrict pulmonary artery catheterization only to devices that offer these advanced capabilities.

The right internal jugular vein is the preferred approach for intraoperative central venous cannulation. Catheters placed through the other sites, particularly on the left side, are more likely to kink following sternal retraction (above) and are not nearly as likely to pass into the superior vena cava as those placed through the right internal jugular vein.

Pulmonary artery catheters migrate distally during CPB and may spontaneously wedge without balloon inflation. Inflation of the balloon under these conditions can rupture a pulmonary artery causing lethal hemorrhage. Pulmonary artery catheters should be routinely retracted 2–3 cm during CPB and the balloon subsequently inflated slowly. If the catheter wedges with less than 1.5 mL of air in the balloon, it should be withdrawn farther.

D. Urinary Output

Once the patient is anesthetized, an indwelling urinary catheter is placed to monitor the hourly output. Bladder temperature is often monitored as a measure of core temperature but may not track core temperature well with reduced urinary flow. The sudden appearance of reddish urine may indicate excessive red cell hemolysis caused by CPB or a transfusion reaction.

E. Temperature

Multiple temperature monitors are usually placed once the patient is anesthetized. Bladder (or rectal), esophageal, and pulmonary artery (blood) temperatures are often simultaneously monitored. Because of the heterogeneity of readings during cooling and rewarming, bladder and rectal readings are generally taken to represent an average body temperature, whereas esophageal represents core temperature. Pulmonary artery temperature provides an accurate estimate of blood temperature, which should be the same as core temperature in the absence of active cooling or warming. Nasopharyngeal and tympanic probes may most closely approximate brain temperature. Myocardial temperature is often measured directly during CPB.

F. Laboratory Parameters

Intraoperative laboratory monitoring is mandatory during cardiac surgery. Blood gases, hematocrit, serum potassium, ionized calcium, and glucose measurements should be immediately available. The **activated clotting time (ACT)** approximates the Lee–White clotting time and is used to monitor heparin anticoagulation. Some centers routinely use thromboelastography (TEG) to identify causes of bleeding after CPB.

G. Surgical Field

One of the most important actions in intraoperative monitoring is inspection of the surgical field. Once the sternum is opened, lung expansion can be observed through the pleura. When the pericardium is opened, the heart (primarily the right ventricle) is visible; thus cardiac rhythm, volume, and contractility can often be judged visually. Blood loss and surgical maneuvers must be closely watched and related to changes in hemodynamics and rhythm.

H. Transesophageal Echocardiography

7 TEE provides valuable information about cardiac anatomy and function during surgery.

Two-dimensional, multiplane TEE can detect regional and global ventricular abnormalities, chamber dimensions, valvular anatomy, and the presence of intracardiac air. Three-dimensional TEE provides a more complete description of valvular anatomy and pathology. TEE can also be helpful in confirming cannulation of the coronary sinus for cardioplegia. Multiple views should be obtained from the upper esophagus, mid-esophagus, and transgastric positions in the transverse, sagittal, and in-between planes (**Figure 22–2**). The two views most commonly used for monitoring during cardiac surgery are the four-chamber view (**Figure 22–3**) and the transgastric (short-axis) view (**Figure 22–4**). Three-dimensional echocardiography offers great promise for better visualization of complex anatomic features, particularly of cardiac valves. The following represent the most important applications of intraoperative TEE.

1. Assessment of valvular function—Valvular morphology can be assessed by multiplane and three-dimensional TEE. Pressure gradients, area and severity of stenosis, and severity of valvular regurgitation can be assessed by Doppler echocardiography and

A		Transverse view	Longitudinal (sagittal) view
Beam angle	0°		
Image orientation	Posterior ↑ Right ← → Left ↓ Anterior	Posterior ↑ Foot ← → Head ↓ Anterior	

FIGURE 22–2 Useful views during transesophageal echocardiography. **A:** The relationship between the angle of the ultrasound beam and image orientation relative to the patient. **B–D:** Echocardiographic views from the upper mid-esophagus, lower mid-esophagus, and transgastric position (C). Note that different views can be obtained in each position as the tip of the probe is tilted either upward (anteflexion) or backward (retroflexion) and the angle of the beam is changed from 0° to 180°. The angle of the

beam is shown in the upper left-hand corner of each image. The probe is also rotated clockwise or counterclockwise to optimize viewing of the various structures. AO, aorta; AV, aortic valve; CS, coronary sinus; IVC, inferior vena cava; LA, left atrium; LAA, left atrial appendage; LUPV, left upper pulmonary vein; LV, left ventricle; MPA, main pulmonary artery; MV, mitral valve; PA, pulmonary artery; RA, right atrium; RPA, right pulmonary artery; RV, right ventricle; SVC, superior vena cava. (*continued*)

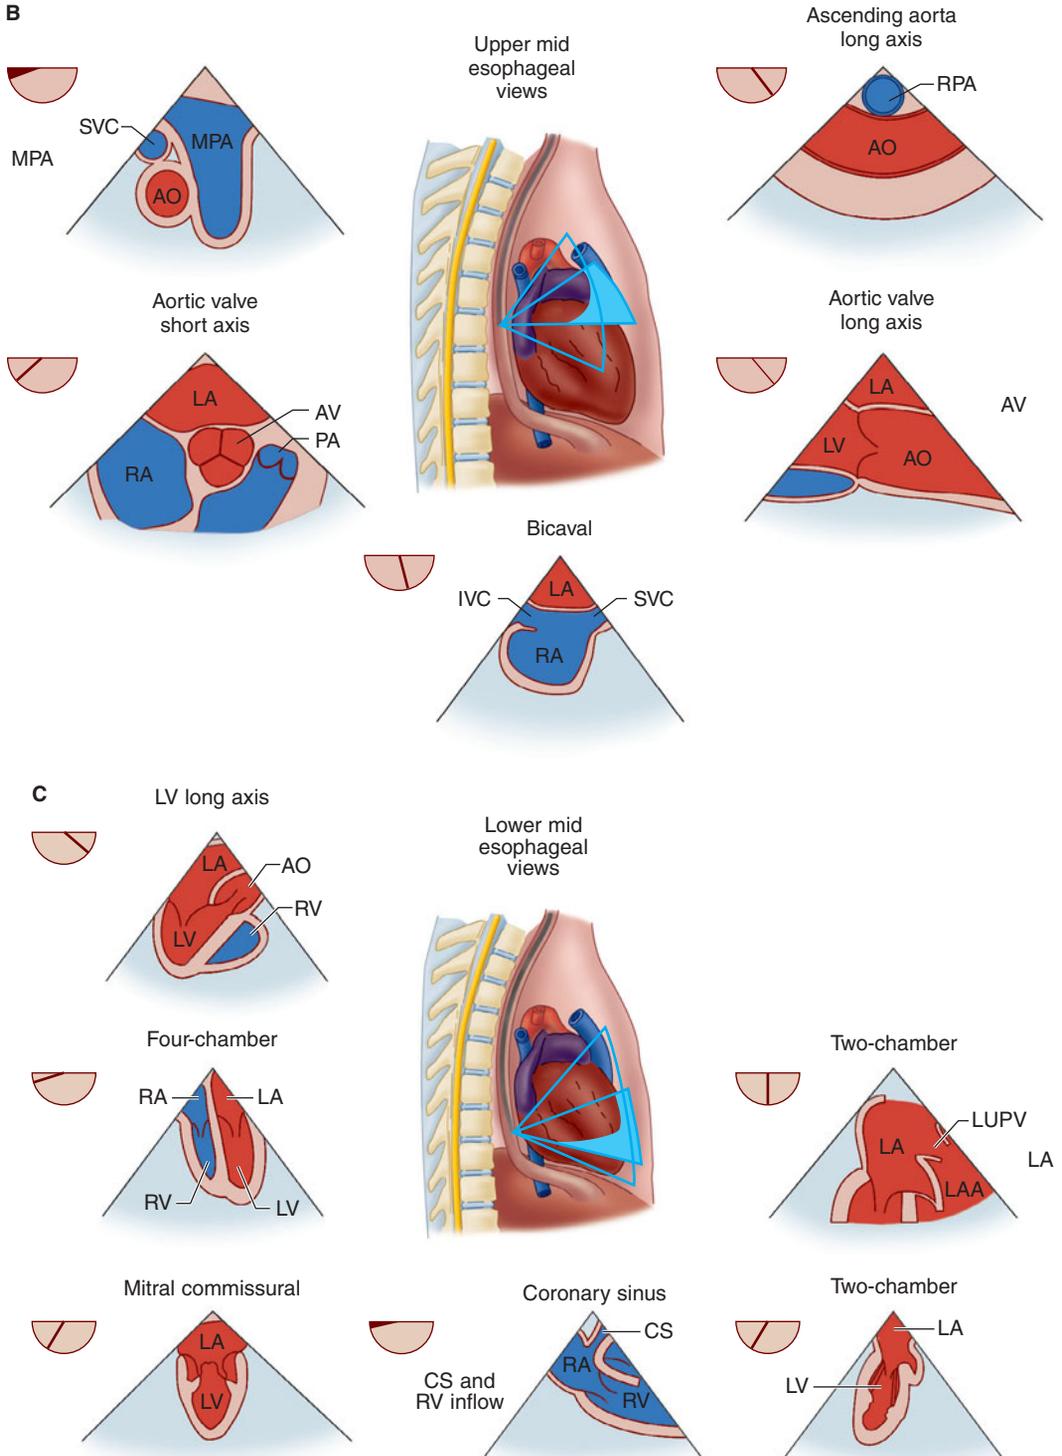

FIGURE 22-2 (continued)

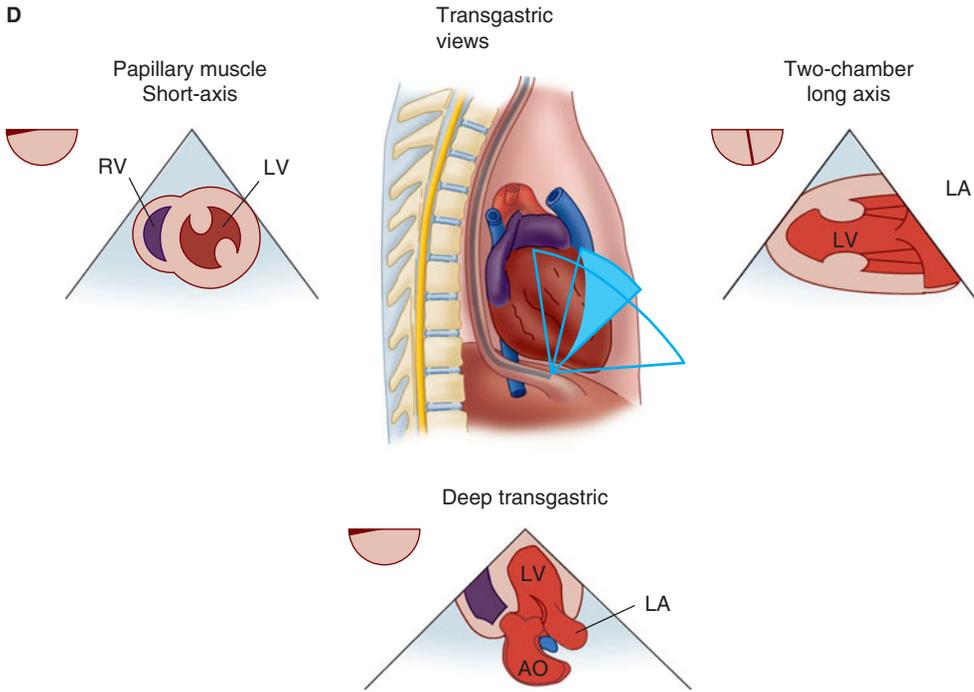

FIGURE 22-2 (continued)

color-flow imaging (Figure 22-5). Colors are usually adjusted so that flow toward the probe is red and flow in the opposite direction is blue. TEE also can detect prosthetic valve dysfunction, such as obstruction or

regurgitation, and can detect vegetations from endocarditis. The TEE images in the upper mid-esophagus at 40–60° and 110–130° are useful for examining the aortic valve and ascending aorta (Figure 22-6). The

(early filling) and A (atrial filling) (A). Color-flow imaging demonstrates backward flow (regurgitant jet) across the mitral valve during systole (mitral regurgitation) (B).

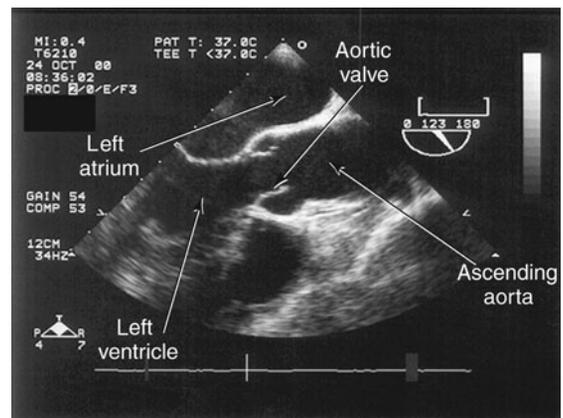

valve annular diameter can also be estimated with reasonable accuracy. Doppler flow across the aortic valve must be measured looking up from the deep transgastric view (Figure 22-7). The anatomic features of the mitral valve relevant to TEE are shown in Figure 22-8. The mitral valve is examined from the mid-esophageal position, looking at the mitral valve apparatus with and without color in the 0° through 150° views (Figure 22-9). TEE is an invaluable aid

to guide and assess the quality of mitral valve repair surgery. The commissural view (at about 60°) is particularly helpful because it cuts across many scallops of the mitral valve.

2. Assessment of ventricular function—Ventricular function can be assessed by global systolic function, estimated by means of ejection fraction (often calculated using Simpson's method of disks) and left ventricular end-diastolic volume; diastolic function

A

B

FIGURE 22-6 Two views of the aortic valve. Between 40° and 60°, all three leaflets are usually visualized (A). Between 110° and 130°, the left ventricular outflow, aortic valve, and ascending aorta are clearly visualized (B).

(ie, looking for abnormal relaxation and restrictive diastolic patterns by checking mitral flow velocity or by measuring movements of the mitral valve annulus using tissue Doppler techniques); and regional systolic function (by assessing wall motion and thickening abnormalities). Regional wall abnormalities from myocardial ischemia often appear before ECG changes. Regional wall motion abnormalities can be classified into three categories based on severity (**Figure 22-10**): hypokinesis (reduced wall motion), akinesis (no wall motion), and dyskinesis (paradoxical wall motion). The location of a regional wall motion abnormality can indicate which coronary artery is experiencing reduced flow. The left ventricular myocardium is supplied by three major arteries: the left anterior descending artery, the left circumflex artery, and the right coronary artery (**Figure 22-11**). The areas of distribution of these arteries on echocardiographic views

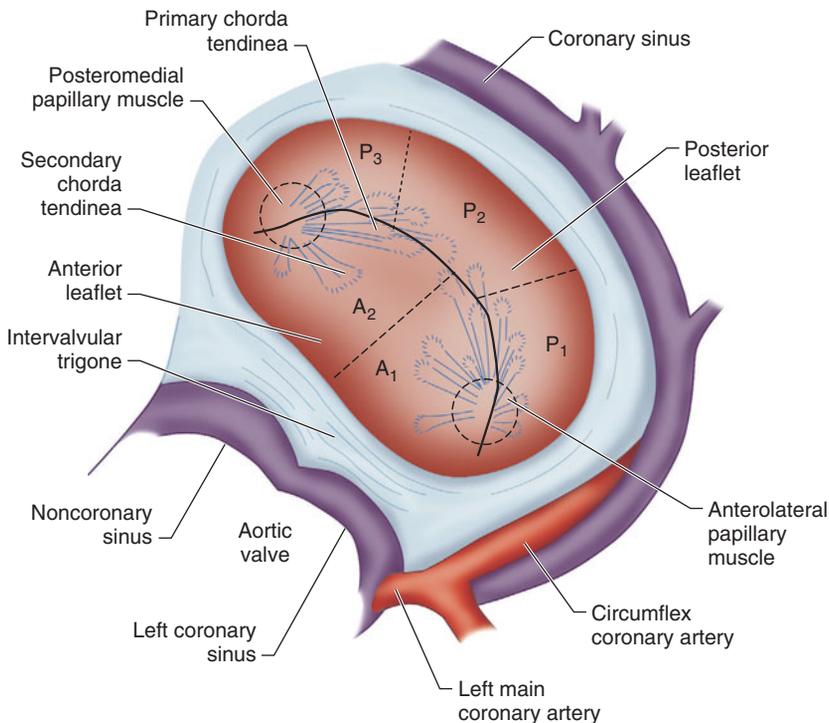

FIGURE 22-8 The anatomy of the mitral valve and its anatomic relationships to the aortic valve and left circumflex coronary artery. The posterior leaflet has three scallops, P₁, P₂, and P₃. The anterior leaflet is usually

divided into A₁ and A₂ regions; in some classifications the anterior leaflet is divided into three areas (A₁, A₂, A₃), corresponding to the opposing corresponding areas of the posterior leaflet.

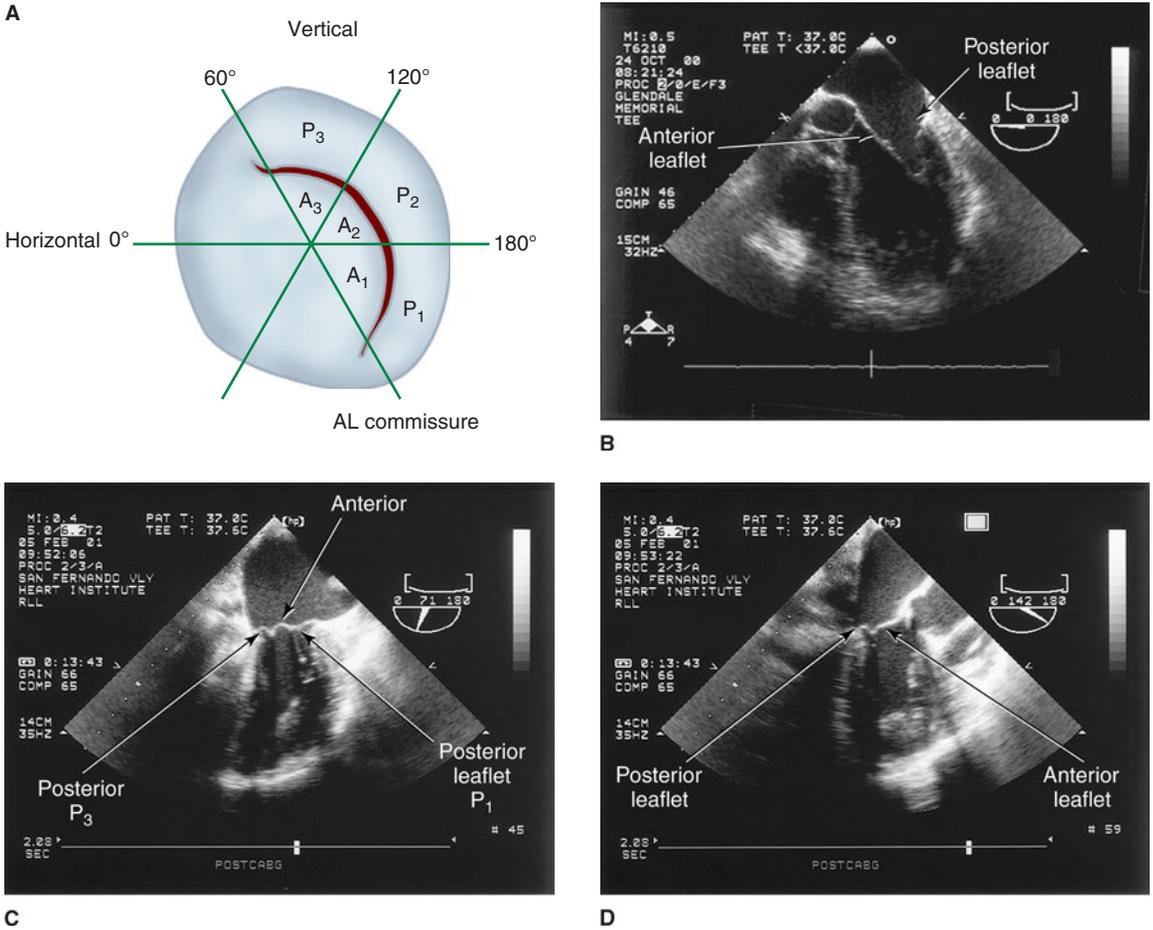

FIGURE 22-9 Multiplane imaging cuts across different segments of the mitral valve apparatus between 0° and 180° (A). Images of the mitral valve at 0°, 71°, and 142° (B, C, and D, respectively).

are shown in [Figure 22-12](#). The ventricular short-axis mid view at the mid-papillary muscle level contains all three blood supplies from the major coronary arteries.

3. Assessment of other cardiac structures and abnormalities

In an adult undergoing elective cardiac surgery TEE can help diagnose previously undetected congenital defects such as an atrial or ventricular septal defect; pericardial diseases such as pericardial effusions and constrictive pericarditis; and cardiac tumors. Doppler color-flow imaging helps delineate abnormal intracardiac blood flows and shunts. TEE can assess the extent of myectomy in patients with hypertrophic cardiomyopathy (idiopathic hypertrophic subaortic stenosis). Upper-, mid-, and lower-esophageal views are valuable in diagnosing aortic disease processes such as dissection, aneurysm, and atheroma ([Figure 22-13](#)). The extent of dissections in the ascending and descending aorta can be accurately defined; however, airway structures prevent complete visualization of the aortic arch. The presence of protruding atheroma in the ascending aorta increases the risk of postoperative stroke and should prompt the use of epiaortic scanning to identify an atheroma-free cannulation site or a change in surgical plans.

4. Examination for residual air—Air is introduced into the cardiac chambers during all “open” heart procedures, such as valve surgery. Residual amounts of air often remain in the left ventricular apex even after the best deairing maneuvers. TEE is helpful in defining the volume of residual air, to determine whether additional surgical maneuvers need to be undertaken to help avoid cerebral or coronary embolism.

I. Electroencephalography

Computer-processed electroencephalographic (EEG) recordings can be used to assess anesthetic depth during cardiac surgery, and either the processed or “raw” EEG can be used to ensure complete drug-induced electrical silence (for brain protection) prior to circulatory arrest. These recordings are generally not useful in detecting neurological insults during CPB. Progressive hypothermia (or progressively deepened anesthesia) is typically associated with EEG slowing, burst suppression, and, finally, an isoelectric recording. Most strokes during CPB are due to small emboli that are not likely to produce changes in the EEG. Artifacts from the CPB roller pump may be seen on the raw EEG (due to

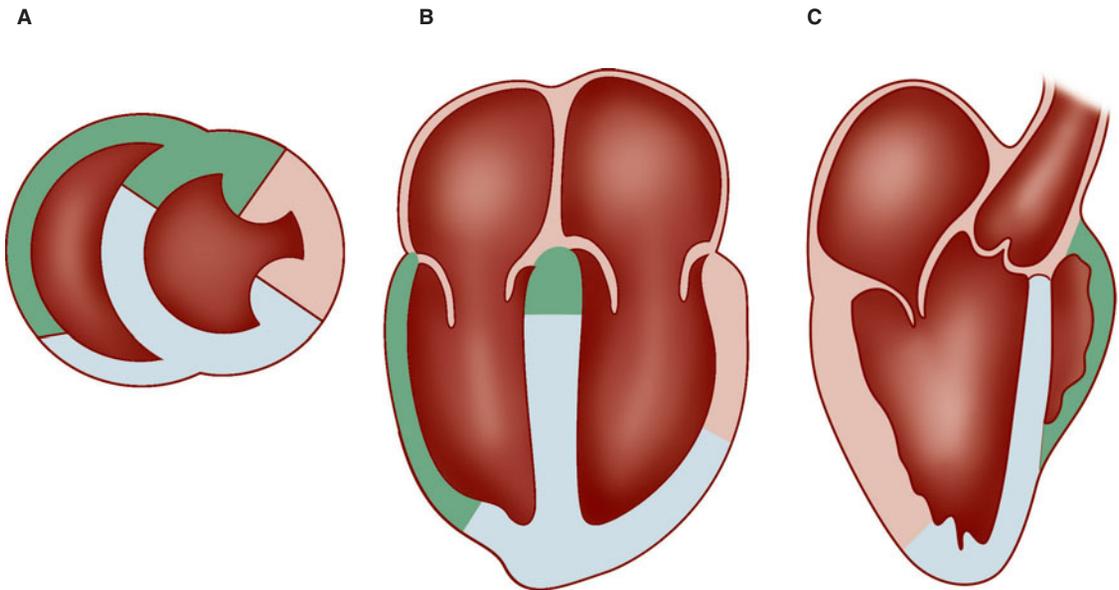

FIGURE 22-12 Coronary artery supply of the left and right ventricles in three views: the short-axis view (A), the four-chamber view (B), and the three-chamber

view (C). Green, right coronary artery; blue, left anterior descending artery; pink, left circumflex artery.

piezoelectric effects from compression of the pump tubing) but can usually be identified as such by computer processing.

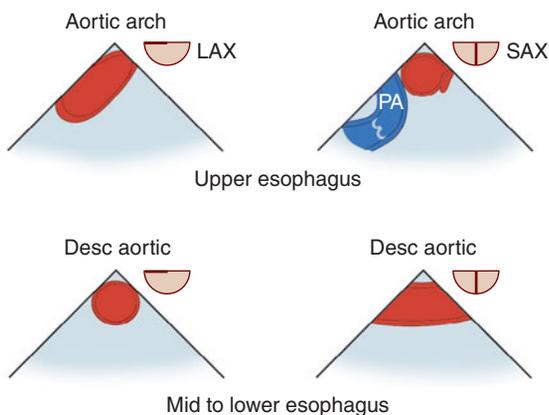

FIGURE 22-13 Upper esophageal TEE views of the aortic arch and descending aorta. The ascending aorta can be visualized in the upper mid-esophagus at 110–130° with antelexion at the aortic valve level (see Figures 22-2B and 22-6B).

J. Transcranial Doppler (TCD)

This modality provides noninvasive measurements of blood flow velocity in the middle cerebral artery, which is insonated through the temporal bone. TCD is useful for detecting cerebral emboli. Increased numbers of emboli detected by TCD or Doppler interrogation of the carotid artery have been associated with an increased risk of postoperative neurobehavioral dysfunction.

Induction of Anesthesia

Cardiac operations usually require general anesthesia, endotracheal intubation, and controlled ventilation. Some centers have used thoracic epidural anesthesia alone for minimally invasive surgery without CPB or combined thoracic epidural with light general endotracheal anesthesia for other forms of cardiac surgery. These techniques have never been popular in North America due to concerns about the risk of spinal hematomas following heparinization, the associated medical–legal consequences, and the limited evidence of an outcome benefit. Other centers use a single intrathecal morphine injection to provide postoperative analgesia.

For elective procedures, induction of general anesthesia should be performed in a smooth, controlled (but not necessarily “slow”) fashion often referred to as a cardiac induction. The principles are discussed in Chapter 21. Selection of anesthetic agents is generally less important than the way they are used. Indeed, studies have failed to show differences in long-term outcome with various anesthetic

8 techniques. Anesthetic dose requirements are variable and patient tolerance of inhaled anesthetics generally declines with declining ventricular function. Severely compromised patients should be given anesthetic agents in incremental, small doses. A series of challenges may be used to judge when anesthetic depth will allow intubation without a marked hypertensive response, while also avoiding hypotension from excessive anesthetic dosing. Blood pressure and heart rate are continuously evaluated following unconsciousness, insertion of an oral airway, urinary catheterization, and tracheal intubation. A sudden increase in heart rate or blood pressure may indicate light anesthesia and the need for more anesthetic prior to the next challenge, whereas a decrease or no change suggests that the patient is ready for the subsequent stimulus. Muscle relaxant is given after consciousness is lost. Reductions in blood pressure greater than 20% generally call for administration of a vasopressor (see below).

The period following intubation is often characterized by a gradual decrease in blood pressure resulting from the anesthetized state (often associated with vasodilation and decreased sympathetic tone) and a lack of surgical stimulation. Patients will usually respond to fluid boluses or a vasoconstrictor. Nevertheless, the administration of large amounts of intravenous fluids prior to the bypass may serve to accentuate the hemodilution associated with CPB (below). Small doses of phenylephrine (25–100 mcg), vasopressin (1–3 units), or ephedrine (5–10 mg) may be useful to avoid excessive hypotension. Following intubation and institution of controlled ventilation; arterial blood gases, hematocrit, serum potassium, and glucose concentrations are measured. The baseline ACT (normal <130 s) is best measured after skin incision.

Choice of Anesthetic Agents

Anesthetic techniques for cardiac surgery have evolved over the years. Successful techniques range from primarily volatile inhalation anesthesia to high-dose opioid totally intravenous techniques. In recent years, total intravenous anesthesia with short-acting agents and combinations of intravenous and volatile agents have become most popular.

A. “High-Dose” Opioid Anesthesia

This technique was originally developed to circumvent the myocardial depression associated with older volatile anesthetics, particularly halothane. But pure high-dose opioid anesthesia (eg, fentanyl, 50–100 mcg/kg, or sufentanil, 15–25 mcg/kg) produces prolonged postoperative respiratory depression (12–24 h), is associated with an unacceptably high incidence of patient awareness (recall) during surgery, and often fails to control the hypertensive response to stimulation in many patients with preserved left ventricular function. Other undesirable effects include skeletal muscle rigidity during induction and prolonged postoperative ileus. Moreover, simultaneous administration of benzodiazepines with large doses of opioids can produce hypotension and myocardial depression. Patients anesthetized with sufentanil (and other shorter acting agents) generally regain consciousness and can be extubated sooner than those anesthetized with fentanyl.

B. Total Intravenous Anesthesia (TIVA)

The drive for cost containment in cardiac surgery was a major impetus for development of anesthesia techniques with short-acting agents. Although the drugs may be costlier, large economic benefits resulted from earlier extubation, decreased intensive care unit (ICU) stays, earlier ambulation, and earlier hospital discharge (“fast-track” management). One technique employs induction with propofol (0.5–1.5 mg/kg followed by 25–100 mcg/kg/min), and modest doses of fentanyl (total doses of 5–7 mcg/kg) or remifentanyl (0–1 mcg/kg bolus followed by 0.25–1 mcg/kg/min). Target controlled infusion (TCI) employs software and hardware (computerized infusion pump) to deliver a drug and achieve a set concentration at the effect site based

on pharmacokinetic modeling. For propofol the clinician sets only the patient's age and weight, and the desired blood concentration on the Diprifusor, a TCI device widely available in countries outside North America. During cardiac surgery, this technique can be used for propofol with a target concentration of 1.5–2 mcg/mL. Whenever the very short-acting remifentanyl is used for painful surgery, provision must be made for postoperative analgesia after its discontinuation.

C. Mixed Intravenous/Inhalation Anesthesia

Renewed interest in volatile agents came about following studies demonstrating the protective effects of volatile agents on ischemic myocardium and an increased emphasis on fast-track recovery of cardiac patients. Selection of anesthetic agents is oriented to hemodynamic stability as well as early extubation (1–6 h). Propofol (0.5–1.5 mg/kg) or etomidate (0.1–0.3 mg/kg) is often used for induction. Induction usually follows sedation with small doses of midazolam (0.05 mg/kg). Opioids are given in small doses together with a volatile agent (0.5–1.5 minimum alveolar concentration [MAC]) for maintenance anesthesia and to blunt the sympathetic response to stimulation. The opioid may be given in small intermittent boluses, by continuous infusion, or both (Table 22–1). To facilitate fast-track management, typical total doses of fentanyl and sufentanil generally do not exceed 15 and 5 mcg/kg, respectively, and some clinicians combine much smaller doses of fentanyl or sufentanil with an analgesic dose of hydromorphone or morphine administered toward the end of CPB. Some clinicians also administer a low-dose infusion of propofol (25–50 mcg/kg/min) for maintenance.

TABLE 22–1 Opioid dosing compatible with early extubation after cardiac surgery.

Opioid	Loading Dose (mcg/kg)	Maintenance Infusion	Boluses (mcg/kg)
Fentanyl	1–5	1–3 mcg/kg/h	0.5–1
Sufentanil	0.25–1.25	0.25–0.75 mcg/kg/h	0.125–0.25
Remifentanyl	0.5–1	0.1–1 mcg/kg/min	0.25–1

The major advantage of volatile agents or infusions of remifentanyl or propofol, or both, is the ability to change the anesthetic concentration and depth rapidly. Isoflurane, sevoflurane, and desflurane are the most commonly used volatile anesthetics. Early laboratory reports of isoflurane inducing intracoronary steal have been overshadowed by later reports of myocardial protection. Isoflurane remains a commonly used volatile agent. Nitrous oxide is generally not used, particularly during the time interval between cannulation and decannulation, because of its tendency to expand any intravascular air bubbles that may form.

D. Other Techniques

The combination of ketamine with midazolam (or diazepam or propofol) for induction and maintenance of anesthesia is a useful technique, particularly in frail patients with hemodynamic compromise. It is associated with stable hemodynamics, reliable amnesia and analgesia, minimal postoperative respiratory depression, and rare (if any) psychotomimetic side effects. Ketamine and midazolam are compatible in solution, and may be mixed together in the same syringe or infusion bag in a 20:1 ratio. For induction, ketamine, 1–2 mg/kg, with midazolam, 0.05–0.1 mg/kg, is given as a slow intravenous bolus. Anesthesia can then be maintained by infusion of ketamine, 1.3–1.5 mg/kg/h, and midazolam, 0.065–0.075 mg/kg/h, or more easily with an inhaled agent. Hypertension following intubation or surgical stimulation can be treated with propofol or a volatile agent.

E. Muscle Relaxants

Muscle relaxation is helpful for intubation, to facilitate sternal retraction, and to prevent patient movement and shivering. Unless airway difficulties are expected, intubation may be accomplished after administration of a nondepolarizing muscle relaxant. The choice of muscle relaxant in the past was often based on the desired hemodynamic response. Modern, shorter acting agents such as rocuronium, vecuronium, and cisatracurium are commonly used and have almost no hemodynamic side effects of their own. Vecuronium, however, has been reported to markedly enhance bradycardia

associated with large doses of opioids, particularly sufentanil. Because of its vagolytic effects, pancuronium was often used in patients with marked bradycardia who were taking β -blocking agents, Succinylcholine remains appropriate for endotracheal intubation, particularly for rapid sequence induction. Judicious dosing and appropriate use of a peripheral nerve stimulator allow fast-tracking with any of these agents.

2. Prebypass Period

Following induction and intubation, the anesthetic course is typically characterized by an initial period of minimal stimulation (skin preparation and draping) that is frequently associated with hypotension, followed by discrete periods of intense stimulation that can produce tachycardia and hypertension. These periods of stimulation include the skin incision, sternotomy and sternal retraction, opening the pericardium, and, sometimes, aortic dissection. The anesthetic agent should be adjusted appropriately in anticipation of these events.

Accentuated vagal responses resulting in marked bradycardia and hypotension may occasionally be seen during sternal retraction or opening of the pericardium, perhaps more commonly in patients who have been taking β -adrenergic blocking agents or diltiazem.

Myocardial ischemia in the prebypass period is not always associated with hemodynamic perturbations such as tachycardia, hypertension, or hypotension. Prophylactic infusion of nitroglycerin (1–2 mcg/kg/min) has been studied many times and continues to be used but does not appear to reduce the incidence of ischemic episodes or to alter outcomes.

Anticoagulation

9 Anticoagulation must be established before CPB to prevent acute disseminated intravascular coagulation and formation of clots in the CPB pump. In most centers the adequacy of anticoagulation will be confirmed by measuring the ACT. An ACT longer than 400–480 s is considered adequate at most centers. Heparin, 300–400 units/kg, is usually given while the aortic pursestring sutures are placed before cannulation. Some surgeons prefer

to administer the heparin themselves directly into the right atrium. If heparin is administered by the anesthesiologist, it should be given through a reliable (usually central) intravenous line, and the ACT should be measured 3–5 min later. If the ACT is less than 400 s, additional heparin (100 units/kg) is given. Some drugs (eg, aprotinin) prolong the celite-activated ACT but not the kaolin-activated ACT; the kaolin-ACT should be used to assess adequacy of anticoagulation in these circumstances. Heparin concentration assays (see Reversal of Anticoagulation, below) measure heparin levels and not necessarily effect; these assays are therefore not reliable for measuring the degree of anticoagulation but can be used as an adjunct. A whole blood heparin concentration of 3–4 units/mL is usually sufficient for CPB. The high-dose thrombin time (HiTT) is not influenced by aprotinin but is more complicated to perform than a kaolin-ACT. HiTT cannot provide a preheparin control and does not provide an index for the adequacy of reversal with protamine (see below).

Resistance to heparin is occasionally encountered; many such patients have antithrombin III deficiency (acquired or congenital). Antithrombin III is a circulating serine protease that irreversibly binds and inactivates thrombin (as well as the activated forms of factors X, XI, XII, and XIII). When heparin complexes with antithrombin III, the anticoagulant activity of antithrombin III is enhanced 1000-fold. Patients with antithrombin III deficiency will achieve adequate anticoagulation following infusion of 2 units of fresh frozen plasma or antithrombin III concentrate. Alternatively, recombinant human antithrombin III may be administered. Milder forms of heparin resistance can be managed by administration of a modestly larger than normal dose of heparin.

Patients with a history of heparin-induced thrombocytopenia (HIT) require special consideration. These patients produce heparin-dependent (platelet factor 4) antibodies that agglutinate platelets and produce thrombocytopenia, sometimes associated with thromboembolism. If the history of HIT is remote and antibodies can no longer be demonstrated, heparin may safely be used for CPB. Other anticoagulants should be preferred in other

circumstances. When significant antibody titers are detected, alternative anticoagulants including hirudin, bivalirudin, ancrod, and argatroban may be considered, but experience with them is limited. Consultation with a hematologist may be helpful.

Bleeding Prophylaxis

Bleeding prophylaxis with antifibrinolytic agents may be initiated before or after anticoagulation. Some clinicians prefer to administer antifibrinolytic agents after heparinization to reduce the possible incidence of thrombotic complications; others fear that delayed administration may reduce antifibrinolytic efficacy. Antifibrinolytic therapy may be particularly useful for patients who are undergoing a repeat operation; who refuse blood products (such as Jehovah's Witnesses); who are at high risk for postoperative bleeding because of recent administration of glycoprotein IIb/IIIa inhibitors (abciximab [RheoPro], eptifibatid [Integrilin], or tirofiban [Aggrastat]); who have preexisting coagulopathy; and who are undergoing long and complicated procedures involving the heart or aorta. The antiplatelet effect of abciximab typically lasts 24–48 h; those of eptifibatid and tirofiban are 2–4 and 4–8 h, respectively. The combination of aspirin and the adenosine diphosphate receptor antagonist clopidogrel (Plavix) is also associated with excessive bleeding.

The antifibrinolytic agents currently available, ϵ -aminocaproic acid and tranexamic acid, do not affect the ACT and only rarely induce allergic reactions. ϵ -Aminocaproic acid is usually administered as a 50–75 mg/kg loading dose followed by a 20–25 mg/kg/h maintenance infusion (some clinicians use a standard 5–10 g loading dose followed by 1 g/h). Tranexamic acid is often dosed at 10 mg/kg followed by 1 mg/kg/h, although pharmacokinetic studies suggest that larger doses may more reliably maintain effective blood concentrations. Intraoperative collection of platelet-rich plasma by pheresis prior to CPB is employed by some centers; reinfusion following bypass may decrease bleeding and reduce transfusion requirements.

Cannulation

Placement of venous and arterial cannulas for CPB is a critical time. *After heparinization*, aortic

cannulation is usually done first because of the hemodynamic problems frequently associated with venous cannulation and to allow convenient and rapid transfusion from the pump oxygenator. The inflow cannula is most often placed in the ascending aorta. The small opening of most arterial cannulas produces a jet stream that, when not positioned properly, can cause aortic dissection or preferential flow of blood to the innominate artery. The systemic arterial pressure is customarily reduced to 90–100 mm Hg systolic during placement of the aortic cannula to reduce the likelihood of dissection. Air bubbles should be absent from the arterial cannula and inflow line, and adequacy of the connection between the arterial inflow line and the patient must be demonstrated before bypass is initiated. Failure to remove all air bubbles will result in air emboli, possibly into the coronary or cerebral circulations, whereas failure to enter the aorta may result in aortic dissection. Some clinicians routinely hand compress the carotid arteries during aortic cannulation to decrease the likelihood of cerebral emboli, but the efficacy of this technique is doubtful.

One or two venous cannulas are placed in the right atrium, usually through the right atrial appendage. One cannula is usually adequate for most coronary artery bypass and aortic valve operations. The single cannula used often has two portals (two-stage); when it is properly positioned, one opening is in the right atrium and the other is in the inferior vena cava.

Separate cannulas in the superior and inferior venae cavae are used for open-heart procedures. **11** Hypotension from impaired ventricular filling may occur during manipulation of the venae cavae and the heart. Venous cannulation also frequently precipitates atrial or, less commonly, ventricular arrhythmias. Premature atrial contractions and transient bursts of a supraventricular tachycardia are common. Sustained paroxysmal atrial tachycardia or atrial fibrillation frequently leads to hemodynamic deterioration, which may be treated pharmacologically, electrically, or by immediate initiation of bypass (provided that full anticoagulation has been confirmed). Malpositioning of the venous cannulas can interfere with venous return or impede venous drainage from the head and neck (superior vena cava

syndrome). Upon initiation of CPB, the former is manifested as inadequate volume in the venous reservoir, whereas the latter produces engorgement of the head and neck. Under these circumstances, central venous pressure may not increase if the tip of the central line is adjacent or very near the cannula.

3. Bypass Period

Initiation

Once the cannulas are properly placed and secured, the ACT is acceptable, and the perfusionist is ready, CPB is initiated. The clamps placed across the venous cannula(s) during insertion are removed, and the main CPB pump is started. Establishing the adequacy of venous return to the pump reservoir is critical. Normally, the reservoir level rises and CPB pump flow is gradually increased. If venous return is poor, as shown by a decreasing reservoir level, the pump prime will quickly empty and air can enter the pump circuit. When the venous reservoir falls the cannulas should be checked for proper placement and for forgotten clamps, kinks, or an air lock. Under these circumstances, pump flow should be slowed until the problem is resolved. Adding volume (blood or colloid) to the reservoir may be necessary. With full CPB and unimpeded venous drainage, the heart should empty; failure to empty or progressive distention implies malpositioning of the venous cannula or aortic regurgitation. In the rare case of severe aortic insufficiency that limits the extent of peripheral perfusion, immediate aortic cross-clamping (and cardioplegia) may be necessary.

Flow & Pressure

Systemic mean arterial pressure is closely monitored as pump flow is gradually increased to 2–2.5 L/min/m². At the onset of CPB, systemic arterial pressure usually decreases abruptly. Initial mean systemic arterial (radial) pressures of 30–40 mm Hg are not unusual. This decrease is usually attributed to abrupt hemodilution, which reduces blood viscosity and effectively lowers SVR. It is often treated with increased flow and vasopressors.

Persistent and excessive decreases (<30 mm Hg) should prompt a search for unrecognized aortic dissection. If dissection is present, CPB must be

temporarily stopped until a cannula can be placed distally in the “true” aortic lumen. Other possible causes for hypotension include inadequate pump flow from poor venous return or a pump malfunction, or pressure transducer error. Factitious hypertension has been reported when the right radial artery is used for monitoring and the aortic cannula is directed toward the innominate artery.

The relationship between pump flow, SVR, and mean systemic arterial blood pressure may be conceptualized as follows:

$$\text{Mean arterial pressure} = \text{Pump flow} \times \text{SVR}$$

Consequently, with a constant SVR, mean arterial pressure is proportional to pump flow. Similarly, at any given pump flow, mean arterial pressure is proportional to SVR. To maintain both adequate arterial pressures and blood flows one can manipulate pump flow and SVR. Most centers strive for blood flows of 2–2.5 L/min/m² (50–60 mL/kg/min) and mean arterial pressures between 50 and 80 mm Hg. Metabolic flow requirements generally decline with decreasing core body temperature. Evidence also suggests that during deep hypothermia (20–25°C), mean blood pressures as low as 30 mm Hg may still be consistent with adequate cerebral blood flow and cerebral oxygen delivery. SVR can be increased with phenylephrine, vasopressin, or norepinephrine.

Increased systemic arterial pressures (>150 mm Hg) are deleterious and may promote aortic dissection or cerebral hemorrhage. Generally, when mean arterial pressure exceeds 100 mm Hg, hypertension is said to exist and is treated by decreasing pump flow or increasing the concentration of a volatile agent to the oxygenator inflow gas. In the rare instance that the hypertension is refractory to these maneuvers or if pump flow is already low, a vasodilator such as clevidipine, nicardipine, or nitroprusside is used.

Monitoring

Additional monitoring during CPB includes the pump flow rate, venous reservoir level, arterial inflow line pressure (see above), blood (perfusate and venous) and myocardial temperatures, and in-line (arterial and venous) oxygen saturations. In-line pH, CO₂ tension, and oxygen tension sensors are also available. Blood gas tensions and pH should be

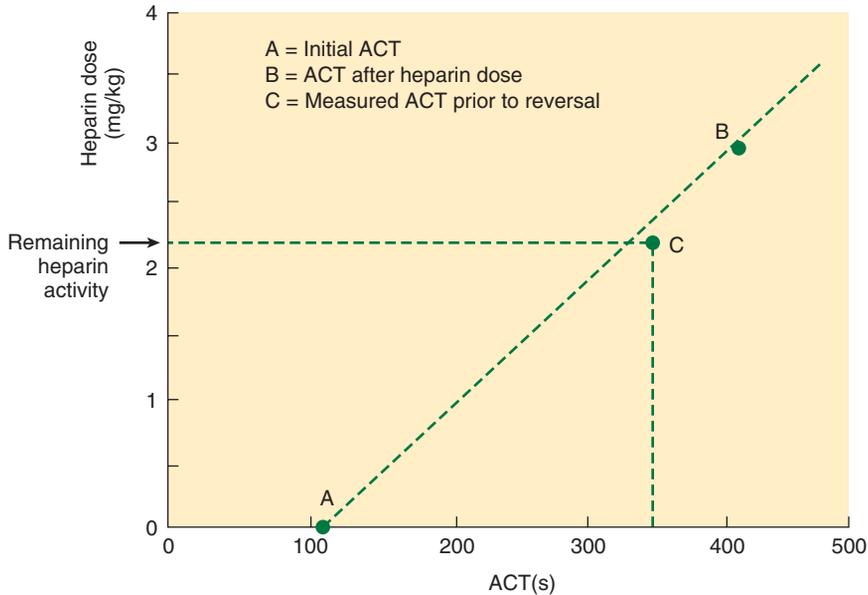

FIGURE 22-14 Heparin dose–response curve.

Activated clotting time (ACT) in seconds versus total heparin dose in milligrams per kilogram. 1. Plot the initial ACT on the x-axis. 2. Plot the ACT after heparinization. 3. Draw the line defined by these two points. 4. If additional anticoagulation is needed, find the desired ACT on that line. The amount of additional heparin needed is the difference on the y-axis between the present ACT

and the desired ACT. 5. If the third point does not lie on the original line, a new line is drawn originating from the baseline ACT and passing midway between the other two points. 6. For reversal of anticoagulation, the protamine dose is based on the remaining heparin activity, estimated to be the heparin dose corresponding to the latest ACT on the dose–response line.

confirmed by direct measurements (see below). In the absence of hypoxemia, low venous oxygen saturations (<70%), a progressive metabolic acidosis, or reduced urinary output may indicate inadequate flow rates.

During bypass, arterial inflow line pressure is almost always greater than the systemic arterial pressure recorded from a radial artery or even an aortic catheter. The difference in pressure represents the pressure drop across the arterial filter, the arterial tubing, and the narrow opening of the aortic cannula. Nonetheless, monitoring this pressure is important in detecting problems with an arterial inflow line. Inflow pressures should remain below 300 mm Hg; higher pressures may indicate a clogged arterial filter, obstruction of the arterial tubing or cannula, or aortic dissection.

Serial ACT, hematocrit, and potassium measurements are performed during CPB. Blood

glucose should be checked even in patients without a history of diabetes. The ACT is measured immediately after bypass and then every 20–30 min thereafter. Cooling generally increases the half-life of heparin and prolongs its effect. Some centers calculate a heparin dose–response curve to guide calculation of heparin dosing and protamine reversal (Figure 22–14). The hematocrit is usually not allowed fall much below 20–25%. Red cell transfusions into the pump reservoir may be necessary. Marked increases in serum potassium concentrations (secondary to cardioplegia) are usually treated with a furosemide-induced diuresis.

Hypothermia & Cardioplegia

Moderate (26–32°C) or deep (20–25°C) hypothermia is used routinely for many procedures. The lower the temperature, the longer the time required for cooling and rewarming. Low temperatures,

however, permit lower CPB flows to be used safely. At a temperature of 20°C, flows as low as 1.2 L/min/m² may be adequate.

Hypothermia produces characteristic changes in the ECG including the Osborne wave, a characteristic positive deflection between the QRS and ST segments. Ventricular fibrillation often occurs as the heart is cooled below 28–29°C. Cardioplegia should be established immediately, as fibrillation consumes high-energy phosphates at a greater rate than slower rhythms. Cardioplegia is achieved by cross-clamping the ascending aorta proximal to the aortic inflow cannula and (as previously described) infusing cardioplegia solution through a small catheter proximal to the cross-clamp or directly into the coronary ostia if the aorta is opened (eg, for aortic valve replacement). Many surgeons routinely employ retrograde cardioplegia via a catheter in the coronary sinus (see above). During aortocoronary bypass grafting, cardioplegia solution may also be given through the graft when the surgeon elects to perform the distal anastomosis first.

Ventilation

Ventilation of the lungs is discontinued when adequate pump flows are reached and the heart stops ejecting blood. Following institution of full CPB, ventricular ejection continues briefly until the left ventricular volume reaches a critically low level. Discontinuing ventilation prematurely when there is any remaining pulmonary blood flow acts as a right-to-left shunt that can promote hypoxemia. The importance of this mechanism depends on the relative ratio of remaining pulmonary blood flow to pump flow. At some centers, once ventilation is stopped, oxygen flow is continued in the anesthesia circuit with a small amount of continuous positive airway pressure (5 cm H₂O) in the hope of preventing postoperative pulmonary dysfunction. Most centers either stop all gas flow or continue a low flow of oxygen (1–2 L/min) in the anesthesia circuit. Ventilation is resumed at the conclusion of CPB in anticipation of the heart beginning to eject blood.

Management of Respiratory Gases

There formerly was controversy about whether to use temperature-corrected (pH stat) or uncorrected (α -stat) arterial blood gas tensions

during hypothermic CPB in adults. The controversy stemmed from the fact that the solubility of a gas increases and the neutral pH (ie, the pH at which concentrations of H⁺ and OH⁻ ions are the same) of water increases with hypothermia. As a result of the former effect, although total CO₂ content does not change (in a closed system), the partial pressure of CO₂ will decrease as blood temperature drops. The problem is most significant for arterial CO₂ tension because of its effect on arterial pH and cerebral blood flow. As the temperature decreases, the plasma bicarbonate concentration does not change, but the decrease in arterial CO₂ tension tends to increase pH and make blood alkalotic (by normothermic definitions). Blood with a CO₂ tension of 40 mm Hg and a pH of 7.40 at 37°C, when cooled to 25°C, will have a CO₂ tension of about 23 mm Hg and a pH of 7.60.

Normally—regardless of the patient's temperature—blood samples are heated to 37°C in blood gas analyzers before gas tensions are measured. If a temperature-corrected reading is desired, a table or a program in the blood gas machine can be used to estimate what would be the gas tension and pH if they had been measured at the patient's temperature. The practice of temperature correcting gas tensions with the goal of maintaining a constant CO₂ tension of 40 mm Hg and a constant pH of 7.40 during hypothermia is referred to as **pH-stat management**. During hypothermic CPB, pH-stat management, which may require adding CO₂ to the oxygenator gas inflow, increases total blood CO₂ content. Under these conditions, cerebral blood flow increases (due to increased CO₂ tension relative to α -stat management) more than is required based on oxygen consumption. Increased cerebral blood flow is useful to increase uniformity of brain cooling prior to deep hypothermic circulatory arrest (more often used in children than adults). On the other hand, increased cerebral blood flow can also direct a greater fraction of atheromatous arterial emboli to the brain—a greater concern than uniformity of brain cooling during cardiac surgery in adults.

The use of uncorrected gas tensions during hypothermia— **α -stat management**—is the rule in adults and is common in children when circulatory arrest will not be used. The basis of this approach is that preservation of normal protein function

depends on maintaining a constant state of intracellular electroneutrality (the balance of charges on proteins). At physiological pH, these charges are primarily located on the imidazole rings of histidine residues (referred to as α residues). Moreover, as temperature decreases, K_w —the dissociation constant for water—also decreases (pK_w increases). Therefore, at lower temperatures, the electroneutrality of aqueous solutions, where $[H^+] = [OH^-]$, corresponds to a lower $[H^+]$ (a higher pH). Hypothermic “alkalosis” thus does not necessarily reflect $[OH^-] > [H^+]$ but rather an absolute decrease in both $[H^+]$ and $[OH^-]$. Hypothermic CPB with α -stat management does not require addition of CO_2 to the oxygenator: the total CO_2 content of blood and the electroneutrality are unchanged. In contrast to pH-stat management, α -stat management appears to preserve cerebral autoregulation of blood flow. Despite the theoretical and observed differences, in most studies comparisons between the two techniques fail to reveal appreciable differences in patient outcomes except in children undergoing circulatory arrest.

Anesthesia

12 Hypothermia ($<34^\circ C$) potentiates general anesthetic potency, but failure to give anesthetic agents, particularly during rewarming on CPB, may result in awareness and recall. With light anesthesia hypertension may be seen and, if muscle paralysis is also allowed to wear off, the patient may move. Consequently, additional doses of anesthetic agents may be necessary during CPB. Reduced concentrations of a volatile agent (eg, 0.5–0.75% isoflurane) via the oxygenator are frequently used. The volatile agent concentration may need to be reduced to a value that does not depress contractility immediately prior to termination of bypass if residual myocardial depression is apparent. Those relying on opioids and benzodiazepines for anesthesia during CPB may need to administer additional doses of these agents or commence a propofol infusion. Some clinicians routinely administer a benzodiazepine (eg, midazolam) or scopolamine (0.2–0.4 mg) when rewarming is initiated. Alternatively, a propofol, opioid, or ketamine–midazolam infusion may be continued throughout CPB. Sweating during rewarming is common and usually indicates a hypothalamic

response to perfusion with warm blood (rather than “light” anesthesia). During rewarming, blood temperature should not exceed core temperature by more than $2^\circ C$.

Cerebral Protection

The incidence of neurobehavioral deficits after CPB varies widely, depending on how long after surgery the examination is performed and the criteria for diagnosis. In the first week after surgery the incidence may be as high as 80%. Fortunately, in most instances, these deficits are transient. Neurobehavioral deficits detectable 8 weeks or more (20–25%) after operation or strokes (2–6%) are less common. Factors that have been associated with neurological sequelae include increased numbers of cerebral emboli, combined intracardiac (valvular) and coronary procedures, advanced age, and preexisting cerebrovascular disease.

During open-heart procedures, deairing of cardiac chambers, assumption of a head-down position, and venting before and during initial cardiac ejection are important in preventing gas emboli. Some centers fill the surgical field with CO_2 , a gas that if entrained and embolized will more rapidly be reabsorbed. TEE can detect residual air within the heart and the need for further deairing procedures. During coronary bypass procedures, minimizing the amount of aortic manipulation, the number of aortic clampings, and the number of graft sites on the surface of the aorta, and using sutureless proximal anastomotic devices may help reduce atheromatous emboli. Palpation of the aorta, TEE, and especially epiaortic echocardiography can help identify high-risk patients and guide management. Epiaortic echocardiography is the most sensitive and specific technique.

Although embolic phenomena appear responsible for most neurological deficits, the contribution of cerebral hypoperfusion remains unclear. The data are controversial and sparse that prophylactic drug infusions (eg, barbiturates or propofol to suppress electroencephalographic activity) immediately before and during intracardiac (open ventricle) procedures will decrease the incidence and severity of neurological deficits. Prior to circulatory arrest with very deep hypothermia, some clinicians administer a corticosteroid (methylprednisolone,

30 mg/kg, or the equivalent dose of dexamethasone) and mannitol (0.5 g/kg). The head is also covered with ice bags (avoiding the eyes). Surface cooling delays rewarming and may also facilitate adequacy of brain cooling. A long list of drugs has been tested and has failed to improve cerebral outcomes after heart surgery. Human studies during cardiac surgery have not shown improved neurobehavioral outcomes with prophylactic administration of calcium channel blockers (nimodipine), *N*-methyl-D-aspartate (NMDA) antagonists (remacemide), free radical scavengers (pegorgotein), sedative-hypnotics (thiopental, propofol, or clome-thiazole), or lazaroids (tirilazad).

4. Termination of CPB

Discontinuation of bypass is accomplished by a series of necessary procedures and conditions:

1. Rewarming must be completed.
2. Air must be evacuated from the heart and any bypass grafts.
3. The aortic cross-clamp must be removed and the heart must beat.
4. Lung ventilation must be resumed.

The surgeon's decision about when to rewarm is important; adequate rewarming requires time, but rewarming too soon removes the protective effects of hypothermia. Rapid rewarming often results in large temperature gradients between well-perfused organs and peripheral vasoconstricted tissues; subsequent equilibration following separation from CPB decreases core temperature again. An excessive gradient between the infusate temperature and the patient's core temperature can result in deleterious brain hyperthermia. Infusion of a vasodilator drug (nitroprusside, isoflurane, or phentolamine [primarily in children]) by allowing higher pump flows often speeds the rewarming process and decreases large temperature gradients. Some believe that allowing some pulsatile flow (ventricular ejection) may also speed rewarming. Excessively rapid rewarming, however, can result in the formation of gas bubbles in the bloodstream as the solubility of gases rapidly decreases. If the heart fibrillates during rewarming, direct electrical defibrillation (5–10 J) may be

necessary. Administration of lidocaine, 100–200 mg, and magnesium sulfate, 1–2 g, prior to removal of aortic cross-clamping is a common protocol and may decrease the likelihood of fibrillation. Many clinicians advocate a head-down position while intracardiac air is being evacuated to decrease the likelihood of cerebral emboli. Lung inflation facilitates expulsion of (left-sided) intracardiac air by compressing pulmonary vessels and returning blood into the left heart. TEE is useful in detecting residual intracardiac air. Initial reinflation of the lungs requires greater than normal airway pressure and should generally be done under direct visualization of the surgical field because excessive lung expansion can interfere with internal mammary artery grafts.

General guidelines for separation from CPB include the following:

- The core body temperature should be at least 37°C.
- A stable rhythm must be present. Atrioventricular pacing is often used and confers the benefit of a properly timed atrial systole. Persistence of atrioventricular block should prompt measurement of serum potassium concentration. If hyperkalemia is present, it can be treated with calcium, NaHCO₃, furosemide, or glucose and insulin.
- The heart rate must be adequate (generally 80–100 beats/min). Slow heart rates are generally treated by pacing. Many inotropic agents will also increase heart rate. Supraventricular tachycardias generally require cardioversion.
- Laboratory values must be within acceptable limits. Significant acidosis (pH < 7.20), hypocalcemia (ionized), and hyperkalemia (>5.5 mEq/L) should be treated; ideally the hematocrit should exceed 22%; however, a hematocrit <22% should not by itself trigger transfusion of red blood cells at this time. When CPB reservoir volume and flow are adequate, ultrafiltration may be used to increase the hematocrit.
- Adequate ventilation with 100% oxygen must have been resumed.
- All monitors should be rechecked for proper function and recalibrated if necessary.

Weaning from CPB

CPB should be discontinued as systemic arterial pressure, ventricular volumes and filling pressures, and cardiac function (on TEE) are assessed. Central aortic pressure may be measured directly and should be compared with the radial artery pressure and cuff pressure (if there is a disparity). A reversal of the normal systolic pressure gradient, with aortic pressure being greater than radial pressure, is often seen immediately postbypass. This has been attributed to opening of arteriovenous connections in the hand as a consequence of rewarming. Central aortic root pressure can also be estimated by palpation by an experienced surgeon. Right ventricular volume and contractility can be estimated visually, whereas filling pressures are measured directly by central venous, pulmonary artery, or left atrial catheters. Cardiac output can be measured by thermodilution. TEE can define adequacy of end-diastolic volumes, right and left ventricular contractility, and valvular function.

Weaning is typically accomplished by progressively clamping the venous return line (tubing). As the beating heart fills, ventricular ejection resumes. Pump flow is gradually decreased as

arterial pressure rises. Once the venous line is completely occluded and systolic arterial pressure is judged to be adequate (>80–90 mm Hg), pump flow is stopped and the patient is evaluated. **Some surgeons wean by clamping the venous line and then progressively “filling” the patient with arterial inflow.**

Most patients fall into one of four groups when coming off bypass (Table 22–2). Patients with good ventricular function are usually quick to develop good blood pressure and cardiac output and can be separated from CPB immediately. Hyperdynamic patients can also be rapidly weaned. These patients emerge from CPB with a very low SVR, demonstrating good contractility and adequate volume, but have low arterial pressure; their hematocrit is often reduced (<22%). Diuresis (off CPB) or red blood cell transfusions increase arterial blood pressure.

Hypovolemic patients include those with normal ventricular function and those with varying degrees of impairment. Those with preserved myocardial function quickly respond to 100-mL aliquots of pump blood infused via the aortic cannula. Blood pressure and cardiac output rise with each bolus,

TABLE 22–2 Post-CPB hemodynamic subgroups.¹

	Group I: Vigorous	Group II: Hypovolemic	Group IIIA: LV Pump Failure	Group IIIB: RV Failure	Group IV: Vasodilated (Hyperdynamic)
Blood pressure	Normal	Low	Low	Low	Low
Central venous pressure	Normal	Low	Normal or high	High	Normal or low
Pulmonary wedge pressure	Normal	Low	High	Normal or high	Normal or low
TEE findings	Normal	Underfilled RV/LV	Reduced LV performance	Dilated RV	Normal or underfilled RV/LV
Cardiac output	Normal	Low	Low	Low	High
Systemic vascular resistance	Normal	Low, normal, or high	Low, normal or high	Normal or high	Low
Treatment	None	Volume	Inotrope; IABP, LVAD	Inotrope, pulmonary vasodilator; RVAD	Vasoconstrictor, volume

and the increase becomes progressively more sustained. Most of these patients maintain good blood pressure and cardiac output with a left ventricular filling pressure below 10–15 mm Hg. Ventricular impairment should be suspected (when definitive diagnosis using TEE is not available) in hypovolemic patients whose filling pressures rise during volume infusion without appreciable changes in blood pressure or cardiac output or in those who require filling pressures above 10–15 mm Hg. Ventricular dysfunction is easily diagnosed by TEE.

Patients with pump failure emerge from CPB with a sluggish, poorly contracting heart that progressively distends. In such cases, CPB may need to be reinstated while inotropic therapy is initiated; alternatively, if the patient is less unstable, a positive inotrope (epinephrine, dopamine, dobutamine) can be administered while the patient is observed for improvement. If the patient does not respond to reasonable doses of one of these three agents, milrinone can be added. In patients with poor preoperative ventricular function milrinone may be administered as the first-line agent prior to separation from CPB. In the rare instance that SVR is increased, afterload reduction with nitroprusside or milrinone can be tried. The patient should be evaluated for unrecognized ischemia (kinked graft or coronary vasospasm), valvular dysfunction, shunting, or right ventricular failure (the distention is primarily right sided). TEE will facilitate the diagnosis in these cases.

If drug therapies fail, **intraaortic balloon pump (IABP)** counterpulsation should be initiated while the patient is “rested” on CPB. The efficacy of IABP depends on proper timing of inflation and deflation of the balloon (**Figure 22–15**). **The balloon should inflate just after the dicrotic notch is seen on the intraaortic pressure tracing to augment diastolic blood pressure and coronary flow after closure of the aortic valve.** Inflation too early increases afterload and exacerbates aortic regurgitation, whereas late inflation reduces diastolic augmentation. Balloon deflation should be timed just prior to left ventricular ejection to decrease its afterload. Early deflation makes diastolic augmentation and afterload reduction less effective. Use of a left or right ventricular assist device (LVAD or

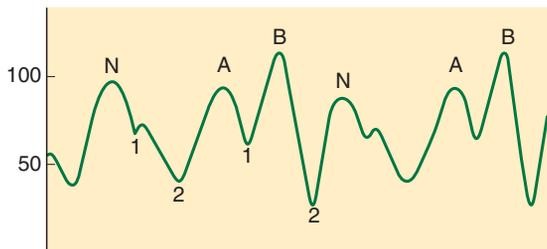

FIGURE 22–15 A central arterial waveform during 1:2 intraaortic balloon pump counterpulsation. Ideally the balloon, which is positioned in the descending aorta just distal to the left subclavian artery, should inflate at the dicrotic notch (1) and be completely deflated just as the left ventricle begins to eject (2). Note the lower end-diastolic pressures after balloon augmentation and slightly lower systolic pressure in the following beat. N, nonaugmented beat; A, augmented beat; B, balloon augmentation.

RVAD, respectively), may be necessary for patients with refractory pump failure. If myocardial stunning is a major contributor or there are areas of hibernating myocardium, a delayed improvement in contractile function may allow complete weaning from all drugs and support devices only after 12–48 h of therapy. Circulatory assist devices, such as the Abiomed and HeartMate, can be used as a bridge to cardiac transplantation; the former can be used for several days whereas the latter device can be left in place for months to years.

Many clinicians believe that positive inotropes should not routinely be used in patients coming off CPB because they increase myocardial oxygen demand. The routine use of calcium similarly may worsen ischemic injury and may contribute to coronary spasm (particularly in patients who were taking calcium channel blockers preoperatively). Nevertheless, there are centers that administer calcium salts or a positive inotrope (eg, dobutamine), or both, to every patient at the conclusion of CPB. Commonly used positive inotropes and vasopressors are listed in **Table 22–3**. Epinephrine, dopamine, and dobutamine are the most commonly used agents. Clinically, epinephrine is the most potent inotrope and is often effective in increasing both cardiac output and systemic blood pressure when others agents have failed. In lower doses, it

TABLE 22-3 Vasopressors and inotropic agents.¹

has predominantly β agonist activity. Dobutamine, unlike dopamine, does not increase filling pressures and *may* be associated with less tachycardia than dopamine; unfortunately, cardiac output often increases without significant changes in blood pressure. On the other hand, dopamine may improve renal blood flow (at reduced doses) and is often more effective in increasing blood pressure than in increasing cardiac output. Interestingly, when infused to increase cardiac output to similar extents, epinephrine is associated with no more increase (and perhaps less) in heart rate than dobutamine. Inamrinone and milrinone, both selective phosphodiesterase type III inhibitors, are inotropes with arterial and venous dilator properties; milrinone may be less likely than inamrinone to decrease the platelet count. In studies of patients with chronic heart failure these two inodilators, unlike other inotropes, did not appreciably increase myocardial

oxygen consumption. The combination of an inodilator (usually milrinone) and a β -adrenergic agonist results in at least additive (and possibly synergistic) inotropic effects. Norepinephrine is useful for increasing SVR but may compromise splanchnic and renal blood flow at increased doses. Some clinicians use norepinephrine in combination with phosphodiesterase inhibitors to prevent excessive reductions in systemic arterial pressure. Arginine vasopressin may be used in patients with refractory hypotension, a low SVR, and resistance to norepinephrine. Inhaled nitric oxide and prostaglandin E₁ may also be helpful for refractory pulmonary hypertension and right ventricular failure (Table 22-4); nitric oxide has the added advantage of not decreasing systemic arterial pressure. Studies have not confirmed outcome benefits to the use of nesiritide, a human B-type natriuretic peptide, thyroid hormone (T₃), or glucose–insulin–potassium

TABLE 22-4 Vasodilators.

Drug	Dosage
Clevidipine	1–16 mg/hr
Fenoldopam	0.03–0.6 mcg/kg/min
Nicardipine	2.5–10 mg/h
Nitric oxide	10–60 ppm (inhaled)
Nitroglycerin	0.5–10 mcg/kg/min
Nitroprusside	0.5–10 mcg/kg/min
Prostaglandin E ₁	0.01–0.2 mcg/kg/min

infusions for vasoactive/inotropic support after CPB.

5. Postbypass Period

Following CPB, bleeding is controlled, bypass cannulas are removed, anticoagulation is reversed, and the chest is closed. Systolic arterial pressure is generally maintained at less than 140 mm Hg to minimize bleeding. Checking for bleeding, particularly from the posterior surface of the heart, requires lifting the heart, which can cause periods of precipitous hypotension. Some surgeons will need to be informed of the extent and duration of the hypotension; others have greater situational awareness. The atrial cannula(s) is removed before the aortic cannula in case the latter must be used to rapidly administer volume to the patient. Most patients need additional blood volume after termination of bypass. Administration of blood, colloids, and crystalloid is guided by filling pressures (and observation of the left ventricle on TEE), and the postbypass hematocrit. A final hematocrit of 25–30% is desirable, but is not mandatory. Blood remaining in the CPB reservoir can be transfused via the aortic cannula (while it remains in place) or washed and processed by a cell-saver device and given intravenously. Frequent ventricular ectopy may reflect electrolyte disturbances or residual ischemia and should be treated with amiodarone (or lidocaine or procainamide); hypokalemia or hypomagnesemia should be corrected. Ventricular

arrhythmias in this setting can rapidly deteriorate into ventricular tachycardia and fibrillation.

Reversal of Anticoagulation

Once hemostasis is judged acceptable and the patient continues to remain stable, heparin activity is reversed with protamine. **Protamine** is a highly positively charged protein that binds and effectively inactivates heparin (a highly negatively charged polysaccharide). Heparin–protamine complexes are then removed by the reticuloendothelial system. Protamine can be dosed in varying ways, but the results of all techniques should be checked for adequacy by repeating the ACT 3–5 min after completion of the protamine infusion. Additional incremental doses of protamine may be necessary.

One dosing technique bases the protamine dose on the amount of heparin initially required to produce the desired ACT; the protamine is then given in a ratio of 1–1.3 mg of protamine per 100 units of heparin. A still simpler approach is to give adult patients a defined dose (eg, 3–4 mg/kg) then check for adequacy of reversal. Another approach calculates the protamine dose based on the heparin dose–response curve (Figure 22-14). Automated heparin–protamine titration assays effectively measure residual heparin concentration and can also be used to calculate the protamine dose. The justification for using this methodology is the observation that when protamine is given in excess it may have anticoagulant activity, although this has never been demonstrated in humans. This approach also assumes that administered protamine remains in circulation for a prolonged time (which has been proven false in studies of patients undergoing cardiac surgery). To accomplish the heparin:protamine titration, premeasured amounts of protamine are added in varying quantities to several wells, each containing a blood sample. The well whose protamine concentration best matches the heparin concentration will clot first. Clotting will be prolonged in wells containing either too much or too little protamine. The protamine dose can then be estimated by multiplying the concentration in the tube that clots first by the patient's calculated blood volume. Supplemental protamine (50–100 mg) should be

considered after administration of unwashed blood remaining in the pump reservoir after CPB because that blood contains heparin.

13 Protamine administration can result in a number of adverse hemodynamic effects, some of which are immunological in origin. Protamine given slowly (5–10 min) usually has few effects; when given more rapidly it produces a fairly consistent vasodilation that is easily treated with blood from the pump oxygenator and small doses of phenylephrine. Catastrophic protamine reactions often include myocardial depression and marked pulmonary hypertension. Diabetic patients previously maintained on protamine-containing insulin (such as NPH) may be at increased risk for adverse reactions to protamine.

Persistent Bleeding

14 Persistent bleeding often follows prolonged durations of bypass (>2 h) and in most instances has multiple causes. Inadequate surgical control of bleeding sites, incomplete reversal of heparin, thrombocytopenia, platelet dysfunction, hypothermia-induced coagulation defects, and undiagnosed preoperative hemostatic defects, or newly acquired factor deficiency or hypofibrinogenemia may be responsible. The absence (or loss) of clot formation may be noted in the surgical field. Normally, the ACT should return to baseline following administration of protamine; additional doses of protamine (25–50 mg) may be necessary. Reheparinization (heparin rebound) after apparent adequate reversal is poorly understood but often attributed to redistribution of peripherally bound heparin to the central compartment and to the exceedingly short persistence of protamine in blood. Hypothermia (<35°C) accentuates hemostatic defects and should be corrected. The administration of platelets and coagulation factors should be guided by additional coagulation studies, but empiric therapy may be necessary when such tests are not readily or promptly available as well as when treating massive transfusion. On the other hand, there can be abnormalities in multiple tests of coagulation whether or not there is bleeding, so the true diagnostic specificity and reliability of these tests is often overstated.

If diffuse oozing continues despite adequate surgical hemostasis and the ACT is normal or the heparin–protamine titration assay shows no residual heparin, thrombocytopenia or platelet dysfunction is most likely. Comparison of a conventional ACT with an ACT measured in the presence of heparinase (an enzyme that cleaves and inactivates heparin) can confirm that no residual heparin requiring protamine reversal remains present when both tests provide the same result. Platelet defects are recognized complications of CPB, which may necessitate platelet transfusion. Significant depletion of coagulation factors, particularly factors V and VIII, during CPB is less commonly responsible for bleeding but should be treated with fresh frozen plasma; both the prothrombin time and partial thromboplastin time are usually prolonged in such instances. Hypofibrinogenemia (fibrinogen level <100 mg/dL or a prolonged thrombin time without residual heparin) should be treated with cryoprecipitate. Desmopressin (DDAVP), 0.3 mcg/kg (intravenously over 20 min), can increase the activity of factors VIII and XII and the von Willebrand factor by releasing them from the vascular endothelium. DDAVP may be effective in reversing qualitative platelet defects in some patients but is not recommended for routine use. Accelerated fibrinolysis may occasionally be encountered following CPB and should be treated with ϵ -aminocaproic acid or tranexamic acid if one or the other of these agents has not already been given; the diagnosis should be confirmed by elevated fibrin degradation products (≥ 32 mg/mL), or evidence of clot lysis on thromboelastography. Increasingly, factor VII concentrate (at a cost of many thousands of dollars) is administered as a “last resort” in the setting of coagulopathic bleeding following cardiac surgery.

Anesthesia

Unless a continuous intravenous infusion technique is used, additional anesthetic agents are necessary following CPB; the choice may be determined by the hemodynamic response of the patient following CPB. Traditional teaching would have unstable patients receive small amounts of an opioid, benzodiazepine, or scopolamine, whereas anesthetic doses of a volatile agent might be recommended for

hyperdynamic patients. Nevertheless, we have found that most patients tolerate modest doses of volatile agents or propofol infusion. Patients with hypertension that is unresponsive to adequate anesthesia with opioids and either a volatile agent or propofol (or both) should receive a vasodilator such as nitroglycerin, nitroprusside, clevidipine, or nicardipine (Table 22-4). Fenoldopam may be used and has the added benefit of increasing renal blood flow which might possibly improve kidney function in the early postoperative period.

It is common for an opioid (morphine or hydromorphone) and either propofol or dexmedetomidine to be given to provide analgesia and sedation during transfer to the ICU and analgesia (after discontinuation of the propofol or dexmedetomidine) during emergence.

Transportation

Transporting patients with critical illness from the operating room to the ICU is a consistently nerve-racking and occasionally hazardous process that is complicated by the possibilities of monitor failure, overdosage or interruption of drug infusions, and hemodynamic instability en route. Portable monitoring equipment, infusion pumps, and a full oxygen cylinder with a self-inflating bag for ventilation should be readied prior to the end of the operation. Minimum monitoring during transportation includes the ECG, arterial blood pressure, and pulse oximetry. A spare endotracheal tube, laryngoscope, succinylcholine, and emergency resuscitation drugs should also accompany the patient. Upon arrival in the ICU, the patient should be attached to the ventilator, breath sounds should be checked, and an orderly transfer of monitors and infusions (one at a time) should follow. The ICU staff should be given a brief summary of the procedure, intraoperative problems, current drug therapy, and any expected difficulties. Many centers insist on a standard protocol for the “hand off.”

6. Postoperative Period

Depending on the patient, the type of surgery, and local practices, most patients are mechanically ventilated for 1–12 h postoperatively. Sedation may be maintained by a propofol or dexmedetomidine

infusion. The emphasis in the first few postoperative hours should be on maintaining hemodynamic stability and monitoring for excessive postoperative bleeding. Chest tube drainage in the first 2 h of more than 250–300 mL/h (10 mL/kg/h)—in the absence of a hemostatic defect—is excessive and may require surgical reexploration. Subsequent drainage that exceeds 100 mL/h is also worrisome. Intrathoracic bleeding at a site not adequately drained may cause cardiac tamponade, requiring immediate reopening of the chest.

Hypertension despite analgesia and sedation is a common postoperative problem and should generally be treated promptly so as not to exacerbate bleeding or myocardial ischemia. Nitroprusside, nitroglycerin, clevidipine, or nicardipine is generally used. β Blockade may be particularly useful for patients recovering from coronary artery surgery.

Fluid replacement may be guided by filling pressures, echocardiography, or by responses to treatment. Most patients present with relative hypovolemia for several hours following operation. Hypokalemia (from intraoperative diuretics) often develops and requires replacement. Postoperative hypomagnesemia is common in patients who receive no magnesium supplementation intraoperatively.

Extubation should be considered only when muscle paralysis has worn off (or been reversed) and the patient is hemodynamically stable. Caution should be exercised in obese and elderly patients and those with underlying pulmonary disease. Cardiothoracic procedures are typically associated with marked decreases in functional residual capacity and postoperative diaphragmatic dysfunction.

Off-Pump Coronary Artery Bypass Surgery

The development of advanced epicardial stabilizing devices, such as the Octopus (Figure 22-16), has facilitated coronary artery bypass grafting without the use of CPB, also known as off-pump coronary artery bypass (OPCAB). This type of retractor uses suction to stabilize and lift the anastomotic site rather than compress it down, which allows for

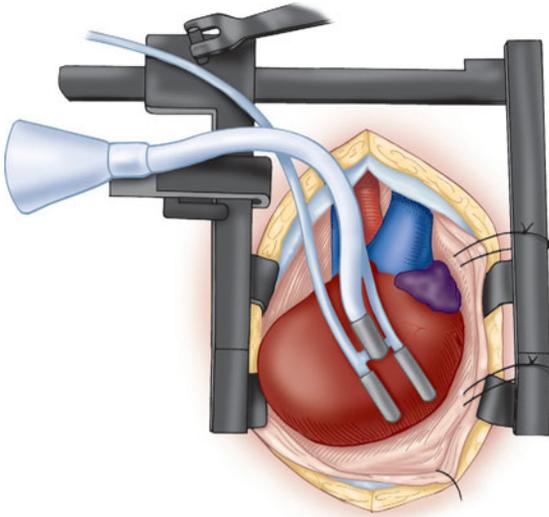

FIGURE 22-16 Schematic illustration of the Octopus retractor for off-pump coronary artery bypass surgery.

greater hemodynamic stability. Full (CPB) dose heparinization is usually given and the CPB machine is usually immediately available if needed.

Intravenous fluid loading together with intermittent or continuous infusion of a vasopressor may be necessary while the distal anastomoses are sewn. In contrast, a vasodilator may be required to reduce the systolic pressure to 90–100 mm Hg during partial clamping of the aorta for the proximal anastomosis. Intravenous nitroglycerin is often used because of its ability to ameliorate myocardial ischemia.

Although OPCAB was initially proposed for “simple” one- or two-vessel bypass grafting in patients with good left ventricular function, careful application of the technique has allowed it to be used routinely for multigraft surgery, redo operations, and patients with compromised left ventricular function (and it may be the “sicker” patients who benefit most from avoidance of CPB). Some surgeons use an intraluminal shunt to maintain coronary blood flow during sewing of distal anastomoses. Myocardial preconditioning, brief periods of coronary occlusion prior to the more prolonged occlusion, reduce areas of necrosis following prolonged periods of ischemia in animal studies, but the technique has found limited use in OPCAB. On the other hand, volatile

anesthetic agents and morphine provide myocardial protection during prolonged periods of ischemia. Maintenance of anesthesia with a volatile agent may therefore be desirable. When the surgeon is skillful, long-term graft patency may be comparable to procedures done with CPB. Patients with extensive coronary disease, particularly those with poor target vessels, may not be good candidates. OPCAB may decrease the incidence of postoperative neurological complications and the need for transfusion relative to conventional coronary bypass with CPB.

PEDIATRIC PATIENTS

Cardiovascular function in infants and young children differs from that in adults. Stroke volume is relatively fixed, so that cardiac output is primarily dependent on heart rate. The immature hearts of neonates and infants often are less forgiving of pressure or volume overload. Furthermore, the functions of both ventricles are more interdependent, so that failure of one ventricle often precipitates failure of the other (**biventricular heart failure**). Transition of the neonate from the fetal to the adult circulation is discussed in Chapter 40.

Preoperative Evaluation

The potentially complex nature of congenital heart defects and their operative repair require close communication among the anesthesiologist, cardiologist, and surgeon. The hemodynamic significance of the lesion and the planned surgical correction must be clearly understood. The patient’s condition must be optimized. Congestive heart failure and pulmonary infections should be treated. Prostaglandin E_1 infusion (0.05–0.1 mcg/kg/min) is used preoperatively to prevent closure of the ductus arteriosus in infants dependent on ductal flow for survival.

Assessment of disease severity relies on both clinical and laboratory evaluation. Deterioration in infants may be manifested by increasing tachypnea, cyanosis, or sweating, particularly during feeding. Older children may complain of easy fatigability. In infants body weight is generally a good indication of disease severity, with the sickest children showing failure to thrive and reduced weight relative to expectations for age. Signs of congestive heart failure

include failure to thrive, tachycardia, an S_3 gallop, weak pulses, tachypnea, pulmonary rales, and hepatomegaly. Cyanosis may be noted, but hypoxemia is best assessed by measurements of arterial blood gases and the hematocrit. In the absence of iron deficiency, the degree of polycythemia is related to the severity and duration of hypoxemia. Clubbing of the fingers is frequent in children with cyanotic defects. The evaluation should also search for other congenital abnormalities, which are present in up to 30% of patients with congenital heart disease.

The results of echocardiography, heart catheterization, electrocardiography, and chest radiography should be reviewed. Laboratory evaluation typically includes a complete blood count (with platelet count), coagulation studies, electrolytes, blood urea nitrogen, and serum creatinine. Measurements of ionized calcium and glucose are also useful in neonates and critically ill children.

Preinduction Period

A. Fasting

Fasting requirements vary according to the patient's age and current guidelines. A preoperative intravenous infusion that provides maintenance fluid requirements should be used in patients susceptible to dehydration, in those with severe polycythemia, and when excessive delays occur prior to surgery.

B. Premedication

Premedication varies according to age and cardiac and pulmonary reserves. Atropine, 0.02 mg/kg intramuscularly (minimum dose, 0.15 mg), has by tradition been given to pediatric cardiac patients to counteract enhanced vagal tone. Neonates and infants younger than 6 months of age may receive no premedication or given only atropine. Sedation is desirable in older patients, particularly those with cyanotic lesions (tetralogy of Fallot), as agitation and crying worsen right-to-left shunting. Patients older than 1 year may be given midazolam orally (0.5–0.6 mg/kg) or intramuscularly (0.08 mg/kg).

Induction of Anesthesia

A. Hemodynamic Anesthetic Goals

1. Obstructive lesions—Anesthetic management should strive to avoid hypovolemia, bradycardia,

tachycardia, and myocardial depression. The optimal heart rate should be selected according to age; slow rates decrease cardiac output, whereas fast rates may impair ventricular filling. Mild cardiac depression may be desirable in some hyperdynamic patients, eg, those with coarctation of the aorta.

2. Shunts—A favorable ratio of pulmonary vascular resistance (PVR) to SVR should be maintained in **16** the presence of shunting. Factors known to increase PVR such as acidosis, hypercapnia, hypoxia, enhanced sympathetic tone, and high mean airway pressures are to be avoided in patients with right-to-left shunting; hyperventilation (hypocapnia) with 100% oxygen is usually effective in lowering PVR. Specific pulmonary vasodilators are not available; alprostadil (prostaglandin E_1) or nitroglycerin may be tried but they often cause systemic hypotension. Systemic vasodilation also worsens right-to-left shunting and should be avoided; phenylephrine may be used to raise SVR. Inhaled nitric oxide has no effect on systemic arterial pressure. Conversely, patients with left-to-right shunting benefit from systemic vasodilation and increases in PVR, although specific hemodynamic manipulation is generally not attempted.

B. Monitoring

Standard intraoperative monitors are generally used until the patient is anesthetized, although they may be “added” during the course of an inhaled induction in some patients. A large discrepancy between end-tidal and arterial CO_2 tensions should be anticipated in patients with large right-to-left shunts because of increased dead space. Following induction, intraarterial and central venous pressure monitoring are employed for thoracotomies and all procedures employing CPB. A 22- or 24-gauge catheter is used to enter the radial artery; 24-gauge catheters may be more appropriate for small neonates and premature infants. A cutdown may be necessary in some instances. The internal jugular or subclavian vein is generally used for central venous cannulation; if this approach is unsuccessful, a right atrial catheter may be placed intraoperatively by the surgeon. Pulmonary artery catheterization is almost never used in pediatric patients. TEE is invaluable for assessing the surgical repair following CPB. Ever smaller probes are yielding better resolution as the

technology advances. Probes are currently available for patients as small as 3 kg. Intraoperative epicardial echocardiography is commonly used either in addition to or instead of TEE.

C. Venous Access

Venous access is desirable but not always necessary for induction. Agitation and crying are particularly undesirable in patients with cyanotic lesions and can increase right-to-left shunting. Intravenous access can be established after induction but before intubation in most patients. Subsequently, at least two intravenous fluid infusion portals are required; one is typically via a central venous catheter. Caution is necessary to avoid even the smallest air bubbles. Shunting lesions allow the passage of venous air into the arterial circulation; paradoxical embolism can occur through the foramen ovale even in patients without obvious right-to-left shunting. Aspiration prior to each injection prevents dislodgment of any trapped air at stopcock injection ports.

D. Route of Induction

To a major extent, the effect of premedication and the presence of venous access determine the induction technique. Intubation is facilitated by a nondepolarizing agent (rocuronium, 1.2 mg/kg, or pancuronium, 0.1 mg/kg) or, much less commonly, succinylcholine, 1.5–2 mg/kg. Pancuronium's vagolytic effects are particularly useful in pediatric patients, but the agent itself is less often seen in North American hospitals.

1. Intravenous—Propofol (2–3 mg/kg), ketamine (1–2 mg/kg), fentanyl (25–50 mcg/kg), or sufentanil (5–15 mcg/kg) can be used for intravenous induction. High-dose opioids may be suitable for very small and critically ill patients when postoperative ventilation is planned. Intravenous agents' onset of action may be more rapid in patients with right-to-left shunting; drug boluses should be given slowly to avoid transiently high arterial blood levels. In contrast, recirculation in patients with large left-to-right shunts dilutes arterial blood concentration and can delay the appearance of intravenous agents' clinical effects.

2. Intramuscular—Ketamine, 4–10 mg/kg, is most commonly used, and onset of anesthesia is within 5 min. Coadministration with atropine helps prevent

excessive secretions. Ketamine is a good choice for agitated and uncooperative patients as well as patients with decreased cardiac reserve. Its safety with cyanotic lesions (particularly in patients with Fallot's tetralogy) is well established. Ketamine does not appear to increase PVR in children.

3. Inhalation—Sevoflurane is the most commonly used volatile agent. The technique is the same as for noncardiac surgery, except for greater concerns about avoiding excessive anesthetic doses. Sevoflurane is particularly suitable for patients with good cardiac reserve. The safety of sevoflurane in patients with cyanotic heart disease and good cardiac reserve is now well established. Nitrous oxide may be used with inhalation inductions; its concentration should be limited to 50% in patients with cyanotic lesions. Nitrous oxide does not appear to increase PVR in pediatric patients. The uptake of inhalation agents may be slowed in patients with right-to-left shunts; in contrast, no significant effect on uptake is generally observed with left-to-right shunting.

Maintenance Anesthesia

Following induction, opioids or inhalation anesthetics are used for maintenance. Fentanyl and sufentanil are the most commonly used intravenous agents, and isoflurane and sevoflurane the most commonly used inhalation agents. Some clinicians choose the anesthetic according to the patient's hemodynamic responses. Isoflurane and sevoflurane may be more suitable than halothane (the most commonly used inhaled agent in years past) for most patients; in equivalent anesthetic doses, they cause less myocardial depression, less slowing of the heart rate, and more vasodilation than halothane. However, one can make a theoretical argument in favor of halothane over sevoflurane for patients with tetralogy of Fallot (and similarly obstructive lesions such as hypertrophic subaortic stenosis), where myocardial depression is much preferred over vasodilation.

Cardiopulmonary Bypass

The circuit and technique used are similar to those used for adults. Because the smallest circuit volume used is still about three times an infant's blood volume, blood is used to prime the circuit for neonates

and infants to prevent excessive hemodilution. CPB may be complicated by intracardiac and extracardiac shunts and a very compliant arterial system (in very young patients); both tend to lower mean arterial pressure (20–50 mm Hg) and can impair systemic perfusion. High flow rates (up to 200 mL/kg/min) may be necessary to ensure adequate perfusion in very young patients. As noted previously, some evidence suggests that pH-stat management during CPB may be associated with better neurological outcome in children who will undergo circulatory arrest. Weaning from CPB is generally not a problem in pediatric patients if the surgical repair is adequate; primary pump failure is unusual. Difficulty in weaning should prompt the surgeon to check the repair and search for undiagnosed lesions. Intraoperative echocardiography, together with measurement of the pressure and oxygen saturation within the various chambers, may reveal the problem. Inotropic support may be provided by any of the agents used for adults. Calcium chloride is more often useful in critically ill young patients than in adults as children more often have impaired calcium homeostasis; ionized calcium measurements are invaluable in such cases. Close monitoring of glucose is required because both hyperglycemia and hypoglycemia may be observed. Dopamine and epinephrine are the most commonly used inotropes in pediatric patients. Addition of a phosphodiesterase inhibitor is also useful when PVR or SVR is increased. Hypocapnia, systemic alkalosis, and a high inspired oxygen concentration should also be used to decrease PVR in patients with pulmonary hypertension; additional pharmacological adjuncts may include prostaglandin E₁ (0.05–0.1 mcg/kg/min) or prostacyclin (1–40 mcg/kg/min). Inhalation nitric oxide may also be helpful for refractory pulmonary hypertension.

Children appear to have an intense inflammatory response during CPB that may be related to their blood being exposed to very large artificial surfaces relative to their size. Corticosteroids are often given to suppress this response. Many centers use modified ultrafiltration after weaning from CPB to partially correct the hemodilution but remove inflammatory vasoactive substances (cytokines); the technique takes blood from the aortic cannula

and venous reservoir, passes it through an ultrafilter, and returns it to the right atrium.

Surgical correction of complex congenital lesions often requires a period of complete circulatory arrest under deep hypothermia (deep hypothermic circulatory arrest; DHCA). Following institution of CPB, cooling is accomplished by a combination of surface cooling and a cold perfusate. At a core temperature of 15°C, up to 60 min of complete circulatory arrest may be safe. Ice packing around the head is used to delay rewarming and for surface cooling of the brain. Pharmacological brain protection is often attempted with methylprednisolone, 30 mg/kg, and mannitol, 0.5 g/kg. Following the repair, CPB flow is restarted and rewarming takes place.

Postbypass Period

Because of the large priming volumes used (often 200–300% of the patient's blood volume), hemostatic defects from dilution of clotting factors and platelets are commonly seen after CPB in infants; in addition to heparin reversal, administration of fresh frozen plasma and platelets is often necessary.

Patients undergoing extensive or complicated procedures will generally remain intubated. Extubation may be considered for older, relatively healthy patients undergoing simple procedures such as closure of a patent ductus or atrial septal defect or repair of coarctation of the aorta.

Cardiac Transplantation

Preoperative Considerations

Cardiac transplantation is the treatment of choice for otherwise healthy patients with end-stage heart disease so severe that they are unlikely to survive the next 6–12 months. The procedure is generally associated with 80–90% postoperative survival at 1 year and 60–90% survival at 5 years. Transplantation improves the quality of life and most patients are able to resume a relatively normal lifestyle. Unfortunately, the number of cardiac transplants performed is limited by the supply of donor hearts, which are obtained from brain-dead patients, most commonly following intracranial hemorrhage or head trauma.

Patients with intractable heart failure have an ejection fraction of less than 20% and fall into NYHA functional class IV (see Chapter 21) and heart failure class D. For most patients, the primary diagnosis is cardiomyopathy. Intractable heart failure may be the result of a severe congenital lesion, ischemic cardiomyopathy, viral cardiomyopathy, peripartum cardiomyopathy, a failed prior transplantation, or valvular heart disease. Medical therapy should include the standard drugs used for heart failure, including angiotensin-converting enzyme inhibitors (or angiotensin receptor blockers, or both) and β blockade (usually with carvedilol). Other drugs may include diuretics, vasodilators, and even oral inotropes; oral anticoagulation with warfarin may also be necessary. Patients may not be able to survive without intravenous inotropes while awaiting transplantation. Intraaortic balloon counterpulsation, an LVAD, or even a total mechanical heart may also be necessary.

Transplant candidates must not have suffered extensive end-organ damage or have other major systemic illnesses. Reversible renal and hepatic dysfunction are common because of chronic hypoperfusion and venous congestion. PVR must be normal or at least responsive to oxygen or vasodilators. Irreversible pulmonary vascular disease is usually associated with a PVR of more than 6–8 Wood units (1 Wood unit = 80 dyn·s·cm⁻⁵), and is a contraindication to orthotopic cardiac transplantation because right ventricular failure is a major cause of early postoperative mortality. Patients with long-standing pulmonary hypertension may, however, be candidates for combined heart–lung transplantation.

Tissue cross-matching is generally not performed. Donor–recipient compatibility is based on size, ABO blood-group typing, and cytomegalovirus serology. Donor organs from patients with hepatitis B or C or HIV infections are excluded.

ANESTHETIC MANAGEMENT

Proper timing and coordination are necessary between the donor organ retrieval team and the transplant center. Premature induction of anesthesia

unnecessarily prolongs the time under anesthesia for the recipient, whereas delayed induction may jeopardize graft function by prolonging the period of ischemia.

Patients may receive little advance warning of the availability of a suitable organ. Many—if not most—will have eaten a recent meal and should be considered to have a full stomach. Oral cyclosporine must be given preoperatively. Administration of a clear antacid (sodium citrate), a histamine H₂-receptor blocker, and metoclopramide should be considered. Any sedating premedication may be administered intravenously just prior to induction.

Monitoring is similar to that used for other cardiac procedures and is often established prior to induction. Strict asepsis should be observed during invasive procedures. Use of the right internal jugular vein for central access does not appear to compromise its future use for postoperative endomyocardial biopsies. A pulmonary artery catheter is used in many centers for postbypass management. It need not be placed in the pulmonary artery before CPB.

A rapid sequence induction may be performed. The principal objective of anesthetic management is to maintain organ perfusion until the patient is on CPB. Induction may be carried out with small doses of opioids (fentanyl, 5–10 mcg/kg) with or without etomidate (0.2–0.3 mg/kg). A low-dose ketamine–midazolam technique (above) may also be suitable. Sufentanil, 5 mcg/kg, followed by succinylcholine, 1.5 mg/kg, can be used as a rapid-sequence technique. Anesthesia is maintained in a similar fashion as for other cardiac operations. A TEE probe is placed following induction, and antirejection drugs are given.

Sternotomy and cannulation for CPB may be complicated by scarring from prior cardiac operations. Aminocaproic acid or tranexamic acid can be used to decrease postoperative bleeding. CPB is initiated following cannulation of the aorta and both cavae. If a pulmonary artery catheter was placed, it must be completely withdrawn from the heart with its tip in the superior vena cava. It must remain within its sterile, protective sheath if it is to be safely refloated again into the pulmonary artery following CPB. The recipient's heart is then

excised, allowing the posterior wall of both atria (with the caval and pulmonary vein openings) to remain. The atria of the donor heart are anastomosed to the recipient's atrial remnants (left side first). The aorta and then the pulmonary artery are anastomosed end to end. The donor heart is then flushed with saline and intracardiac air is evacuated. Methylprednisolone is given before the aortic cross-clamp is released.

Inotropic support is usually started prior to separation from CPB to counteract bradycardia from sympathetic denervation. Prolonged graft ischemia may result in transient myocardial depression. Slow junctional rhythms are common and may require epicardial pacing. Although the transplanted heart is totally denervated and direct autonomic influences are absent, its response to circulating catecholamines is usually normal. The pulmonary artery catheter can be refloatated into position after CPB and is used in conjunction with TEE to evaluate the patient. The most common post-CPB problem is right ventricular failure from pulmonary hypertension, which should be treated with hyperventilation, prostaglandin E_1 (0.025–0.2 mcg/kg/min), nitric oxide (10–60 ppm), and an RVAD, if necessary. Bleeding is a common problem because of extensive suture lines and preoperative hemostatic defects.

Patients will be extubated when they meet criteria, as with other major cardiac operations. The postoperative course may be complicated by acute rejection, renal and hepatic dysfunction, and infections.

PERICARDIAL DISEASE

The parietal pericardium is a fibrous membrane surrounding the heart, to which it normally is not adherent. The pericardium encompasses a relatively fixed intrapericardiac volume that includes a small volume of pericardial fluid (20–50 mL in adults), the heart, and blood. As a result, the pericardium normally limits acute dilation of the ventricles and promotes diastolic coupling of the two ventricles (distention of one ventricle interferes with filling of the other). The latter effect is also due to the inter-ventricular septal wall they share. Moreover, diseases

of the pericardium or larger pericardial fluid collections can seriously impair cardiac output.

1. Cardiac Tamponade

Preoperative Considerations

Cardiac tamponade exists when increased pericardial pressure impairs diastolic filling of the heart. Cardiac filling is ultimately related to the diastolic transmural (distending) pressure across each chamber. Consequently, any increase in pericardial pressure relative to the pressure within the chamber reduces filling. Pressure is applied equally to each cardiac chamber when the problem is a pericardial fluid collection; or, it can be applied “selectively,” as for example when an isolated pericardial blood clot compresses the left atrium. In general, the thin-walled atria and the right ventricle are more susceptible to pressure-induced abnormalities of filling than the left ventricle.

Pericardial pressure is normally similar to pleural pressure, varying with respiration between -4 and $+4$ mm Hg. Elevations in pericardial pressure are most commonly due to increases in pericardial fluid volume (as a consequence of effusions or bleeding). The magnitude of the increased pressure depends on both the volume of fluid and the rate of fluid accumulation; sudden increases exceeding 100–200 mL precipitously increase pericardial pressure, whereas very slow accumulations up to 1000 mL allow the pericardium to stretch with minimal increases in pericardial pressure.

The principal hemodynamic features of cardiac tamponade include decreased cardiac output from reduced stroke volume with an increase in central venous pressure. In the absence of severe left ventricular dysfunction, equalization of diastolic pressure occurs throughout the heart (right atrial pressure [RAP] = right ventricular end-diastolic pressure [RVEDP] = left atrial pressure [LAP] = left ventricular end-diastolic pressure [LVEDP]).

The central venous pressure waveform is characteristic in cardiac tamponade. Impairment of both diastolic filling and atrial emptying abolishes the y descent; the x descent (systolic atrial filling) is normal or even accentuated. Reflex sympathetic

activation is a prominent compensatory response in cardiac tamponade. The resulting increases in heart rate and contractility help maintain cardiac output. Arterial vasoconstriction (increased SVR) supports systemic blood pressure, whereas sympathetic activation reduces vascular capacitance, having the effect of an autotransfusion. Because stroke volume remains relatively fixed, cardiac output becomes primarily dependent on heart rate.

Acute cardiac tamponade usually presents as sudden hypotension, tachycardia, and tachypnea. Physical signs include jugular venous distention, a narrowed arterial pulse pressure, and muffled heart sounds. The patient may complain of an inability to lie flat. A friction rub may be audible. A prominent pulsus paradoxus (a cyclic inspiratory decrease in systolic blood pressure of more than 10 mm Hg) is typically present. The latter actually represents an exaggeration of a normal phenomenon related to inspiratory decreases in intrathoracic pressure. (A marked pulsus paradoxus may also be seen with severe airway obstruction or right ventricular infarction.) The heart may appear normal or enlarged on a chest radiograph. Electrocardiographic signs are generally nonspecific and are often limited to decreased voltage in all leads and nonspecific ST-segment and T-wave abnormalities. Electrical alternans (a cyclic alteration in magnitude of the P waves, QRS complex, and T waves) may be seen with large pericardial effusions and is thought to be due to pendular swinging of the heart within the pericardium. Generalized ST-segment elevation may also be seen in two or three limb leads as well as V_2 to V_6 in the early phase of pericarditis. Echocardiography is invaluable in diagnosing and measuring pericardial effusions and cardiac tamponade, and as a guide for accurate needle insertion for pericardiocentesis. Signs of tamponade include diastolic compression or collapse of the right atrium and right ventricle, leftward displacement of the ventricular septum, and an exaggerated increase in right ventricular size with a reciprocal decrease in left ventricular size during inspiration.

Pericardial effusions may be due to viral, bacterial, or fungal infections; malignancies; bleeding after cardiac surgery; trauma; uremia; myocardial

infarction; aortic dissection; hypersensitivity or autoimmune disorders; drugs; or myxedema.

Anesthetic Considerations

Symptomatic cardiac tamponade requires evacuation of the pericardial fluid, either surgically or by pericardiocentesis. The latter is associated with a risk of lacerating the heart or coronary arteries and of pneumothorax. Traumatic postoperative (following thoracotomy) cardiac tamponade is nearly always treated surgically, whereas tamponade from other causes may more often be amenable to pericardiocentesis. Surgical treatment is also often undertaken for large recurrent pericardial effusions (infectious, malignant, autoimmune, uremic, or radiation induced) to prevent tamponade. Simple drainage of pericardial fluid may be achieved through a subxiphoid approach, whereas drainage combined with pericardial biopsy or pericardiectomy may be performed via a left anterior thoracotomy or median sternotomy. Drainage and biopsies can also be accomplished through left-sided thoracoscopy.

The anesthetic approach must be tailored to the patient. For the intubated postoperative cardiac patient in extremis, the chest may be reopened immediately in the ICU. For awake conscious patients who will undergo left thoracotomy or median sternotomy, general anesthesia and endotracheal intubation are necessary. Local anesthesia may be used for patients undergoing simple drainage through a subxiphoid approach or pericardiocentesis. Removal of even a small volume of fluid may be sufficient to greatly improve cardiac output and allow safe induction of general anesthesia. Small doses (10 mg intravenously at a time) of ketamine also provide excellent supplemental analgesia.

17 Induction of general anesthesia in patients with cardiac tamponade can precipitate severe hypotension and cardiac arrest. We find it useful to have an epinephrine infusion available and we sometimes initiate it before induction.

Large-bore intravenous access is mandatory. Monitoring of intraarterial pressure is useful, but placement of monitors should not delay pericardial drainage if the patient is unstable. The anesthetic technique should maintain a high sympathetic tone until the tamponade is relieved; in other

words, “deep” anesthesia is not the object. Cardiac depression, vasodilation, and slowing of the heart rates should be avoided. Similarly, increases in mean airway pressures can seriously jeopardize venous return. Awake intubation with maintenance of spontaneous ventilation is theoretically desirable, but coughing, straining, hypoxemia, and respiratory acidosis are equally detrimental and should be avoided. Thoracoscopy requires one-lung anesthesia.

Ketamine is the agent of choice for induction and maintenance until the tamponade is relieved. Small doses of epinephrine (5–10 mcg) may be useful as a temporary inotrope and chronotrope. Generous intravenous fluid administration is useful in maintaining cardiac output.

2. Constrictive Pericarditis

Preoperative Considerations

Constrictive pericarditis may develop as a sequela of acute or recurrent pericarditis. Pathologically, the pericardium is thickened, fibrotic, and often calcified. The parietal pericardium is typically adherent to the visceral pericardium on the heart, often obliterating the pericardial space. The stiffened parietal pericardium limits diastolic filling of the heart to a fixed and reduced volume. In contrast to acute cardiac tamponade, filling during early diastole is typically accentuated and manifested by a prominent y descent on the central venous pressure waveform.

Patients with constrictive pericarditis display jugular venous distention, hepatomegaly, and often ascites. Liver function may be abnormal. In contrast to acute tamponade, constrictive pericarditis prevents respiratory fluctuations in pericardial pressure; because venous return to the heart does not increase during inspiration, a pulsus paradoxus is uncommon. In fact, venous pressure does not fall or may paradoxically rise during inspiration (Kussmaul’s sign). The chest radiograph will often reveal pericardial calcification. Low QRS voltage and diffuse T-wave abnormalities are usually present on the ECG. Atrial fibrillation and conduction blocks may be present. Echocardiography may be helpful in making the diagnosis.

Anesthetic Considerations

Pericardiectomy is usually reserved for patients with moderate to severe disease. The procedure is usually performed through a median sternotomy. It is complicated by the necessity for extensive manipulations of the heart that interfere with cardiac filling and ejection, induce frequent arrhythmias, and risk cardiac perforation. CPB may be required.

Selection of specific anesthetic agents is less important than avoiding excessive cardiac depression, vasodilation, and bradycardia. Cardiac output is generally rate dependent. Adequate large-bore intravenous access and direct arterial and central venous pressure monitoring are usually employed. Although cardiac function usually improves immediately following pericardiectomy, some patients display a persistently low cardiac output and require temporary postoperative inotropic support.

Anesthetic Management of Vascular Surgery

ANESTHESIA FOR SURGERY ON THE AORTA

Preoperative Considerations

Surgery on the aorta represents one of the greatest challenges for anesthesiologists. Regardless of which part of the vessel is involved, the procedure is complicated by the need to cross-clamp the aorta and by the potential for large intraoperative blood losses. Aortic cross-clamping without CPB acutely increases left ventricular afterload and severely compromises organ perfusion distal to the point of occlusion. Severe hypertension, myocardial ischemia, left ventricular failure, or aortic valve regurgitation may be precipitated. Interruption of blood flow to the spinal cord, kidneys, and intestines can produce paraplegia, kidney failure, or intestinal infarction, respectively. Moreover, emergency aortic surgery is frequently necessary in critically ill patients who are acutely hypovolemic and have a high incidence of coexistent cardiac, renal, and pulmonary disease; hypertension; and diabetes.

Indications for aortic surgery include aortic dissections, aneurysms, occlusive disease, trauma, and coarctation. Lesions of the ascending aorta lie between the aortic valve and the innominate artery, whereas lesions of the aortic arch lie between the innominate and left subclavian arteries. Disease distal to the left subclavian artery but above the diaphragm involves the descending thoracic aorta; lesions below the diaphragm involve the abdominal aorta.

SPECIFIC LESIONS OF THE AORTA

Aortic Dissection

In an aortic dissection an intimal tear allows blood to track into the aortic wall (the media), creating a new pathway for blood flow. In many cases, a primary degenerative process called cystic medial necrosis predisposes for dissection to occur. Patients with hereditary connective tissue defects such as Marfan syndrome and Ehlers–Danlos syndrome eventually develop cystic medial necrosis and are at risk for aortic dissection. Propagation of the dissection is thought to occur as a result of hemodynamic shear forces acting on the intimal tear; indeed, hypertension is a common finding in patients with aortic dissection. Dissection can also occur from hemorrhage into an atheromatous plaque or at the aortic cannulation site following cardiac surgery.

Dissections may occlude the orifice of any artery arising directly from the aorta; they may extend into the aortic root, producing incompetence of the aortic valve; or may rupture into the pericardium or pleura, producing cardiac tamponade or hemothorax, respectively. TEE plays an important role in diagnosing and characterizing aortic dissections. Dissections are most commonly of the proximal type (Stanford type A, De Bakey types I and II) involving the ascending aorta. Type II dissections do not extend beyond the innominate artery. Distal dissections (Stanford type B, De Bakey type III) originate beyond the left subclavian artery and propagate only distally. Proximal dissections are nearly always treated surgically, whereas distal dissections may be treated medically. In either case, from the time the diagnosis is suspected, measures to reduce systolic

blood pressure (usually to 90–120 mm Hg) and aortic wall stress are initiated. This usually includes intravenous vasodilators (nicardipine or nitroprusside) and β -adrenergic blockade (esmolol or a longer acting agent). The latter is important in reducing the shear forces related to the rate of rise of aortic pressure (dp/dt), which may actually increase with nitroprusside alone.

Aortic Aneurysms

Aneurysms more commonly occur in the abdominal than in the thoracic aorta. The vast majority of aortic aneurysms are due to atherosclerosis; cystic medial necrosis is also an important cause of thoracic aortic aneurysms. Syphilitic aneurysms characteristically involve the ascending aorta. Other etiologies include rheumatoid arthritis, spondyloarthropathies, and trauma. Dilation of the aortic root often produces aortic regurgitation. Expanding aneurysms of the upper thoracic aorta can also cause tracheal or bronchial compression or deviation, hemoptysis, and superior vena cava syndrome. Compression of the left recurrent laryngeal nerve produces hoarseness and left vocal cord paralysis. Distortion of the normal anatomy may also complicate endotracheal or endobronchial intubation or cannulation of the internal jugular and subclavian veins.

The greatest danger from untreated aortic aneurysms is rupture and exsanguination. A pseudoaneurysm forms when the intima and media are ruptured and only adventitia or blood clot forms the outer layer. Acute expansion (from leaking), manifested as sudden severe pain, may herald rupture. The likelihood of catastrophic rupture is related to size. The normal aorta in adults varies from 2 to 3 cm in width (it is wider cephalad). The data are clear for abdominal aortic aneurysms; rupture occurs in 50% of patients within 1 year when an aneurysm is 6 cm or greater in diameter. Elective treatment is generally performed in most patients with aneurysms 5 cm or greater. Most often this is accomplished with an intravascular stent; less often, open surgery and a prosthetic graft is used. The operative mortality rate is about 2–5% in good-risk patients and exceeds 50% if leaking or rupture has already occurred. The risks are much less with intravascular stenting, which has become the preferred procedure whenever the anatomy permits.

Occlusive Disease of the Aorta

Atherosclerotic obliteration of the aorta most commonly occurs near the aortic bifurcation (Leriche's syndrome). Occlusion results from a combination of atherosclerotic plaque and thrombosis. Atherosclerosis is usually generalized and affects other parts of the arterial system, including the cerebral, coronary, and renal arteries (see Chapters 21 and 28). Treatment may be accomplished by intravascular stenting or by open surgery with an aortobifemoral bypass graft; proximal thromboendarterectomy may also be necessary.

Aortic Trauma

Aortic trauma may be penetrating or nonpenetrating. Both types of injuries can result in massive hemorrhage and require immediate operation. Whereas penetrating injuries are usually obvious, blunt aortic trauma may be easily overlooked if not suspected and the appropriate diagnostic testing performed. Nonpenetrating aortic trauma typically results from sudden high-speed decelerations such as those caused by automobile accidents (eg, in which the driver's chest impacts the steering wheel) and falls. The injury can vary from a partial tear to a complete aortic transection. Because the aortic arch is relatively fixed whereas the descending aorta is relatively mobile, the shear forces are greatest and the site of injury most common just distal to the subclavian artery. The most consistent initial finding is a widened mediastinum on a chest radiograph. Definitive diagnosis can be accomplished with magnetic resonance or computed tomographic imaging or TEE.

Coarctation of the Aorta

This congenital heart defect may be classified according to the position of the narrowed segment relative to the position of the ductus arteriosus. In the *preductal* (infantile) type, the narrowing occurs proximal to the opening of the ductus. This lesion, which is often associated with other congenital heart defects, is recognized in infancy because of a marked difference in perfusion between the upper and lower halves of the body; the lower half is cyanotic. Perfusion to the upper body is derived from

the aorta, whereas perfusion to the lower body is primarily from the pulmonary artery. *Postductal* coarctation of the aorta may not be recognized until adulthood. The symptoms and hemodynamic significance of this lesion depend on the severity of the narrowing and the extent of collateral circulation that develops to the lower body (internal mammary, subscapular, and lateral thoracic to intercostal arteries). Hypertension in the upper body, with or without left ventricular failure, is usually present. So-called "rib notching" may be present on the chest radiograph as a result of dilated collateral intercostal arteries.

ANESTHETIC MANAGEMENT

Surgery on the Ascending Aorta

Surgery on the ascending aorta routinely uses median sternotomy and CPB. The conduct of anesthesia is similar to that for cardiac operations involving CPB, but the intraoperative course may be complicated by long aortic cross-clamp times and large intraoperative blood losses. TEE is especially useful. Blood loss can be reduced by administration of ϵ -aminocaproic acid or tranexamic acid. Concomitant aortic valve replacement and coronary reimplantation are often necessary (Bentall procedure). The radial artery cannulation site should be guided by the possible need for clamping of either the subclavian or innominate arteries during the procedure. Nicardipine or nitroprusside may be used for precise blood pressure control. β -Adrenergic blockade should also be employed in the presence of an aortic dissection. On the other hand, bradycardia worsens aortic regurgitation and should be avoided. The arterial inflow cannula for CPB is placed in a femoral artery for patients with dissections. In the event that sternotomy may rupture an aneurysm, prior establishment of partial CPB (using the femoral artery and femoral vein) should be considered.

Surgery Involving the Aortic Arch

These procedures are usually performed through a median sternotomy with deep hypothermic circulatory arrest (following institution of CPB). Additional considerations focus on achieving optimal cerebral

protection with systemic and topical hypothermia (above). Hypothermia to 15°C, barbiturate or propofol infusion to maintain a flat EEG, methylprednisolone or dexamethasone, mannitol, and phenytoin are also commonly administered (but there is vanishingly small evidence for efficacy of these drug treatments). The necessarily long rewarming periods probably contribute to the larger intraoperative blood losses commonly observed after CPB.

Surgery Involving the Descending Thoracic Aorta

Surgery limited to the descending thoracic aorta may be performed through a left thoracotomy without CPB, with or without (so-called “clamp-and-run” technique) a heparin-impregnated left ventricular apex to femoral artery shunt; or using partial right atrium to femoral artery bypass. A thoracoabdominal incision is necessary for lesions that also involve the abdominal aorta. One-lung anesthesia greatly facilitates surgical exposure. Correct positioning of the endobronchial tube (even with fiberoptic bronchoscopy) may be difficult because of distortion of the anatomy. A right-sided double-lumen tube or a regular endotracheal tube with a bronchial blocker may be necessary.

The aorta must be cross-clamped above and below the lesion. Acute hypertension develops above the clamp, with hypotension below when there is no shunt or partial bypass. Arterial blood pressure should be monitored from the right radial artery, as clamping of the left subclavian artery may be necessary. The sudden increase in left ventricular afterload after application of the aortic cross-clamp during aortic surgery may precipitate acute left ventricular failure and myocardial ischemia, particularly in patients with underlying ventricular dysfunction or coronary disease; it can also exacerbate preexisting aortic regurgitation. Cardiac output falls and left ventricular end-diastolic pressure and volume rise. The magnitude of these changes is inversely related to ventricular function. These effects can be ameliorated by the use of shunting or partial bypass. Moreover, the adverse effects of aortic clamping become less pronounced the more distal on the aorta that the clamp is applied. A vasodilator infusion is often needed to prevent

excessive increases in blood pressure. In patients with good ventricular function, increasing anesthetic depth just prior to cross-clamping may also be helpful.

Excessive intraoperative bleeding may occur during these procedures. Prophylaxis with anti-fibrinolytic agents may be helpful. A blood scavenging device (cell saver) for autotransfusion is routinely used. Adequate venous access and intraoperative monitoring are critical. Multiple large-bore (14-gauge) intravenous catheters (preferably with blood warmers) are useful. Pulmonary artery catheterization and intraoperative TEE are often used. The period of greatest hemodynamic instability follows the release of the aortic cross-clamp; the abrupt decrease in afterload together with bleeding and the release of vasodilating acid metabolites from the ischemic lower body can precipitate severe systemic hypotension and less commonly hyperkalemia. Decreasing anesthetic depth, volume loading, and partial or slow release of the cross-clamp are helpful in avoiding severe hypotension. A bolus dose of a vasopressor may be necessary. Sodium bicarbonate is often used, particularly for persistent severe metabolic acidosis ($\text{pH} < 7.20$) in association with hypotension. Calcium chloride may be necessary when symptomatic hypocalcemia follows massive transfusion of citrated blood products.

A. Paraplegia

Spinal cord ischemia can complicate thoracic aortic cross-clamping. The incidence of transient postoperative deficits and postoperative paraplegia are 11% and 6%, respectively. Increased rates are associated with cross-clamping periods longer than 30 min, extensive surgical dissections, and emergency procedures. The classic deficit is an anterior spinal artery syndrome with loss of motor function and pinprick sensation but preservation of vibration and proprioception. Anatomic variations in spinal cord blood supply are responsible for the unpredictable occurrence and variable nature of deficits. The spinal cord receives its blood supply from the vertebral arteries and from the thoracic and abdominal aorta. One anterior and two posterior arteries descend along the cord. Intercostal arteries feed the anterior and posterior arteries in the upper thoracic

aorta. Textbook descriptions suggest that in the lower thoracic and lumbar cord, the anterior spinal artery is supplied by the thoracolumbar artery of Adamkiewicz. The truth is that a single large feeding artery usually cannot be identified. When present, this artery has a variable origin from the aorta, arising between T5 and T8 in 15%, between T9 and T12 in 60%, and between L1 and L2 in 25% of individuals; it nearly always arises on the left side. It may be damaged during surgical dissection or occluded by the aortic cross-clamping. Monitoring motor and somatosensory evoked potentials may be useful in preventing paraplegia, but clearly surgical technique and speed are most important.

As noted earlier, use of a temporary heparin-coated shunt or partial CPB with hypothermia maintains distal perfusion and decreases the incidence of paraplegia, hypertension, and ventricular failure. Partial CPB has the disadvantage of requiring heparinization, which increases blood loss. Using a heparin-coated shunt precludes the need for heparinization. It is usually positioned proximally in the left ventricular apex and distally in a femoral artery. Other therapeutic measures that may be protective of the spinal cord include methylprednisolone, mild hypothermia, mannitol, and drainage of cerebrospinal fluid (CSF) to reduce the CSF pressure in the spine; magnesium is also protective in some animal models. The efficacy of mannitol appears to be related to its ability to lower CSF pressure by decreasing its production. Spinal cord perfusion pressure is mean arterial blood pressure minus CSF pressure; the rise in CSF pressure following experimental cross-clamping of the aorta may explain how a mannitol-induced decrease in CSF pressure could improve spinal cord perfusion pressure during cross-clamping. Any protective effect of drainage of CSF via a lumbar catheter may have a similar mechanism.

The excessive use of vasodilators to control the hypertensive response to cross-clamping may be a contributing factor in spinal cord ischemia, as drug actions also occur distal to the cross-clamp. Excessive reduction in blood pressure above the cross-clamp should therefore be avoided to prevent inadequate blood flow and excessive hypotension below it.

B. Kidney Failure

An increased incidence of kidney failure following aortic surgery is reported after emergency procedures, prolonged cross-clamping periods, and prolonged hypotension, particularly in patients with preexisting kidney disease. A variety of “cocktails” have been employed in the hope of reducing the risk of kidney failure, including infusion of mannitol (0.5 g/kg) prior to cross-clamping, furosemide, fenoldopam (or low-dose dopamine), etc. Low (renal)-dose dopamine or fenoldopam will increase renal blood flow and may be used as an adjunct for a persistently low urinary output after the cross-clamp is released, however there is no convincing evidence that these treatments alter renal outcomes.

Surgery on the Abdominal Aorta

Stents are most often placed via catheters inserted in a femoral artery. When an open technique is chosen, either an anterior transperitoneal or an anterolateral retroperitoneal approach can be used to access the abdominal aorta. Depending on the location of the lesion, the cross-clamp can be applied to the suprarenal, suprarenal, or infrarenal aorta. Heparin is usually administered prior to aortic clamping. Intraarterial blood pressure can be monitored from either upper extremity. In general, the more distally the clamp is applied to the aorta, the less the effect on left ventricular afterload. In fact, occlusion of the infrarenal aorta frequently results in minimal hemodynamic changes. In contrast, release of the clamp usually produces hypotension; the same techniques that were described earlier (see above) may be used. The large incision and extensive retroperitoneal surgical dissection increase fluid requirements beyond intraoperative blood loss. We recommend colloid to maintain intravascular volume and crystalloid for maintenance fluids. Fluid replacement may be guided by monitoring central venous pressure, noninvasive monitors of stroke volume, or TEE. Pulmonary artery catheters are rarely used.

Renal prophylaxis with mannitol should be considered, particularly in patients with preexisting renal impairment. Clamping of the infrarenal aorta has been shown to decrease renal blood flow, which may contribute to postoperative kidney failure. The decrease in renal blood flow is not

prevented by epidural anesthesia or blockade of the renin–angiotensin system.

Some centers use continuous epidural anesthesia combined with general anesthesia for abdominal aortic surgery. This combined technique decreases the general anesthetic requirement and appears to suppress the release of stress hormones. It also provides an excellent route for administering postoperative epidural analgesia. Systemic heparinization during surgery introduces concern regarding the risk of paraplegia secondary to an epidural hematoma; however, all credible studies suggest that there when the catheter is placed well in advance of heparinization and removed after reversal of anticoagulation there is no increased risk of neuraxial hematomas as a consequence of epidural catheter placement.

Postoperative Considerations

Those undergoing stenting may not require intubation either during or after the procedure. Most patients undergoing open surgery on the ascending aorta, the arch, or the thoracic aorta will remain intubated and ventilated for 1–24 h postoperatively. As with cardiac surgery, the initial emphasis in their postoperative care should be on hemodynamic stability and monitoring for postoperative bleeding. Patients undergoing open abdominal aortic surgery may be extubated at the end of the procedure. These patients typically continue to require a marked increase in maintenance fluids for several hours postoperatively.

ANESTHESIA FOR CAROTID ARTERY SURGERY

Preoperative Considerations

Ischemic cerebrovascular disease accounts for 80% of strokes; the remaining 20% are due to hemorrhage. Ischemic strokes are usually the result of embolism or (less commonly) thrombosis in one of the blood vessels supplying the brain. Ischemic stroke may follow severe vasospasm after subarachnoid hemorrhage. By convention, a stroke is defined as a neurological deficit that lasts more than 24 h; its pathological correlate is typically focal infarction of brain. Transient ischemic attacks (TIAs), on the other hand, are neurological deficits that resolve

within 24 h; they may be due to a low-flow state at a tightly stenotic lesion or to emboli that arise from an extracranial vessel or the heart. When a stroke is associated with progressive worsening of signs and symptoms, it is frequently termed a *stroke in evolution*. A second distinction is also often made between complete and incomplete strokes, based on whether the territory involved is completely affected or additional brain remains at risk for focal ischemia (eg, hemiplegia versus hemiparesis). The bifurcation of the common carotid artery (the origin of the internal carotid artery) is the most common site of atherosclerotic plaques that may lead to TIA or stroke. The mechanism may be embolization of platelet-fibrin or plaque material, stenosis, or complete occlusion. The last may be the result of thrombosis or hemorrhage into a plaque. Symptoms depend on the adequacy of collateral circulation. Emboli distal to regions lacking collateral blood flow are more likely to produce symptoms. Small emboli in the ophthalmic branches can cause transient monocular blindness (amaurosis fugax). Larger emboli usually enter the middle cerebral artery, producing contralateral motor and sensory deficits that primarily affect the arm and face. Aphasia also develops if the dominant hemisphere is affected. Emboli in the anterior cerebral artery territory typically result in contralateral motor and sensory deficits that are worse in the leg. It is common for TIAs or minor strokes to precede a major stroke.

Indications for open surgery or intravascular interventions include TIAs associated with ipsilateral severe carotid stenosis (>70% occlusion), severe ipsilateral stenosis in a patient with a minor (incomplete) stroke, and 30–70% occlusion in a patient with ipsilateral symptoms (usually an ulcerated plaque). In the past, carotid endarterectomy was recommended for asymptomatic but significantly stenotic lesions (>60%). Currently, stenting would often be the recommendation. Operative mortality for open surgery is 1–4% and is primarily due to cardiac complications (myocardial infarction). Perioperative morbidity is 4–10% and is principally neurological; patients with preexisting neurological deficits have the greatest risk of perioperative neurological events. **Studies suggest that age greater than 75 years,**

symptomatic lesions, uncontrolled hypertension, angina, carotid thrombus, and occlusions near the carotid siphon increase operative risk.

Preoperative Anesthetic Evaluation & Management

Most patients undergoing carotid endarterectomy are elderly and hypertensive, with generalized arteriosclerosis. Many are also diabetic. Preoperative evaluation and management should focus on defining preexisting neurological deficits as well as optimizing the patient's clinical status in terms of coexisting diseases. Most postoperative neurological deficits appear to be related to surgical technique. Uncontrolled perioperative hyperglycemia can increase morbidity by enhancing ischemic cerebral injury.

With the possible exception of diuretics, patients should receive their usual medications on schedule until the time of surgery. Blood pressure and the blood glucose concentration should be controlled. Angina should be stable and controlled, and signs of overt congestive heart failure should be absent. Because most patients are elderly, enhanced sensitivity to premedication should be expected.

General Anesthesia

19 The emphasis of anesthetic management during carotid surgery is on maintaining adequate perfusion to the brain and heart. Traditionally, this is accomplished by close regulation of arterial blood pressure and avoidance of tachycardia. Monitoring of intraarterial pressure is therefore nearly always done. Electrocardiographic monitoring should include the V₅ lead to detect ischemia. Continuous computerized ST-segment analysis is desirable. Carotid endarterectomy is not usually associated with significant blood loss or fluid shifts.

Regardless of the anesthetic agents selected, mean arterial blood pressure should be maintained at—or slightly above—the patient's usual range. Propofol and etomidate are popular choices for induction because they reduce cerebral metabolic rate proportionately more than cerebral blood flow. Small doses of an opioid or β -adrenergic blocker can be used to blunt the hypertensive response to

endotracheal intubation. In theory, isoflurane may be the volatile agent of choice because it appears to provide the greatest protection against cerebral ischemia. Desflurane qualitatively has similar cerebral effects but may not be as effective as isoflurane; however, desflurane is very useful in accelerating awakening and allowing immediate neurological assessment in the operating room. We do not regard the differences in neuroprotection among inhaled agents as clinically important. Some clinicians also prefer remifentanyl as the opioid for rapid emergence.

Intraoperative hypertension is common and generally necessitates the use of an intravenous vasodilator. Nitroglycerin is usually a good choice for mild to moderate hypertension because of its beneficial effects on the coronary circulation. Marked hypertension requires a more potent agent, such as nicardipine, nitroprusside, or clevidipine. β -Adrenergic blockade facilitates management of the hypertension and prevents reflex tachycardia from vasodilators, but should be used cautiously. Hypotension should be treated with vasopressors. Many clinicians consider phenylephrine the vasopressor of choice; if selected, it should be administered in small increments to prevent excessive hypertension.

Pronounced or sustained reflex bradycardia or heart block caused by manipulation of the carotid baroreceptor can be treated with atropine. To prevent this response, some surgeons infiltrate the area of the carotid sinus with lidocaine, but the infiltration itself can induce bradycardia. Arterial CO₂ tension should be maintained in the normal range because hypercapnia can induce intracerebral steal, whereas extreme hypocapnia decreases cerebral perfusion. Ventilation should be adjusted to maintain normocapnia. Maintenance intravenous fluids should consist of glucose-free solutions because of the potentially adverse effects of hyperglycemia. Heparin (5000–7500 units intravenously) is usually administered prior to occlusion of the carotid artery. Some clinicians routinely use a shunt (see below). Protamine, 50–150 mg, is usually given to reverse heparin prior to skin closure.

Rapid emergence from anesthesia is desirable because it allows immediate neurological

assessment, but the clinician must be prepared to treat hypertension and tachycardia. **Postoperative hypertension may be related to surgical denervation of the ipsilateral carotid baroreceptor. Denervation of the carotid body blunts the ventilatory response to hypoxemia.** Following extubation, patients should be observed closely for the development of a wound hematoma. When an expanding wound hematoma compromises the airway, the initial treatment maneuver may require opening the wound to release the hematoma. Transient postoperative hoarseness and ipsilateral deviation of the tongue may be noted; they are due to intraoperative retraction of the recurrent laryngeal or hypoglossal nerves, respectively.

Monitoring Cerebral Function

Unless regional anesthesia is used (see below), indirect methods must be relied upon to assess the adequacy of cerebral perfusion during carotid cross-clamping. Some surgeons routinely use a shunt, but this practice may increase the incidence of postoperative neurological deficits; shunt insertion can dislodge emboli. Carotid stump pressure distal to the cross-clamp, EEG, somatosensory evoked potentials (SSEPs), and cerebral oximetry have been used in some centers to determine whether a shunt is needed. A distal stump pressure of less than 50 mm Hg has traditionally been used as an indication for a shunt. Electrophysiological signs of ischemia (or a marked decline in cerebral oxygen saturation) after cross-clamping dictate the use of a shunt; changes lasting more than 10 min may be associated with a new postoperative neurological deficit. Although multichannel recordings and computer processing can enhance the sensitivity of the EEG, neither EEG nor SSEP monitoring is sufficiently sensitive or specific to reliably predict the need for shunting or the occurrence of postoperative deficits (see Case Discussion in Chapter 26). Other techniques, including measurements of regional cerebral blood flow with radioactive xenon-133, transcranial Doppler measurement of middle cerebral artery flow velocity, cerebral oximetry, jugular venous oxygen saturation, and transconjunctival oxygen tension, are also not sufficiently reliable.

Regional Anesthesia

Carotid surgery may be performed under regional anesthesia. Blockade of the superficial cervical plexus effectively blocks the C2–C4 nerves and allows the patient to remain comfortably awake during surgery. Deep cervical plexus block is not required. A substantial fraction of patients will require administration of local anesthetic by the surgeon into the carotid sheath (whether or not a deep cervical block is performed). The principal advantage of regional anesthesia (and it is a tremendous advantage) is that the patient can be examined intraoperatively; thus, the need for a temporary shunt can be assessed and any new neurological deficits diagnosed immediately during surgery. In fact, intraoperative neurological examination may be the most reliable method for assessing the adequacy of cerebral perfusion during carotid cross-clamping. The examination minimally consists of level of consciousness, speech, and contralateral handgrip. Experienced clinicians use minimal sedation and “cocktail conversation” with the patient to monitor the neurological status. Some studies also suggest that when compared with general anesthesia, regional anesthesia results in more stable hemodynamics but outcomes appear similar. Regional anesthesia for carotid surgery requires the cooperation of the surgeon and patient.

CASE DISCUSSION

A Patient for Cardioversion

A 55-year-old man with new-onset atrial fibrillation is scheduled for elective cardioversion.

What are the indications for an elective cardioversion?

Direct current (DC) cardioversion may be used to terminate supraventricular and ventricular tachyarrhythmias caused by reentry. It is not effective for arrhythmias from enhanced automaticity (multifocal atrial tachycardia) or triggered activity (digitalis toxicity). By simultaneously depolarizing the entire myocardium and possibly prolonging the refractory period, DC cardioversion can terminate atrial fibrillation and flutter, atrioventricular

nodal reentry, reciprocating tachycardias from pre-excitation syndromes, and ventricular tachycardia or fibrillation.

Specific indications for cardioversion of patients with atrial fibrillation include symptomatic fibrillation, recent onset, and no response to medications. Patients with long-standing fibrillation, a large atrium, chronic obstructive lung disease, congestive heart failure, or mitral regurgitation have a high recurrence rate. A TEE is usually performed shortly before cardioversion to rule out a left atrial blood clot. Such clots are typically located in the left atrial appendage and can be embolized by cardioversion or sinus rhythm.

Emergency cardioversion is indicated for any tachyarrhythmia associated with hypotension, congestive heart failure, or angina.

How is cardioversion performed?

Although the procedure is usually performed by cardiologists, the need for immediate cardioversion may arise in the operating room, ICU, or during cardiopulmonary resuscitation. Anesthesiologists must therefore be familiar with the technique. Following heavy sedation or light general anesthesia, DC shock is applied by either self-adhesive pads or 8- to 13-cm paddles. Larger paddles help reduce any shock-induced myocardial necrosis by distributing the current over a wider area. The energy output should be kept at the minimally effective level to prevent myocardial damage. Placement of the electrodes can be anterolateral or anteroposterior. In the first position, one electrode is placed on the right second intercostal space next to the sternum and the other is placed on the left fifth intercostal space in the midclavicular line. When pads are used for the anteroposterior technique, one is placed anteriorly over the ventricular apex in the fifth intercostal space and the other underneath the patient in the left infrascapular region.

For supraventricular tachycardias, with the notable exception of atrial fibrillation, energy levels of 25–50 J can successfully reestablish normal sinus rhythm. Synchronized shocks should be used for all tachyarrhythmias except ventricular

fibrillation. Synchronization times the delivery so that it is given during the QRS complex. If the shock occurs in the ST segment or the T wave (unsynchronized), it can precipitate a more serious arrhythmia, including ventricular fibrillation. All medical personnel should stand clear of the patient and the bed during the shock.

Atrial fibrillation usually requires a minimum of 50–100 J and larger energy levels are often used. Hemodynamically stable ventricular tachycardia can often be terminated with 25–50 J, but ventricular fibrillation and unstable ventricular tachycardia require 200–360 J. Regardless of the arrhythmia, a higher energy level is necessary when the first shock is ineffective.

The cardiologist wants to do the cardioversion in the postanesthesia care unit (PACU). Is this an appropriate place for cardioversion?

Elective cardioversion can be performed in any setting in which full provisions for cardiopulmonary resuscitation, including cardiac pacing capabilities, are immediately available. A physician skilled in airway management should be in attendance. Cardioversions are commonly performed in an ICU, emergency department, PACU, procedure room, or cardiac catheterization suite.

How would you evaluate this patient?

The patient should be fasted, evaluated, and treated as though he were receiving a general anesthetic in the operating room. An ECG is performed immediately before the procedure to confirm that the arrhythmia is still present; another is performed immediately afterward to confirm the new rhythm. Preoperative laboratory values should be within normal limits because metabolic disorders, particularly electrolyte and acid–base abnormalities, may contribute to the arrhythmia. If not corrected preoperatively, they can reinitiate the tachycardia following cardioversion. An antiarrhythmic agent is often started in patients with atrial fibrillation 1–2 days prior to the procedure to help maintain normal sinus rhythm. Patients may also be anticoagulated with warfarin for 1–2 weeks prior to cardioversion.

What are the minimum monitors and anesthetic equipment required?

Minimum monitoring consists of the ECG, blood pressure, and pulse oximetry. A precordial stethoscope is useful for monitoring breath sounds. Maintaining continuous verbal contact with the patient may be the best method for assessing whether a sufficient amnestic dose of (usually) propofol has been given.

In addition to a DC defibrillator capable of delivering up to 400 J (synchronized or unsynchronized) and transcutaneous pacing, the minimum equipment should include the following:

- Reliable intravenous access.
- A functional bag-mask device capable of delivering 100% oxygen (see Chapter 3).
- An oxygen source from a wall outlet or a full tank.
- An airway kit with oral and nasal airways and appropriate laryngoscopes and endotracheal tubes.
- A functional suction apparatus.
- An anesthetic drug kit that includes at least one sedative-hypnotic as well as succinylcholine.
- A cart that includes all necessary drugs and equipment for cardiopulmonary resuscitation (see Chapter 55).

What anesthetic techniques would be appropriate?

Premedication is not necessary. Only very brief (1–2 min) amnesia or light general anesthesia is required. A short-acting agent such as propofol or a benzodiazepine (eg, midazolam, diazepam) can be used. Etomidate may be used but may be associated with phonation. Following preoxygenation with 60–100% oxygen for 3–5 min, the sedative-hypnotic is given in small increments every 30–60 sec while maintaining verbal contact with the patient. The shock is delivered when the patient is no longer able to respond verbally; some clinicians use loss of the eyelid reflex as an end point. The shock usually arouses the patient. Transient airway obstruction or apnea may be observed, particularly if more than one shock is necessary.

What are the complications of cardioversion?

Complications include transient myocardial depression, postshock arrhythmias, and arterial embolism. Arrhythmias are usually due to inadequate synchronization, but even a properly timed cardioversion can occasionally result in ventricular fibrillation. Most arrhythmias are transient and resolve spontaneously. Although patients may develop ST-segment elevation, serum creatine phosphokinase levels (MB fraction) are usually normal. Embolism may be responsible for delayed awakening.

How should the patient be cared for following cardioversion?

Although recovery of consciousness is usually very rapid, patients should be treated like others receiving general anesthesia (see Chapter 56). Recovery also specifically includes monitoring for both recurrence of the arrhythmia and signs of cerebral embolism.

GUIDELINES

Hiratzka LF, Bakris GL, Beckman JA, et al: 2010 ACCF/AHA/AATS/ACR/ASA/SCA/SCAI/SIR/STS/SVM Guidelines for the diagnosis and management of patients with thoracic aortic disease: Executive summary: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines, American Association for Thoracic Surgery, American College of Radiology, American Stroke Association, Society of Cardiovascular Anesthesiologists, Society for Cardiovascular Angiography and Interventions, Society of Interventional Radiology, Society of Thoracic Surgeons, and Society for Vascular Medicine. *Anesth Analg* 2010;111:279.

Respiratory Physiology & Anesthesia

KEY CONCEPTS

- 1 The trachea serves as a conduit for ventilation and the clearance of tracheal and bronchial secretions and has an average length of 10–13 cm. The trachea bifurcates at the carina into the right and left main stem bronchi. The right main stem bronchus lies in a more vertical orientation relative to the trachea, whereas the left main stem bronchus lies in a more horizontal orientation.
- 2 The periodic exchange of alveolar gas with the fresh gas from the upper airway reoxygenates desaturated blood and eliminates CO_2 . This exchange is brought about by small cyclic pressure gradients established within the airways. During spontaneous ventilation, these gradients are secondary to variations in intrathoracic pressure; during mechanical ventilation, they are produced by intermittent positive pressure in the upper airway.
- 3 The lung volume at the end of a normal exhalation is called functional residual capacity (FRC). At this volume, the inward elastic recoil of the lung approximates the outward elastic recoil of the chest (including resting diaphragmatic tone).
- 4 Closing capacity is normally well below FRC, but it rises steadily with age. This increase is probably responsible for the normal age-related decline in arterial O_2 tension.
- 5 Whereas both forced expiratory volume in 1 sec (FEV_1) and forced vital capacity (FVC) are effort dependent, forced midexpiratory flow ($\text{FEF}_{25-75\%}$) is more effort independent and may be a more reliable measure of obstruction.
- 6 Changes in lung mechanics due to general anesthesia occur shortly after induction. The supine position reduces the FRC by 0.8–1.0 L, and induction of general anesthesia further reduces the FRC by 0.4–0.5 L. FRC reduction is a consequence of alveolar collapse and compression atelectasis due to loss of inspiratory muscle tone, change in chest wall rigidity, and upward shift of the diaphragm.
- 7 Local factors are more important than the autonomic system in influencing pulmonary vascular tone. Hypoxia is a powerful stimulus for pulmonary vasoconstriction (the opposite of its systemic effect).
- 8 Because alveolar ventilation (\dot{V}_A) is normally about 4 L/min and pulmonary capillary perfusion (\dot{Q}) is 5 L/min, the overall \dot{V}/\dot{Q} ratio is about 0.8.
- 9 Shunting denotes the process whereby desaturated, mixed venous blood from the right heart returns to the left heart without being resaturated with O_2 in the lungs. The overall effect of shunting is to decrease (dilute) arterial O_2 content; this type of shunt is referred to as right-to-left.

—Continued next page

Continued—

- 10 General anesthesia commonly increases venous admixture to 5% to 10%, probably as a result of atelectasis and airway collapse in dependent areas of the lung.
- 11 Note that large increases in P_{aCO_2} (>75 mm Hg) readily produce hypoxia (P_{aO_2} <60 mm Hg) at room air, but not at high inspired O_2 concentrations.
- 12 The binding of O_2 to hemoglobin seems to be the principal rate-limiting factor in the transfer of O_2 from alveolar gas to blood.
- 13 The greater the shunt, the less likely the possibility that an increase in the fraction of inspired oxygen (F_{IO_2}) will prevent hypoxemia.
- 14 A rightward shift in the oxygen–hemoglobin dissociation curve lowers O_2 affinity, displaces O_2 from hemoglobin, and makes more O_2 available to tissues; a leftward shift increases hemoglobin’s affinity for O_2 , reducing its availability to tissues.
- 15 Bicarbonate represents the largest fraction of CO_2 in blood.
- 16 Central chemoreceptors are thought to lie on the anterolateral surface of the medulla and respond primarily to changes in cerebrospinal fluid (CSF) $[H^+]$. This mechanism is effective in regulating P_{aCO_2} , because the blood–brain barrier is permeable to dissolved CO_2 but not to bicarbonate ions.
- 17 With increasing depth of anesthesia, the slope of the P_{aCO_2} /minute ventilation curve decreases, and the apneic threshold increases.

The importance of pulmonary physiology to anesthetic practice is obvious. The most commonly used anesthetics—the inhalation agents—depend on the lungs for uptake and elimination. The most important side effects of both inhalation and intravenously administered anesthetics are primarily respiratory. Moreover, muscle paralysis, unusual positioning during surgery, and techniques such as one-lung anesthesia and cardiopulmonary bypass profoundly alter normal pulmonary physiology.

Much of modern anesthetic practice is based on a thorough understanding of pulmonary physiology and may be considered applied pulmonary physiology. This chapter reviews the basic pulmonary concepts necessary for understanding and applying anesthetic techniques. Although the pulmonary effects of each of the various anesthetic agents are discussed elsewhere in the book, this chapter also reviews the overall effects of general anesthesia on lung function.

FUNCTIONAL RESPIRATORY ANATOMY

1. Rib Cage & Muscles of Respiration

The rib cage contains the two lungs, each surrounded by its own pleura. The apex of the chest is small, allowing only for entry of the trachea, esophagus, and blood vessels, whereas the base is formed by the diaphragm. Contraction of the diaphragm—the principal pulmonary muscle—causes the base of the thoracic cavity to descend 1.5–7 cm and its contents (the lungs) to expand. Diaphragmatic movement normally accounts for 75% of the change in chest volume. Accessory respiratory muscles also increase chest volume (and lung expansion) by their action on the ribs. Each rib (except for the last two) articulates posteriorly with a vertebra and is angulated downward as it attaches anteriorly to the sternum. Upward and outward rib movement expands the chest.

During normal breathing, the diaphragm, and, to a lesser extent, the external intercostal muscles are responsible for inspiration; expiration is generally passive. With increasing effort, the sternocleidomastoid, scalene, and pectoralis muscles can be recruited during inspiration. The sternocleidomastoid muscles assist in elevating the rib cage, whereas the scalene muscles prevent inward displacement of the upper ribs during inspiration. The pectoralis muscles can assist chest expansion when the arms are placed on a fixed support. Expiration is normally passive in the supine position, but becomes active in the upright position and with increased effort. Exhalation may be facilitated by the abdominal muscles (rectus abdominis, external and internal oblique, and transversus) and perhaps the internal intercostal muscles—aiding the downward movement of the ribs.

Although not usually considered respiratory muscles, some pharyngeal muscles are important in maintaining the patency of the airway. Tonic and reflex inspiratory activity in the genioglossus keeps the tongue away from the posterior pharyngeal wall. Tonic activity in the levator palati, tensor palati, palatopharyngeus, and palatoglossus prevents the soft palate from falling back against the posterior pharynx, particularly in the supine position.

2. Tracheobronchial Tree

1 The trachea serves as a conduit for ventilation and the clearance of tracheal and bronchial secretions. The trachea begins at the lower border of the cricoid cartilage and extends to the level of the carina and has an average length of 10–13 cm. It is composed of C-shaped cartilaginous rings, which form the anterior and lateral walls of the trachea and are connected posteriorly by the membranous wall of the trachea. The external diameters of the trachea measure approximately 2.3 cm coronally and 1.8 cm sagittally in men, with corresponding values of 2.0 cm and 1.4 cm, respectively, in women. The cricoid cartilage is the narrowest part of the trachea, with an average diameter of 17 mm in men and 13 mm in women.

The trachea bifurcates at the carina into the right and left main stem bronchi. The tracheal lumen narrows slightly as it progresses toward the carina,

with the tracheal bifurcation located at the level of the sternal angle. The right main stem bronchus lies in a more vertical orientation relative to the trachea, whereas the left main stem bronchus lies in a more horizontal orientation. The right main stem bronchus continues as the bronchus intermedius after the take-off of the right upper lobe bronchus. The distance from the tracheal carina to the take-off of the right upper lobe bronchus is an average of 2.0 cm in men and approximately 1.5 cm in women. One in every 250 individuals in the general population may have an abnormal take-off of the right upper lobe bronchus emerging from above the tracheal carina on the right side. The left main stem bronchus is longer than the right main stem bronchus and measures an average of 5.0 cm in men and 4.5 cm in women. The left main stem bronchus divides into the left upper lobe bronchus and the left lower lobe bronchus.

Humidification and filtering of inspired air are functions of the upper airway (nose, mouth, and pharynx). The function of the tracheobronchial tree is to conduct gas flow to and from the alveoli. Dichotomous division (each branch dividing into two smaller branches), starting with the trachea and ending in alveolar sacs, is estimated to involve 23 divisions, or generations (Figure 23–1). With each generation, the number of airways is approximately doubled. Each alveolar sac contains, on average, 17 alveoli. An estimated 300 million alveoli provide an enormous membrane (50–100 m²) for gas exchange in the average adult.

With each successive division, the mucosal epithelium and supporting structures of the airways gradually change. The mucosa makes a gradual transition from ciliated columnar to cuboidal and finally to flat alveolar epithelium. Gas exchange can occur only across the flat epithelium, which begins to appear on respiratory bronchioles (generations 17–19). The wall of the airway gradually loses its cartilaginous support (at the bronchioles) and then its smooth muscle. Loss of cartilaginous support causes the patency of smaller airways to become dependent on radial traction by the elastic recoil of the surrounding tissue; as a corollary, airway diameter becomes dependent on total lung volume.

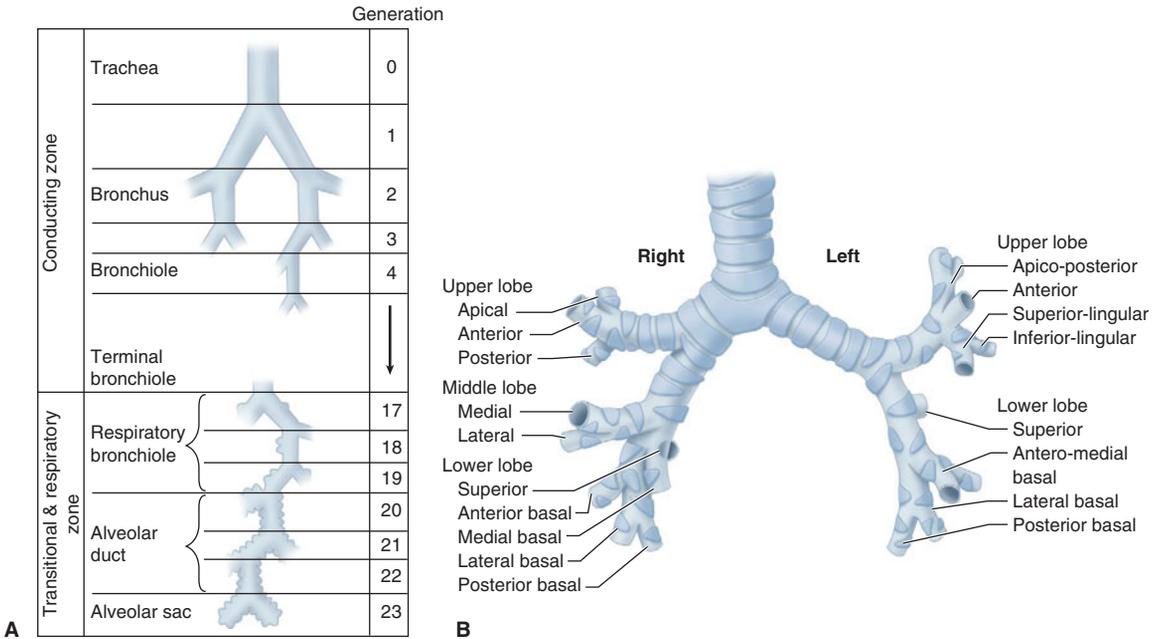

FIGURE 23-1 A: Dichotomous division of the airways. (Reproduced, with permission, from Guyton AC: *Textbook of Medical Physiology*, 7th ed. W.B. Saunders, 1986.) B: The segmental

bronchi. (Reproduced, with permission, from Minnich DJ, Mathisen DJ: *Anatomy of the trachea, carina, and bronchi*. *Thorac Surg Clin* 2007 Nov;17(4):571-585.)

Cilia on the columnar and cuboidal epithelium normally beat in a synchronized fashion, such that the mucus produced by the secretory glands lining the airway (and any associated bacteria or debris) moves up toward the mouth.

Alveoli

Alveolar size is a function of both gravity and lung volume. The average diameter of an alveolus is thought to be 0.05–0.33 mm. In the upright position, the largest alveoli are at the pulmonary apex, whereas the smallest tend to be at the base. With inspiration, discrepancies in alveolar size diminish.

Each alveolus is in close contact with a network of pulmonary capillaries. The walls of each alveolus are asymmetrically arranged (Figure 23-2). On the thin side, where gas exchange occurs, the alveolar epithelium and capillary endothelium are separated only by their respective cellular and basement membranes; on the thick side, where fluid and solute exchange occurs, the pulmonary interstitial space

separates alveolar epithelium from capillary endothelium. The pulmonary interstitial space contains mainly elastin, collagen, and perhaps nerve fibers. Gas exchange occurs primarily on the thin side of the alveolocapillary membrane, which is less than 0.4 μm thick. The thick side (1–2 μm) provides structural support for the alveolus.

The pulmonary epithelium contains at least two cell types. Type I pneumocytes are flat and form tight (1-nm) junctions with one another. These tight junctions are important in preventing the passage of large oncologically active molecules such as albumin into the alveolus. Type II pneumocytes, which are more numerous than type I pneumocytes (but because of their shape occupy less than 10% of the alveolar space), are round cells that contain prominent cytoplasmic inclusions (lamellar bodies). These inclusions contain surfactant, an important substance necessary for normal pulmonary mechanics (see below). Unlike type I cells, type II pneumocytes are capable of cell division and can produce type I

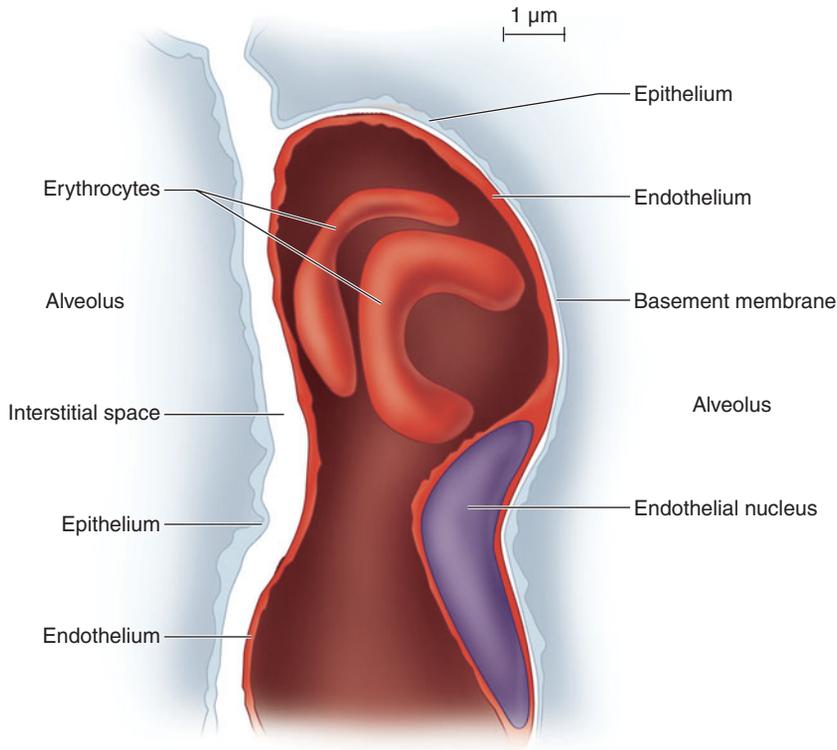

FIGURE 23-2 The pulmonary interstitial space, with a capillary passing between the two alveoli. The capillary is incorporated into the thin (gas-exchanging) side of the alveolus on the right. The interstitial space is incorporated

into the thick side of the alveolus on the left. (Reproduced, with permission, from Nunn JF: *Nunn's Applied Physiology*, 4th ed. Butterworth, 2000.)

pneumocytes if the latter are destroyed. They are also resistant to O_2 toxicity.

Other cell types present in the lower airways include pulmonary alveolar macrophages, mast cells, lymphocytes, and amino precursor uptake and decarboxylation (APUD) cells. Neutrophils are also typically present in smokers and patients with acute lung injury.

3. Pulmonary Circulation & Lymphatics

The lungs are supplied by two circulations, pulmonary and bronchial. The bronchial circulation arises from the left heart and sustains the metabolic needs of the tracheobronchial tree. The bronchial circulation provides a small amount of

blood flow (ie, less than 4% of the cardiac output). Branches of the bronchial artery supply the wall of the bronchi and follow the airways as far as the terminal bronchioles. Along their courses, the bronchial vessels anastomose with the pulmonary arterial circulation and continue as far as the alveolar duct. Below that level, lung tissue is supported by a combination of the alveolar gas and pulmonary circulation. Except for the main bronchi within the mediastinum, almost all the blood carried by the bronchial arteries enters the pulmonary circulation.

The pulmonary circulation normally receives the total output of the right heart via the pulmonary artery, which divides into right and left branches to supply each lung. Deoxygenated blood passes

through the pulmonary capillaries, where O_2 is taken up and CO_2 is eliminated. The oxygenated blood is then returned to the left heart by four main pulmonary veins (two from each lung). Although flows through the systemic and pulmonary circulations are equal, the lower pulmonary vascular resistance results in pulmonary vascular pressures that are one-sixth of those in the systemic circulation; as a result, both pulmonary arteries and veins normally have thinner walls than systemic vessels with less smooth muscle.

There are connections between the bronchial and the pulmonary circulations. Direct pulmonary arteriovenous communications, bypassing the pulmonary capillaries, are normally insignificant but may become important in certain pathological states. The importance of the bronchial circulation in contributing to the normal venous admixture is discussed below.

Pulmonary Capillaries

Pulmonary capillaries are incorporated into the walls of alveoli. The average diameter of these capillaries (about 10 μm) is barely enough to allow passage of a single red cell. Because each capillary network supplies more than one alveolus, blood may pass through several alveoli before reaching the pulmonary veins. Because of the relatively low pressure in the pulmonary circulation, the amount of blood flowing through a given capillary network is affected by both gravity and alveolar size. Large alveoli have a smaller capillary cross-sectional area and consequently increased resistance to blood flow. In the upright position, apical capillaries tend to have reduced flows, whereas basal capillaries have higher flows.

The pulmonary capillary endothelium has relatively large junctions (5 nm wide), allowing the passage of large molecules such as albumin. As a result, pulmonary interstitial fluid is relatively rich in albumin. Circulating macrophages and neutrophils are able to pass through the endothelium, as well as the smaller alveolar epithelial junctions, with relative ease. Pulmonary macrophages are commonly seen in the interstitial space and inside alveoli; they serve to prevent bacterial infection and to scavenge foreign particles.

Pulmonary Lymphatics

Lymphatic channels in the lung originate in the interstitial spaces of large septa and are close to the bronchial arteries. Bronchial lymphatics return fluids, lost proteins, and various cells that have escaped in the peribronchovascular interstitium into the blood circulation, thus ensuring homeostasis and permitting lung function. Because of the large endothelial junctions, pulmonary lymph has a relatively high protein content, and total pulmonary lymph flow may be as much as 20 mL/hr. Large lymphatic vessels travel upward alongside the airways, forming the tracheobronchial chain of lymph nodes. Lymphatic drainage channels from both lungs communicate along the trachea.

4. Innervation

The diaphragm is innervated by the phrenic nerves, which arise from the C3–C5 nerve roots. Unilateral phrenic nerve block or palsy only modestly reduces most indices of pulmonary function (about 25%) in normal subjects. Although bilateral phrenic nerve palsies produce more severe impairment, accessory muscle activity may maintain adequate ventilation in some patients. Intercostal muscles are innervated by their respective thoracic nerve roots. Cervical cord injuries above C5 are incompatible with spontaneous ventilation because both phrenic and intercostal nerves are affected.

The vagus nerves provide sensory innervation to the tracheobronchial tree. Both sympathetic and parasympathetic autonomic innervation of bronchial smooth muscle and secretory glands is present. Vagal activity mediates bronchoconstriction and increases bronchial secretions via muscarinic receptors. Sympathetic activity (T1–T4) mediates bronchodilation and also decreases secretions via β_2 -receptors. The nerve supply of the larynx is reviewed in Chapter 19.

Both α - and β -adrenergic receptors are present in the pulmonary vasculature, but the sympathetic system normally has little effect on pulmonary vascular tone. α_1 -Activity causes vasoconstriction; β_2 -activity mediates vasodilation. Parasympathetic vasodilatory activity seems to be mediated via the release of nitric oxide.

MECHANISMS OF BREATHING

2 The periodic exchange of alveolar gas with the fresh gas from the upper airway reoxygenates desaturated blood and eliminates CO₂. This exchange is brought about by small cyclic pressure gradients established within the airways. During spontaneous ventilation, these gradients are secondary to variations in intrathoracic pressure; during mechanical ventilation, they are produced by intermittent positive pressure in the upper airway.

Spontaneous Ventilation

Normal pressure variations during spontaneous breathing are shown in [Figure 23–3](#). The pressure within alveoli is always greater than the surrounding (intrathoracic) pressure unless the alveoli are collapsed. Alveolar pressure is normally atmospheric (zero for reference) at end-inspiration and end-expiration. By convention in pulmonary physiology, pleural pressure is used as a measure of intrathoracic pressure. Although it may not be entirely correct to refer to the pressure in a potential space, the concept allows the calculation of transpulmonary pressure. Transpulmonary pressure, or P_{transpulmonary}, is then defined as follows:

$$P_{\text{transpulmonary}} = P_{\text{alveolar}} - P_{\text{intrapleural}}$$

At end-expiration, intrapleural pressure normally averages about -5 cm H₂O, and because alveolar pressure is 0 (no flow), transpulmonary pressure is $+5$ cm H₂O.

Diaphragmatic and intercostal muscle activation during inspiration expands the chest and decreases intrapleural pressure from -5 cm H₂O to -8 or -9 cm H₂O. As a result, alveolar pressure also decreases (between -3 and -4 cm H₂O), and an alveolar–upper airway gradient is established; gas flows from the upper airway into alveoli. At end-inspiration (when gas inflow has ceased), alveolar pressure returns to zero, but intrapleural pressure remains decreased; the new transpulmonary pressure (5 cm H₂O) sustains lung expansion.

During expiration, diaphragmatic relaxation returns intrapleural pressure to -5 cm H₂O. Now the transpulmonary pressure does not support the new lung volume, and the elastic recoil of the lung causes

a reversal of the previous alveolar–upper airway gradient; gas flows out of alveoli, and original lung volume is restored.

Mechanical Ventilation

Most forms of mechanical ventilation intermittently apply positive airway pressure at the upper airway. During inspiration, gas flows into alveoli until alveolar pressure reaches that in the upper airway. During the expiratory phase of the ventilator, the positive airway pressure is removed or decreased; the gradient reverses, allowing gas flow out of alveoli.

LUNG MECHANICS

The movement of the lungs is passive and determined by the impedance of the respiratory system, which can be divided into the elastic resistance of tissues and the gas–liquid interface and the nonelastic resistance to gas flow. Elastic resistance governs lung volume and the associated pressures under static conditions (no gas flow). Resistance to gas flow relates to frictional resistance to airflow and tissue deformation. The work necessary to overcome elastic resistance is stored as potential energy, but the work necessary to overcome nonelastic resistance is lost as heat.

1. Elastic Resistance

Both the lungs and the chest have elastic properties. The chest has a tendency to expand outward, whereas the lungs have a tendency to collapse. When the chest is exposed to atmospheric pressure (open pneumothorax), it usually expands about 1 L in adults. In contrast, when the lung is exposed to atmospheric pressure, it collapses completely and all the gas within it is expelled. The recoil properties of the chest are due to structural components that resist deformation and chest wall muscle tone. The elastic recoil of the lungs is due to their high content of elastin fibers, and, even more important, the surface tension forces acting at the air–fluid interface in alveoli.

Surface Tension Forces

The gas–fluid interface lining the alveoli causes them to behave as bubbles. Surface tension forces tend to

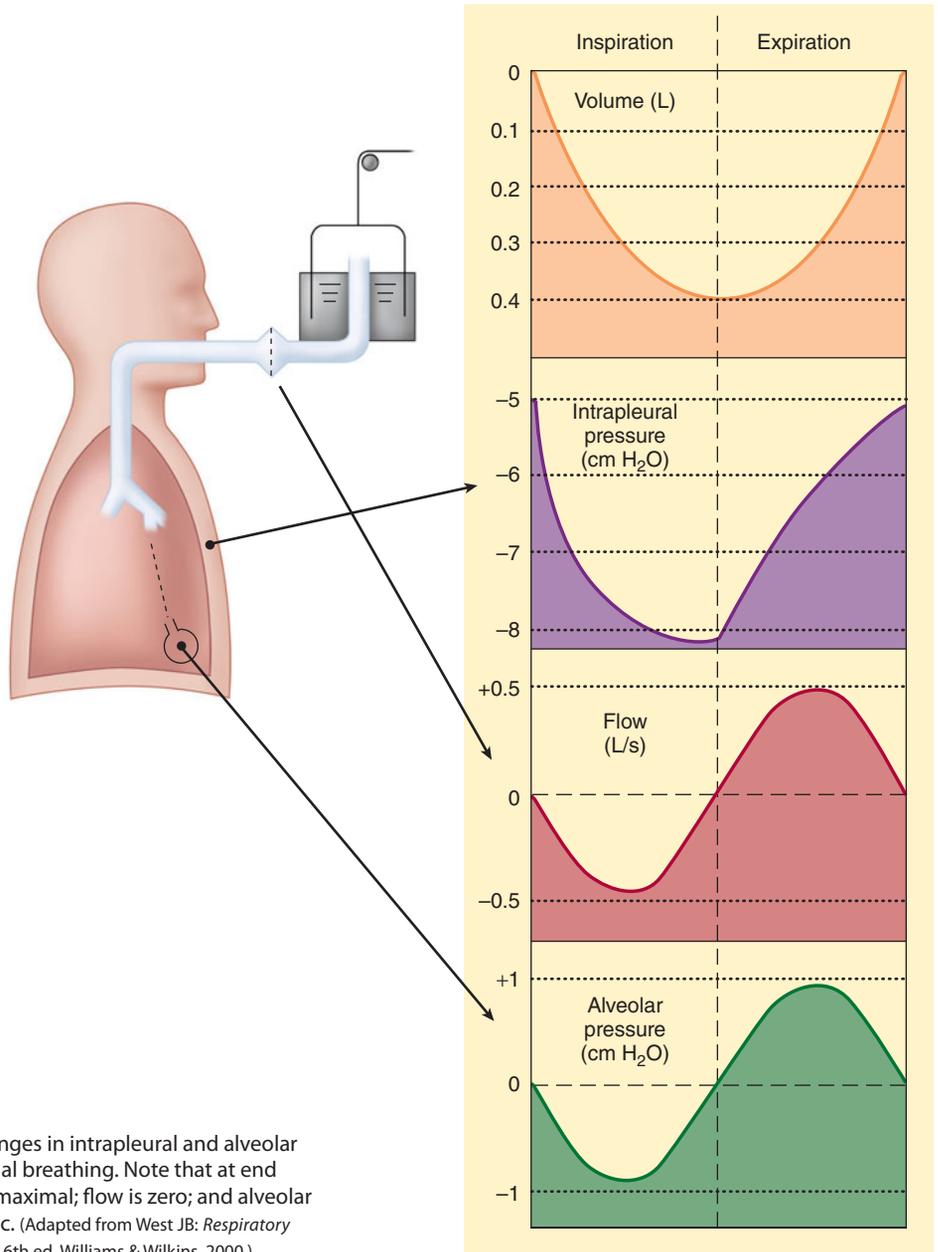

FIGURE 23-3 Changes in intrapleural and alveolar pressures during normal breathing. Note that at end inspiration, volume is maximal; flow is zero; and alveolar pressure is atmospheric. (Adapted from West JB: *Respiratory Physiology—The Essentials*, 6th ed. Williams & Wilkins, 2000.)

reduce the area of the interface and favor alveolar collapse. Laplace's law can be used to quantify these forces:

$$\text{Pressure} = \frac{2 \times \text{Surface tension}}{\text{Radius}}$$

The pressure derived from the equation is that within the alveolus. Alveolar collapse is therefore directly proportional to surface tension. **Fortunately, in contrast to a bubble, pulmonary surfactant decreases alveolar surface tension.** Moreover, the

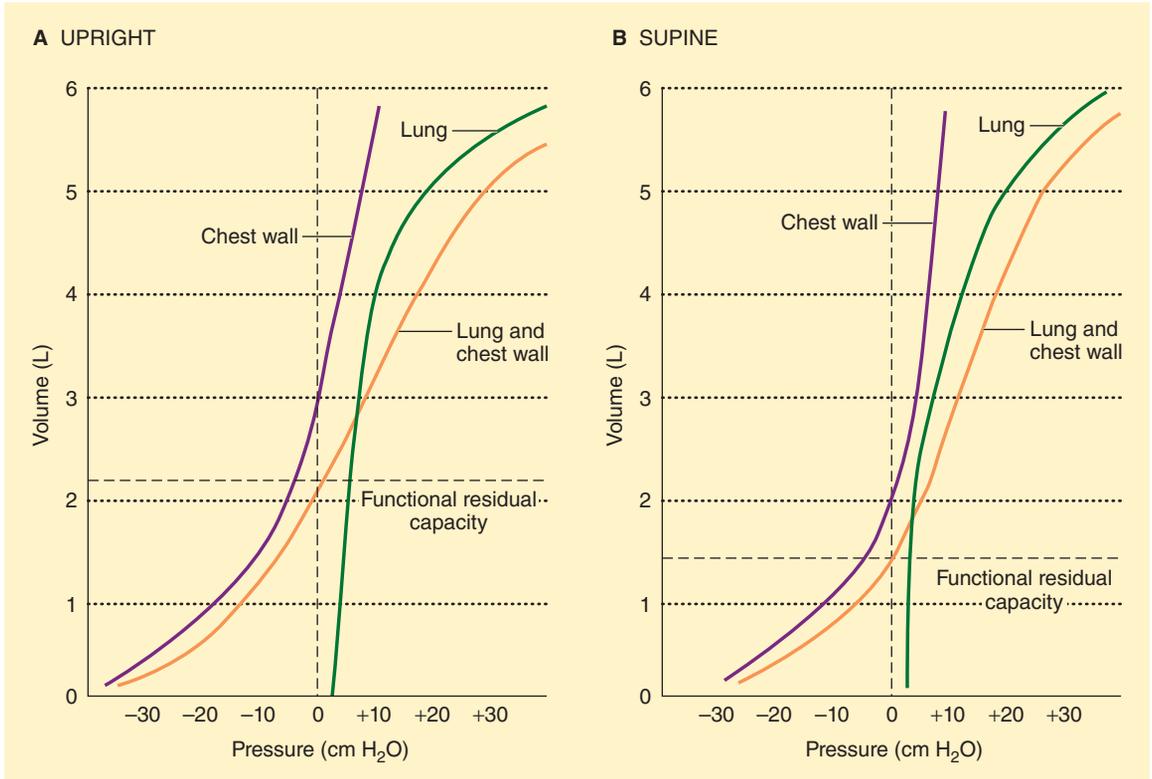

FIGURE 23-4 The pressure–volume relationship for the chest wall, lung, and both together in the upright (A) and supine (B) positions. (Modified and reproduced, with permission, from Scurr C, Feldman S: *Scientific Foundations of Anesthesia*. Heinemann, 1982.)

ability of the surfactant to lower surface tension is directly proportional to its concentration within the alveolus, resulting in lower intraalveolar pressure in smaller alveoli. As alveoli become smaller, the surfactant within becomes more concentrated, and surface tension is more effectively reduced. Conversely, when alveoli are overdistended, surfactant becomes less concentrated, and surface tension increases. The net effect is to stabilize alveoli; small alveoli are prevented from getting smaller, whereas large alveoli are prevented from getting larger.

Compliance

Elastic recoil is usually measured in terms of compliance (C), which is defined as the change in volume divided by the change in distending pressure. Compliance measurements can be obtained for either the chest, the lung, or both together (Figure 23-4).

In the supine position, chest wall compliance (C_w) is reduced because of the weight of the abdominal contents against the diaphragm. Measurements are usually obtained under static conditions, (ie, at equilibrium). (Dynamic lung compliance [$C_{dyn,L}$], which is measured during rhythmic breathing, is also dependent on airway resistance.) **Lung compliance (C_L)** is defined as

$$C_L = \frac{\text{Change in lung volume}}{\text{Change in transpulmonary pressure}}$$

C_L is normally 150–200 mL/cm H₂O. A variety of factors, including lung volume, pulmonary blood volume, extravascular lung water, and pathological processes (eg, inflammation and fibrosis) affect C_L .

$$\text{Chest wall compliance} = \frac{\text{Change in chest volume}}{\text{Change in transthoracic pressure}} \quad (C_w)$$

where transthoracic pressure equals atmospheric pressure minus intrapleural pressure.

Normal chest wall compliance is 200 mL/cm H₂O. Total compliance (lung and chest wall together) is 100 mL/cm H₂O and is expressed by the following equation:

$$\frac{1}{C_{\text{total}}} = \frac{1}{C_{\text{W}}} + \frac{1}{C_{\text{L}}}$$

2. Lung Volumes

Lung volumes are important parameters in respiratory physiology and clinical practice (Table 23-1 and Figure 23-5). The sum of all of the named lung volumes equals the maximum to which the lung can be inflated. Lung capacities are clinically useful measurements that represent a combination of two or more volumes.

TABLE 23-1 Lung volumes and capacities.

Measurement	Definition	Average Adult Values (mL)
Tidal volume (V _T)	Each normal breath	500
Inspiratory reserve volume (IRV)	Maximal additional volume that can be inspired above V _T	3000
Expiratory reserve volume (ERV)	Maximal volume that can be expired below V _T	1100
Residual volume (RV)	Volume remaining after maximal exhalation	1200
Total lung capacity (TLC)	RV + ERV + V _T + IRV	5800
Functional residual capacity (FRC)	RV + ERV	2300

Functional Residual Capacity

3 The lung volume at the end of a normal exhalation is called functional residual capacity (FRC). At this volume, the inward elastic recoil of the lung approximates the outward elastic recoil of

the chest (including resting diaphragmatic tone). Thus, the elastic properties of both chest and lung define the point from which normal breathing takes place. Functional residual capacity can be measured by nitrogen washout or helium washin technique or

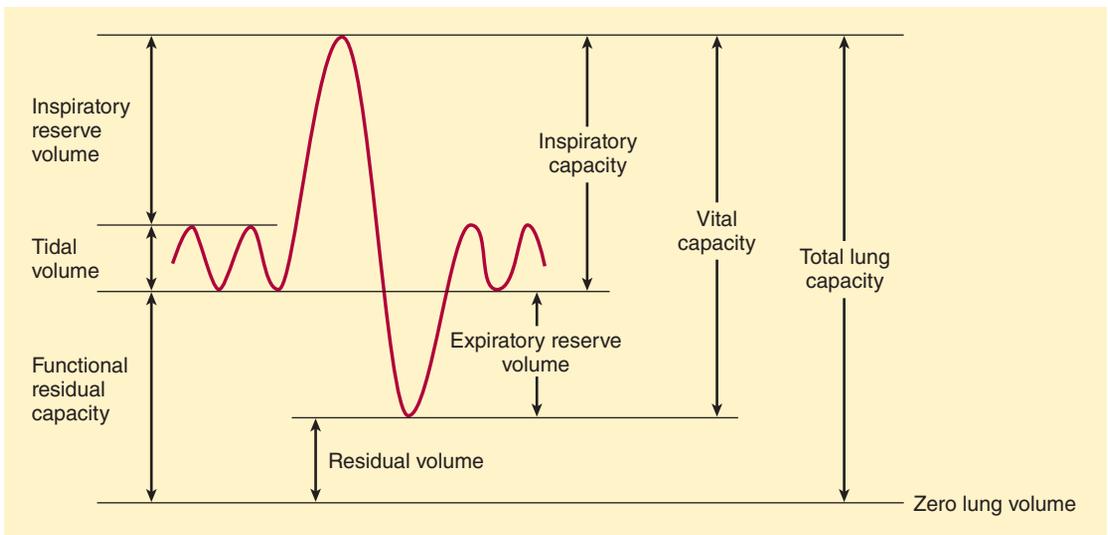

FIGURE 23-5 Spirogram showing static lung volumes. (Reproduced, with permission, from Nunn JF: *Nunn's Applied Physiology*, 4th ed. Butterworth, 2000.)

by body plethysmography. Factors known to alter the FRC include the following:

- **Body habitus:** FRC is directly proportional to height. Obesity, however, can markedly decrease FRC (primarily as a result of reduced chest compliance).
- **Sex:** FRC is reduced by about 10% in females compared with males.
- **Posture:** FRC decreases as a patient is moved from an upright to a supine or prone position. This is the result of reduced chest compliance as the abdominal contents push up against the diaphragm. The greatest change occurs between 0° and 60° of inclination. No further decrease is observed with a head-down position of up to 30°.
- **Lung disease:** Decreased compliance of the lung, chest, or both is characteristic of restrictive pulmonary disorders all of which are associated with a low FRC.
- **Diaphragmatic tone:** This normally contributes to FRC.

Closing Capacity

As described above (see the section on Functional Respiratory Anatomy), small airways lacking cartilaginous support depend on radial traction caused by the elastic recoil of surrounding tissue to keep them open; patency of these airways, particularly in basal areas of the lung, is highly dependent on lung volume. The volume at which these airways begin to close in dependent areas of the lung is called the **closing capacity**. At lower lung volumes, alveoli in dependent areas continue to be perfused but are no longer ventilated; **intrapulmonary shunting** of deoxygenated blood promotes hypoxemia (see below).

Closing capacity is usually measured using a tracer gas (xenon-133), which is inhaled near residual volume and then exhaled from total lung capacity.

4 Closing capacity is normally well below FRC (Figure 23-6), but rises steadily with age (Figure 23-7). This increase is probably responsible for the normal age-related decline in arterial O₂ tension. At an average age of 44 years, closing capacity

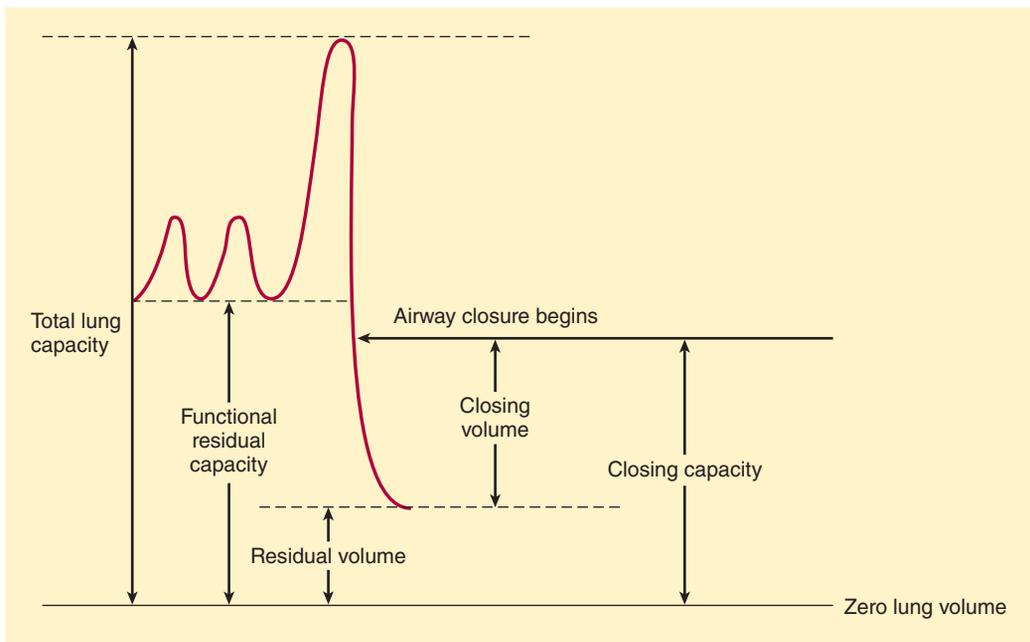

FIGURE 23-6 The relationship between functional residual capacity, closing volume, and closing capacity. (Reproduced, with permission, from Nunn JF: *Nunn's Applied Physiology*, 4th ed. Butterworth, 2000.)

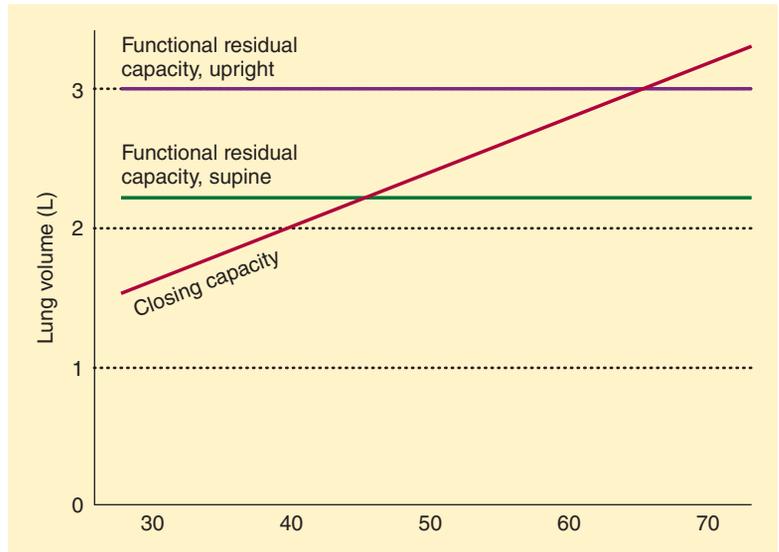

FIGURE 23-7 The effect of age on closing capacity and its relationship to functional residual capacity (FRC). Note that FRC does not change. (Reproduced, with permission, from Nunn JF: *Nunn's Applied Physiology*, 4th ed. Butterworth, 2000.)

equals FRC in the supine position; by age 66, closing capacity equals or exceeds FRC in the upright position in most individuals. Unlike FRC, closing capacity is unaffected by posture.

Vital Capacity

Vital capacity (VC) is the maximum volume of gas that can be exhaled following maximal inspiration. In addition to body habitus, VC is also dependent on respiratory muscle strength and chest–lung compliance. Normal VC is about 60–70 mL/kg.

3. Nonelastic Resistances

Airway Resistance to Gas Flow

Gas flow in the lung is a mixture of laminar and turbulent flow. Laminar flow can be thought of as consisting of concentric cylinders of gas flowing at different velocities; velocity is highest in the center and decreases toward the periphery. During laminar flow,

$$\text{Flow} = \frac{\text{Pressure gradient}}{R_{aw}}$$

where R_{aw} is airway resistance.

$$R_{aw} = \frac{8 \times \text{Length} \times \text{Gas viscosity}}{\pi \times (\text{Radius})^4}$$

Turbulent flow is characterized by random movement of the gas molecules down the air passages. Mathematical description of turbulent flow is considerably more complex:

$$\text{Pressure gradient} \approx \text{Flow}^2 \times \frac{\text{Gas density}}{\text{Radius}^5}$$

Resistance is not constant but increases in proportion to gas flow. Moreover, resistance is directly proportional to gas density and inversely proportional to the fifth power of the radius. As a result, turbulent gas flow is extremely sensitive to airway caliber.

Turbulence generally occurs at high gas flows, at sharp angles or branching points, and in response to abrupt changes in airway diameter. Whether turbulent or laminar flow occurs can be predicted by the Reynolds number, which results from the following equation:

$$\text{Reynolds number} = \frac{\text{Linear velocity} \times \text{Diameter} \times \text{Gas density}}{\text{Gas viscosity}}$$

A low Reynolds number (<1000) is associated with laminar flow, whereas a high value (>1500) produces turbulent flow. Laminar flow normally occurs only distal to small bronchioles (<1 mm). Flow in larger airways is probably turbulent. Of the

TABLE 23–2 Physical properties of several gas mixtures.¹

Mixture	Viscosity ²	Density ²	Density/Viscosity ²
Oxygen (100%)	1.11	1.11	1.00
N ₂ /O ₂	0.89	1.41	1.49
Helium/O ₂ (80:20)	1.08	0.33	0.31

¹Data from Nunn JF: *Nunn's Applied Physiology*, 4th ed. Butterworth, 2000.

²Viscosities and densities are expressed relative to air.

gases used clinically, only helium has a significantly lower density-to-viscosity ratio, making it useful clinically during severe turbulent flow (as caused by upper airway obstruction). A helium–O₂ mixture not only is less likely to cause turbulent flow but also reduces airway resistance when turbulent flow is present (Table 23–2).

Normal total airway resistance is about 0.5–2 cm H₂O/L/sec, with the largest contribution coming from medium-sized bronchi (before the seventh generation). Resistance in large bronchi is low because of their large diameters, whereas resistance in small bronchi is low because of their large total cross-sectional area. The most important causes of increased airway resistance include bronchospasm, secretions, and mucosal edema as well as volume-related and flow-related airway collapse.

A. Volume-Related Airway Collapse

At low lung volumes, loss of radial traction increases the contribution of small airways to total resistance; airway resistance becomes inversely proportional to lung volume (Figure 23–8). Increasing lung volume up to normal with positive end-expiratory pressure (PEEP) can reduce airway resistance.

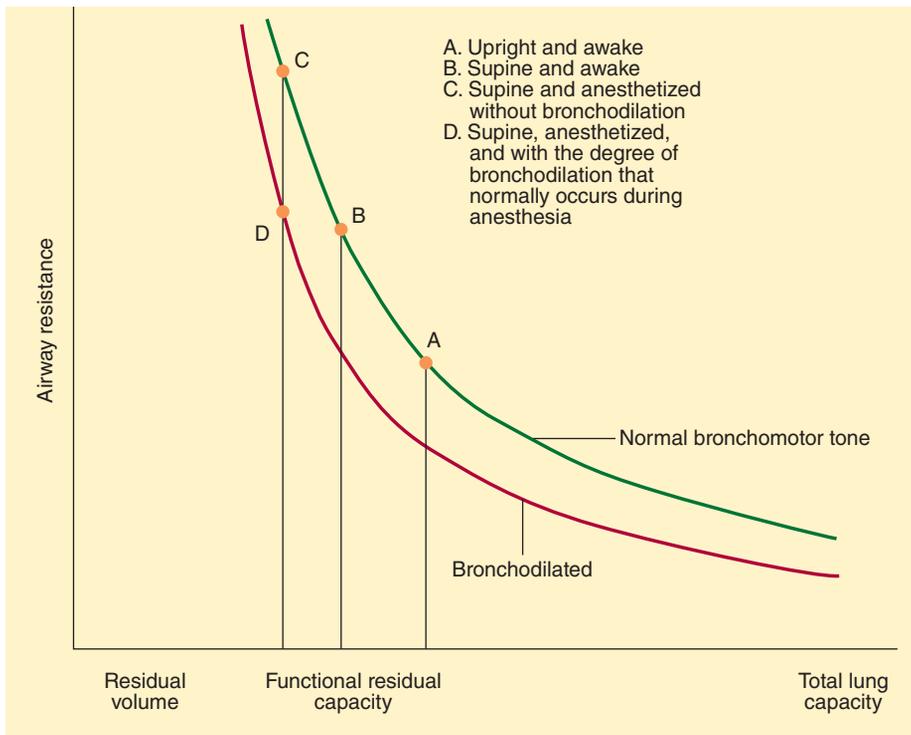

FIGURE 23–8 The relationship between airway resistance and lung volume. (Reproduced, with permission, from Nunn JF: *Nunn's Applied Physiology*, 4th ed. Butterworth, 2000.)

B. Flow-Related Airway Collapse

During forced exhalation, reversal of the normal transmural airway pressure can cause collapse of these airways (dynamic airway compression). Two contributing factors are responsible: generation of a positive pleural pressure and a large pressure drop across intrathoracic airways as a result of increased airway resistance. The latter is in turn due to high

(turbulent) gas flow and the reduced lung volume. The terminal portion of the flow/volume curve is therefore considered to be effort independent (**Figure 23-9**).

The point along the airways where dynamic compression occurs is called the equal pressure point. It is normally beyond the eleventh to thirteenth generation of bronchioles where cartilaginous support is

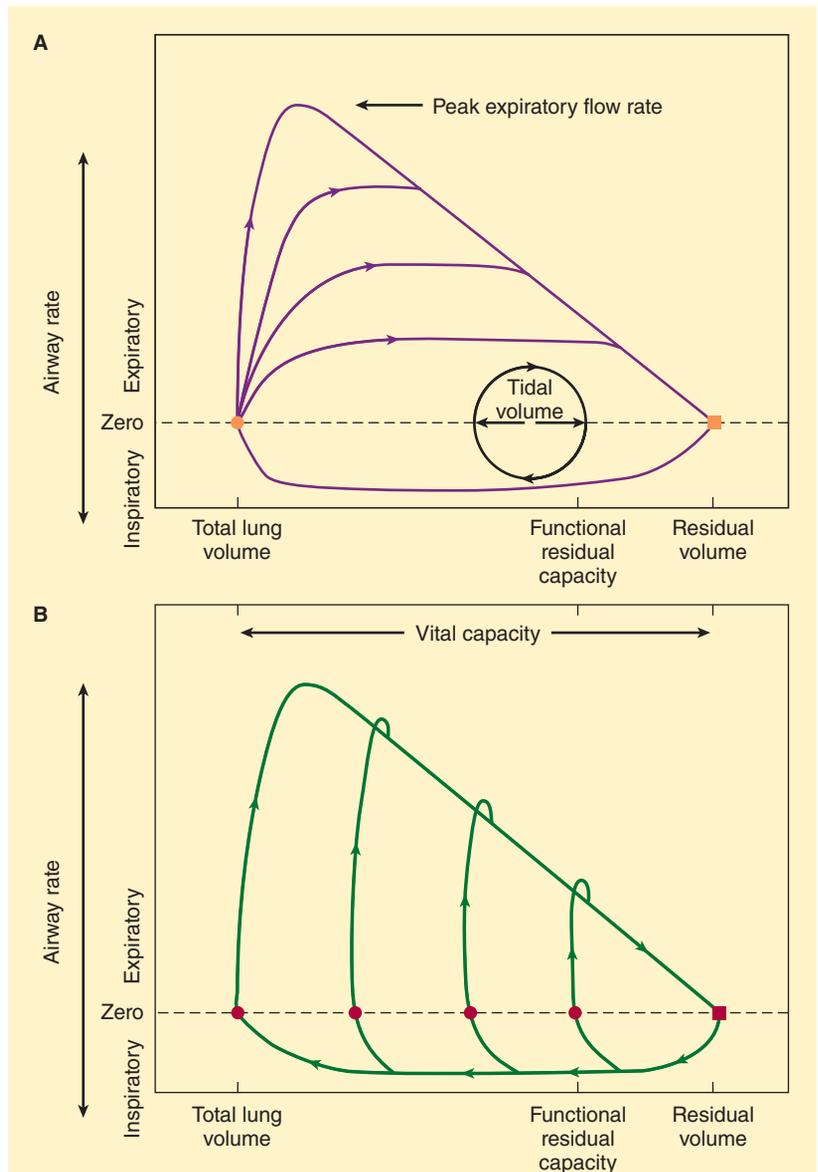

FIGURE 23-9 Gas flow (A) during forced exhalation from total lung capacity with varying effort and (B) with maximal effort from different lung volumes. Note that regardless of initial lung volume or effort, terminal expiratory flows are effort independent. (Reproduced, with permission, from Nunn JF: *Nunn's Applied Physiology*, 4th ed. Butterworth, 2000.)

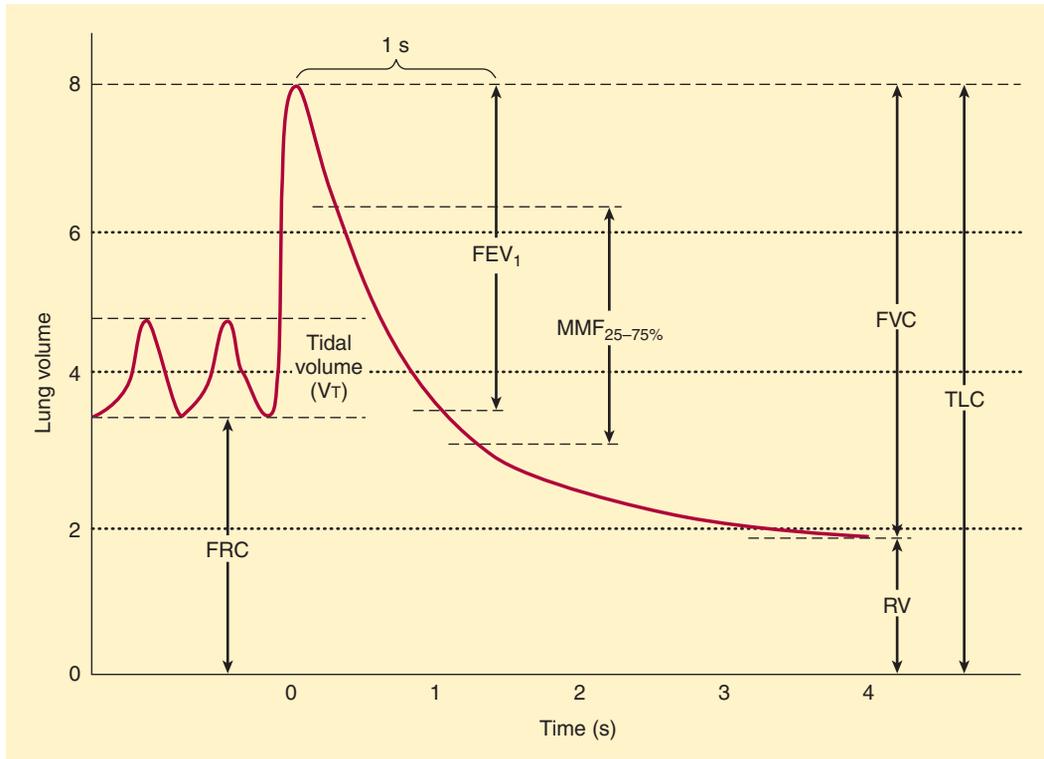

FIGURE 23-10 The normal forced exhalation curve. $FEF_{25-75\%}$ is also called the maximum midexpiratory flow rate ($MMF_{25-75\%}$). FRC, functional residual capacity;

FEV_1 , forced expiratory volume in 1 sec; FVC, forced vital capacity; RV, residual volume; TLC, total lung capacity.

absent (see above). The equal pressure point moves toward smaller airways as lung volume decreases. Emphysema or asthma predisposes patients to dynamic airway compression. Emphysema destroys the elastic tissues that normally support smaller airways. In patients with asthma, bronchoconstriction and mucosal edema intensify airway collapse and promote reversal of transmural pressure gradients across airways. Patients may terminate exhalation prematurely or purse their lips to increase expiratory resistance at the mouth. Premature termination of exhalation may increase FRC above normal, resulting in air trapping and auto-PEEP.

C. Forced Vital Capacity

Measuring vital capacity as an exhalation that is as forceful and rapid as possible (Figure 23-10)

provides important information about airway resistance. The ratio of the forced expiratory volume in the first second of exhalation (FEV_1) to the total forced vital capacity (FVC) is proportional to the degree of airway obstruction. Normally, FEV_1/FVC is $\geq 80\%$. Whereas both FEV_1 and FVC are effort dependent, forced midexpiratory flow ($FEF_{25-75\%}$) is more effort independent and may be a more reliable measurement of obstruction.

Tissue Resistance

This component of nonelastic resistance is generally underestimated and often overlooked, but may account for up to half of total airway resistance. It seems to be primarily due to viscoelastic (frictional) resistance of tissues to gas flow.

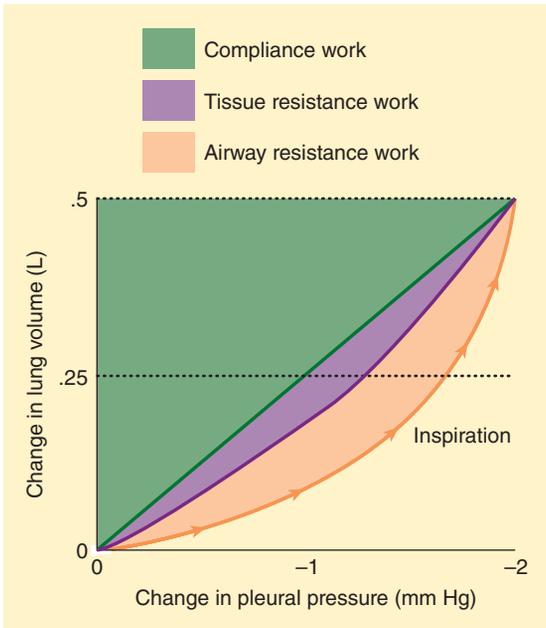

FIGURE 23-11 The work of breathing and its components during inspiration. (Reproduced, with permission, from Guyton AC: *Textbook of Medical Physiology*, 7th ed. W.B. Saunders, 1986.)

4. Work of Breathing

Because expiration is normally entirely passive, both the inspiratory and the expiratory work of breathing is performed by the inspiratory muscles (primarily the diaphragm). Three factors must be overcome during ventilation: the elastic recoil of the chest and lung, frictional resistance to gas flow in the airways, and tissue frictional resistance.

Respiratory work can be expressed as the product of volume and pressure (Figure 23-11). During inhalation, both inspiratory airway resistance and pulmonary elastic recoil must be overcome; nearly 50% of the energy expended is stored pulmonary elastic recoil. During exhalation, the stored potential energy is released and overcomes expiratory airway resistance. Increases in either inspiratory or expiratory resistance are compensated by increased inspiratory muscle effort. When expiratory resistance increases, the normal compensatory response is to increase lung volume such that V_T breathing occurs at an abnormally high FRC. The greater elastic recoil

energy stored at a higher lung volume overcomes the added expiratory resistance. Excessive amounts of expiratory resistance also activate expiratory muscles (see above).

Respiratory muscles normally account for only 2% to 3% of O_2 consumption but operate at about 10% efficiency. Ninety percent of the work is dissipated as heat (due to elastic and airflow resistance). In pathological conditions that increase the load on the diaphragm, muscle efficiency usually progressively decreases, and contraction may become uncoordinated with increasing ventilatory effort; moreover, a point may be reached whereby any increase in O_2 uptake (because of augmented ventilation) is consumed by the respiratory muscles themselves.

The work required to overcome elastic resistance increases as V_T increases, whereas the work required to overcome airflow resistance increases as respiratory rate (and, necessarily, expiratory flow) increases. Faced with either condition, patients minimize the work of breathing by altering the respiratory rate and V_T (Figure 23-12). **Patients with reduced compliance tend to have rapid, shallow breaths, whereas those with increased airflow resistance have a slow, deep breathing pattern.**

5. Effects of Anesthesia on Pulmonary Mechanics

The effects of anesthesia on breathing are complex and relate to changes both in position and anesthetic agent.

Effects on Lung Volumes & Compliance

6 Changes in lung mechanics due to general anesthesia occur shortly after induction. The supine position reduces the FRC by 0.8–1.0 L, and induction of general anesthesia further reduces the FRC by 0.4–0.5 L. FRC reduction is a consequence of alveolar collapse and compression atelectasis due to loss of inspiratory muscle tone, change in chest wall rigidity, and upward shift of the diaphragm. The mechanisms may be more complex; for example, only the dependent (dorsal) part of the diaphragm in the supine position moves cephalad. Other factors are likely due to a change in intrathoracic volume secondary to increased blood volume in the lung and changes in

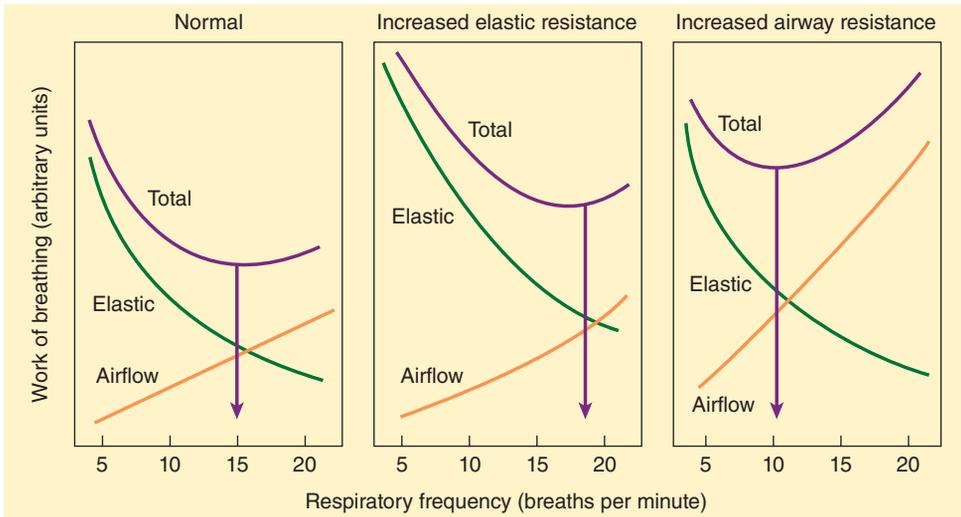

FIGURE 23-12 The work of breathing in relation to respiratory rate for normal individuals, patients with increased elastic resistance, and patients with increased

airway resistance. (Reproduced, with permission, from Nunn JF: *Nunn's Applied Physiology*, 4th ed. Butterworth, 2000.)

chest wall shape (Figure 23-13). The higher position of the dorsal diaphragm and changes in the thoracic cavity itself decrease lung volumes. This decrease in FRC is not related to anesthetic depth and may persist for several hours or days after anesthesia. Steep head-down (Trendelenburg) position ($>30^\circ$) may reduce FRC even further as intrathoracic blood volume increases. In contrast, induction of anesthesia in the sitting position seems to have little effect on FRC. Muscle paralysis does not seem to change FRC significantly when the patient is already anesthetized.

The effects of anesthesia on closing capacity are more variable. Both FRC and closing capacity, however, are generally reduced to the same extent under anesthesia. Thus, the risk of increased intrapulmonary shunting under anesthesia is similar to that in the conscious state; it is greatest in the elderly, in obese patients, and in those with underlying pulmonary disease.

Effects on Airway Resistance

The reduction in FRC associated with general anesthesia would be expected to increase airway resistance. Increases in airway resistance are not usually observed, however, because of the bronchodilating properties of the volatile inhalation anesthetics.

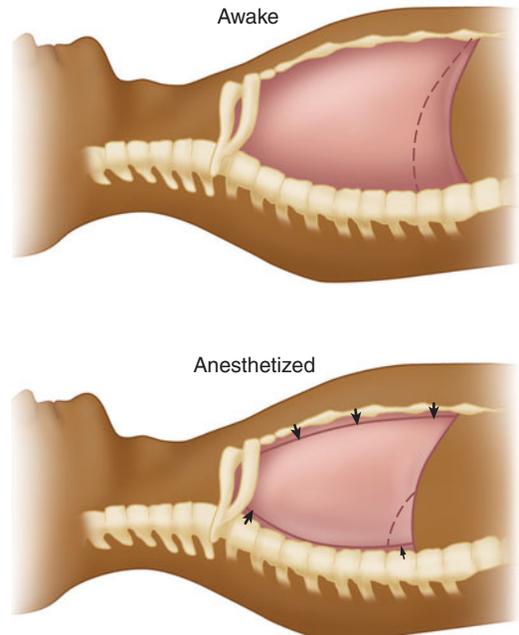

FIGURE 23-13 With induction of anesthesia in the supine position, the abdominal contents exert cephalad pressure on the diaphragm. At end-expiration, the dorsal portion of the diaphragm is more cephalad and the ventral portion is more caudal than when awake, the thoracic spine is more lordotic, and the rib cage moves inward, all secondary to loss of motor tone.

Increased airway resistance is more commonly due to pathological factors (posterior displacement of the tongue; laryngospasm; bronchoconstriction; or secretions, blood, or tumor in the airway) or equipment problems (small tracheal tubes or connectors, malfunction of valves, or obstruction of the breathing circuit).

Effects on the Work of Breathing

Increases in the work of breathing under anesthesia are most often secondary to reduced lung and chest wall compliance, and, less commonly, increases in airway resistance (see above). The problems of increased work of breathing are usually circumvented by controlled mechanical ventilation.

Effects on the Respiratory Pattern

Regardless of the agent used, light anesthesia often results in irregular breathing patterns; breath holding is common. Breaths become regular with deeper levels of anesthesia. Inhalation agents generally produce rapid, shallow breaths, whereas nitrous–opioid techniques result in slow, deep breaths.

VENTILATION/PERFUSION RELATIONSHIPS

1. Ventilation

Ventilation is usually measured as the sum of all exhaled gas volumes in 1 min (minute ventilation, or \dot{V}).

Minute ventilation = Respiratory rate \times Tidal volume

For the average adult at rest, minute ventilation is about 5 L/min.

Not all of the inspired gas mixture reaches alveoli; some of it remains in the airways and is exhaled without being exchanged with alveolar gases. The part of the V_T not participating in alveolar gas exchange is known as dead space (V_D). Alveolar ventilation (\dot{V}_A) is the volume of inspired gases actually taking part in gas exchange in 1 min.

$$\dot{V}_A = \text{Respiratory rate} \times V_T - V_D$$

Dead space is actually composed of gases in nonrespiratory airways (**anatomic dead space**) and

TABLE 23-3 Factors affecting dead space.

Factor	Effect

Emphysema	↑

alveoli that are not perfused (**alveolar dead space**). The sum of the two components is referred to as **physiological dead space**. In the upright position, dead space is normally about 150 mL for most adults (approximately 2 mL/kg) and is nearly all anatomic. The weight of an individual in pounds is roughly equivalent to dead space in milliliters. Dead space can be affected by a variety of factors (Table 23-3).

Because V_T in the average adult is approximately 450 mL (6 mL/kg), V_D/V_T is normally 33%. This ratio can be derived by the Bohr equation:

$$\frac{V_D}{V_T} = \frac{P_{ACO_2} - P_{ECO_2}}{P_{ACO_2}}$$

where P_{ACO_2} is the alveolar CO_2 tension and P_{ECO_2} is the mixed expired CO_2 tension. This equation is useful clinically if arterial CO_2 tension (P_{aCO_2}) is used to approximate the alveolar concentration and the CO_2 tension in expired air gases is the average measured over several minutes.

Distribution of Ventilation

Regardless of body position, alveolar ventilation is unevenly distributed in the lungs. The right lung receives more ventilation than the left lung

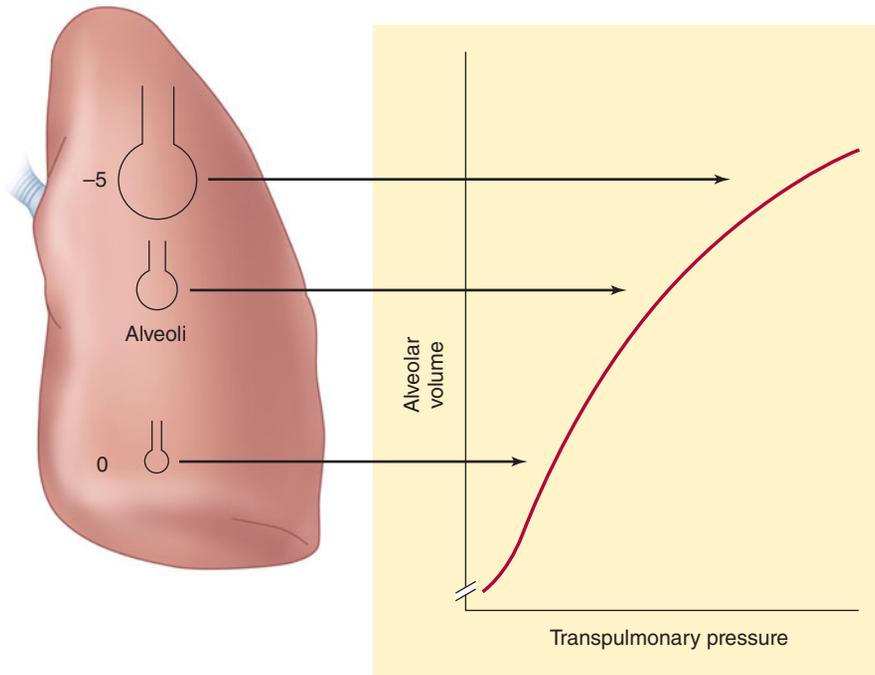

FIGURE 23-14 The effect of gravity on alveolar compliance in the upright position.

(53% vs 47%), and the lower (dependent) areas of both lungs tend to be better ventilated than do the upper areas because of a gravitationally induced gradient in intrapleural pressure (transpulmonary pressure). Pleural pressure decreases about 1 cm H₂O (becomes less negative) per 3-cm decrease in lung height. This difference places alveoli from different areas at different points on the pulmonary compliance curve (Figure 23-14). Because of a higher transpulmonary pressure, alveoli in upper lung areas are near-maximally inflated and relatively noncompliant, and they undergo little expansion during inspiration. In contrast, the smaller alveoli in dependent areas have a lower transpulmonary pressure, are more compliant, and undergo greater expansion during inspiration.

Airway resistance can also contribute to regional differences in pulmonary ventilation. Final alveolar inspiratory volume is solely dependent on compliance only if inspiratory time is unlimited. In reality, inspiratory time is necessarily limited by the respiratory rate and the time necessary for expiration; consequently,

an excessively short inspiratory time will prevent alveoli from reaching the expected change in volume. Moreover, alveolar filling follows an exponential function that is dependent on both compliance and airway resistance. Therefore, even with a normal inspiratory time, abnormalities in either compliance or resistance can prevent complete alveolar filling.

Time Constants

Lung inflation can be described mathematically by the time constant, τ .

$$\tau = \text{Total compliance} \times \text{Airway resistance}$$

Regional variations in resistance or compliance not only interfere with alveolar filling but can cause asynchrony in alveolar filling during inspiration; some alveolar units may continue to fill as others empty.

Variations in time constants within the normal lung can be demonstrated in normal individuals breathing spontaneously during abnormally high respiratory rates. Rapid shallow breathing reverses

the normal distribution of ventilation, preferentially favoring upper (nondependent) areas of the lung over the lower areas.

2. Pulmonary Perfusion

Of the approximately 5 L/min of blood flowing through the lungs, only about 70–100 mL at any one time are within the pulmonary capillaries undergoing gas exchange. At the alveolar–capillary membrane, this small volume forms a 50–100 m²-sheet of blood approximately one red cell thick. Moreover, to ensure optimal gas exchange, each capillary perfuses more than one alveolus.

Although capillary volume remains relatively constant, total pulmonary blood volume can vary between 500 mL and 1000 mL. Large increases in either cardiac output or blood volume are tolerated with little change in pressure as a result of passive dilation of open vessels and perhaps some recruitment of collapsed pulmonary vessels. Small increases in pulmonary blood volume normally occur during cardiac systole and with each normal (spontaneous) inspiration. A shift in posture from supine to erect decreases pulmonary blood volume (up to 27%); Trendelenburg positioning has the opposite effect. Changes in systemic capacitance also influence pulmonary blood volume: systemic venoconstriction shifts blood from the systemic to the pulmonary circulation, whereas vasodilation causes a pulmonary-to-systemic redistribution. In this way, the lung acts as a reservoir for the systemic circulation.

7 Local factors are more important than the autonomic system in influencing pulmonary vascular tone (above). Hypoxia is a powerful stimulus for pulmonary vasoconstriction (the opposite of its systemic effect). Both pulmonary arterial (mixed venous) and alveolar hypoxia induce vasoconstriction, but the latter is a more powerful stimulus. This response seems to be due to either the direct effect of hypoxia on the pulmonary vasculature or increased production of leukotrienes relative to vasodilatory prostaglandins. Inhibition of nitric oxide production may also play a role. Hypoxic pulmonary vasoconstriction is an important physiological mechanism

in reducing intrapulmonary shunting and preventing hypoxemia (see below). Hyperoxia has little effect on the pulmonary circulation in normal individuals. Hypercapnia and acidosis have a constrictor effect, whereas hypocapnia causes pulmonary vasodilation, the opposite of what occurs in the systemic circulation.

Distribution of Pulmonary Perfusion

Pulmonary blood flow is also not uniform. Regardless of body position, lower (dependent) areas of the lung receive greater blood flow than upper (nondependent) areas. This pattern is the result of a gravitational gradient of 1 cm H₂O/cm lung height. The normally low pressures in the pulmonary circulation allow gravity to exert a significant influence on blood flow. Also, *in vivo* perfusion scanning in normal individuals has shown an “onion-like” layering distribution of perfusion, with reduced flow at the periphery of the lung and increased perfusion toward the hilum.

Although the pulmonary perfusion pressure is not uniform across the lung, the alveolar distending pressure is relatively constant. The interplay of these pressures results in the dividing of the lung into four distinct zones (ie, the West Zones) (Figure 23–15). In zone 1 ($P_A > P_a > P_v$), alveolar pressure (P_A) is greater than both the arterial pulmonary pressure (P_a) and venous pulmonary pressure (P_v), resulting in obstruction of blood flow and creation of alveolar dead space. Zone 1 is fairly small in a spontaneously breathing individual, but can enlarge during positive pressure ventilation. In lower areas of the lungs, P_a progressively increases due to lower elevation above the heart. In zone 2 ($P_a > P_A > P_v$), P_a is higher than P_A , but P_v remains lower than both, resulting in blood flow that is dependent on the differential between P_a and P_A . The bulk of the lung is described by zone 3 ($P_a > P_v > P_A$), where both P_a and P_v are higher than P_A , resulting in blood flow independent of the alveolar pressure. Zone 4, the most dependent part of the lung, is where atelectasis and/or interstitial pulmonary edema occur, resulting in blood flow that is dependent on the differential between P_a and pulmonary interstitial pressure.

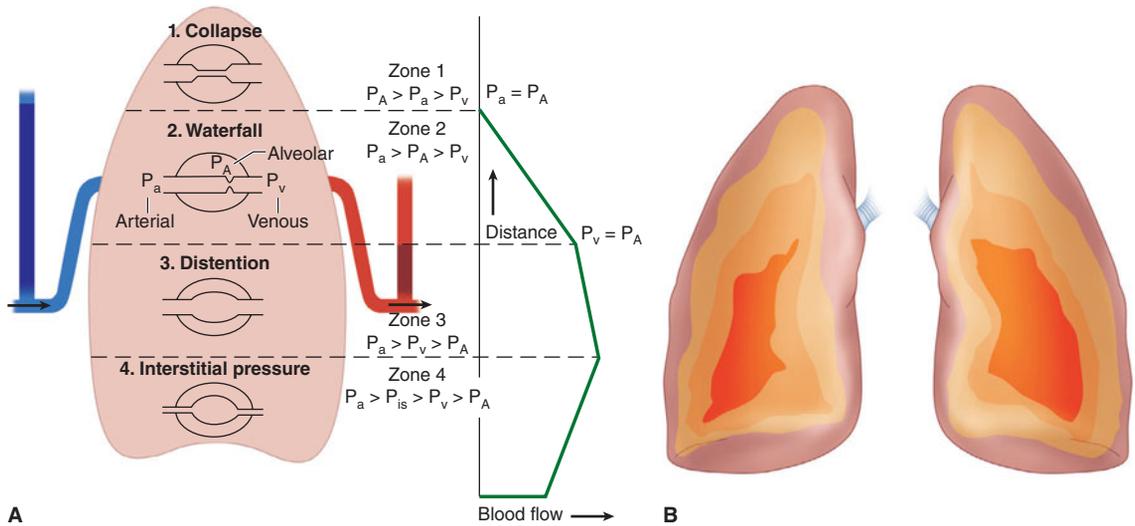

FIGURE 23-15 Pulmonary blood flow distribution relative to the alveolar pressure (P_A), the pulmonary arterial pressure (P_a), the pulmonary venous pressure (P_v), and the interstitial pressure (P_{is}) at various gravitation levels. **A:** Classic West Zones of blood flow distribution in the upright position. Ventilation/Perfusion Ratios

8 Because alveolar ventilation (\dot{V}_A) is normally about 4 L/min, and pulmonary capillary perfusion (\dot{Q}) is 5 L/min, the overall \dot{V}/\dot{Q} ratio is about 0.8. \dot{V}/\dot{Q} for individual lung units (each alveolus and its capillary) can range from 0 (no ventilation) to infinity (no perfusion); the former is referred to as intrapulmonary shunt, whereas the latter constitutes alveolar dead space. \dot{V}/\dot{Q} normally ranges between 0.3 and 3.0; the majority of lung areas, however, are close to 1.0 (Figure 23-16A). Because perfusion increases at a greater rate than ventilation, nondependent (apical) areas tend to have higher \dot{V}/\dot{Q} ratios than do dependent (basal) areas (Figure 23-16B).

The importance of \dot{V}/\dot{Q} ratios relates to the efficiency with which lung units resaturate venous blood with O_2 and eliminate CO_2 . **Pulmonary venous blood (the effluent) from areas with low \dot{V}/\dot{Q} ratios has a low O_2 tension and high CO_2 tension—similar to systemic mixed venous blood.**

Blood from these units tends to depress arterial O_2 tension and elevate arterial CO_2 tension. Their effect on arterial O_2 tension is much more profound than that on CO_2 tension; in fact, arterial CO_2 tension often decreases from a hypoxemia-induced reflex increase in alveolar ventilation. An appreciable compensatory increase in O_2 uptake cannot take place in remaining areas where \dot{V}/\dot{Q} is normal, because pulmonary end-capillary blood is usually already maximally saturated with O_2 (see below).

3. Shunts

9 Shunting denotes the process whereby desaturated, mixed venous blood from the right heart returns to the left heart without being resaturated with O_2 in the lungs (Figure 23-17). The overall effect of shunting is to decrease (dilute) arterial O_2 content; this type of shunt is referred to as right-to-left. Left-to-right shunts (in the absence of

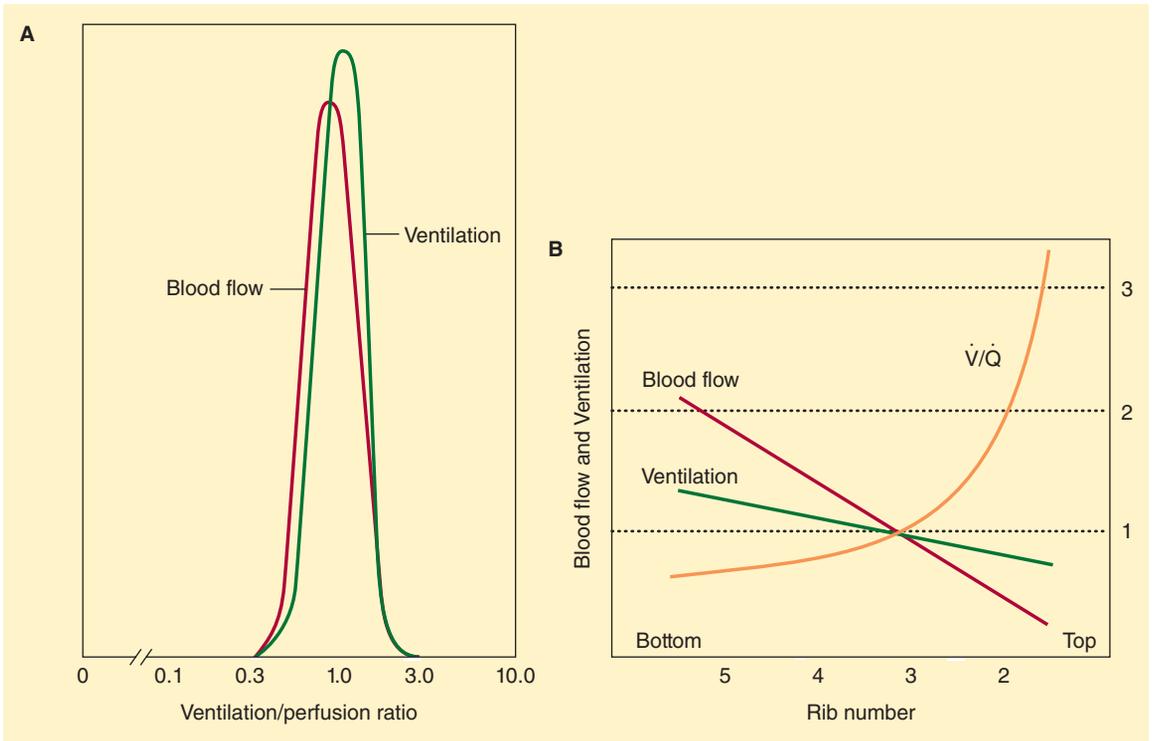

FIGURE 23-16 The distribution of \dot{V}/\dot{Q} ratios for the whole lung (**A**) and according to height (**B**) in the upright position. Note that blood flow increases more rapidly than

ventilation in dependent areas. (Reproduced, with permission, from West JB: *Ventilation/Blood Flow and Gas Exchange*, 3rd ed. Blackwell, 1977.)

pulmonary congestion), however, do not produce hypoxemia.

Intrapulmonary shunts are often classified as absolute or relative. Absolute shunt refers to anatomic shunts and lung units where \dot{V}/\dot{Q} is zero. A relative shunt is an area of the lung with a low \dot{V}/\dot{Q} ratio. Clinically, hypoxemia from a relative shunt can usually be partially corrected by increasing the inspired O_2 concentration; hypoxemia caused by an absolute shunt cannot.

Venous Admixture

Venous admixture refers to a concept rather than an actual physiological entity. **Venous admixture** is the amount of mixed venous blood that would have to be mixed with pulmonary end-capillary blood to account for the difference in O_2 tension between arterial and pulmonary end-capillary blood. Pulmonary end-capillary blood is considered to have the same

concentrations as alveolar gas. Venous admixture is usually expressed as a fraction of total cardiac output (\dot{Q}_s/\dot{Q}_T). The equation for \dot{Q}_s/\dot{Q}_T may be derived with the law for the conservation of mass for O_2 across the pulmonary bed:

$$\dot{Q}_T \times Ca_{O_2} = (\dot{Q}_s \times C\bar{V}O_2) + (\dot{Q}_c' \times Cc'_{O_2})$$

where

Q_s = blood flow through the physiologic shunt compartment

Q_T = total cardiac output

\dot{Q}_c' = blood flow across normally ventilated pulmonary capillaries

$\dot{Q}_T = \dot{Q}_c' + \dot{Q}_s$

Cc'_{O_2} = oxygen content of ideal pulmonary end-capillary blood

Ca_{O_2} = arterial oxygen content

$C\bar{V}O_2$ = mixed venous content

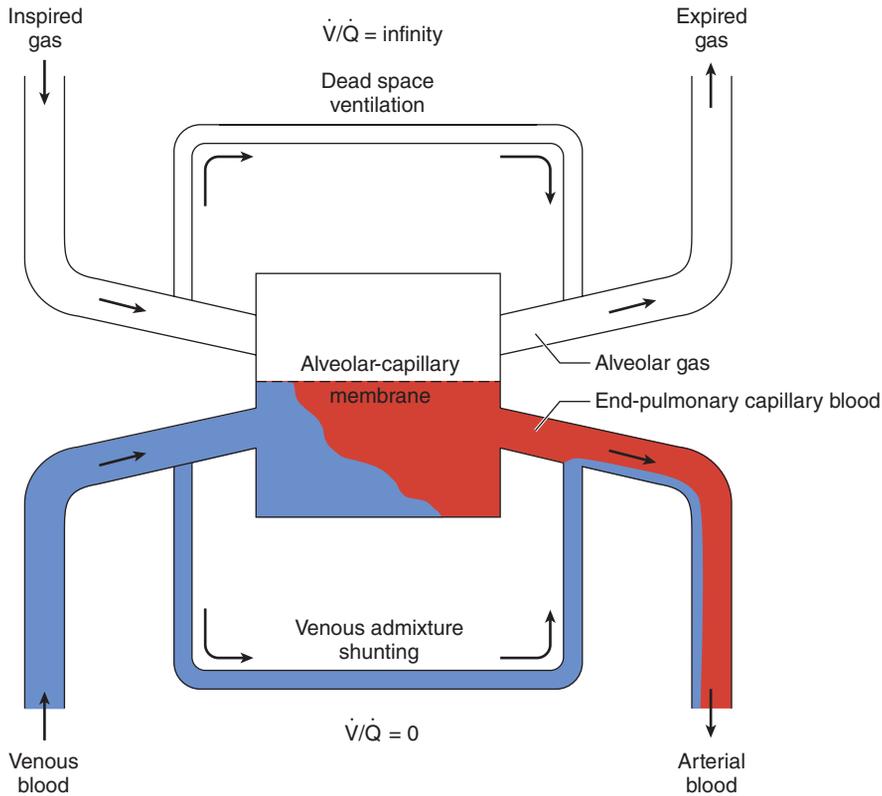

FIGURE 23-17 A three-compartment model of gas exchange in the lungs, showing dead space ventilation, normal alveolar–capillary exchange, and shunting (venous

admixture). (Reproduced, with permission, from Nunn JF: *Nunn's Applied Physiology*, 4th ed. Butterworth, 2000.)

The simplified equation is

$$\dot{Q}_s/\dot{Q}_T = \frac{C_c\dot{O}_2 - C_{aO_2}}{C_c\dot{O}_2 - C_{\bar{V}O_2}}$$

The formula for calculating the O_2 content of blood is given below.

\dot{Q}_s/\dot{Q}_T can be calculated clinically by obtaining mixed venous and arterial blood gas measurements; the former requires a pulmonary artery catheter. The alveolar gas equation is used to derive pulmonary end-capillary O_2 tension. Pulmonary capillary blood is usually assumed to be 100% saturated for an $FIO_2 \geq 0.21$.

The calculated venous admixture assumes that all shunting is intrapulmonary and due to absolute shunts ($\dot{V}/\dot{Q} = 0$). In reality, neither is ever the case;

nonetheless, the concept is useful clinically. Normal \dot{Q}_s/\dot{Q}_T is primarily due to communication between deep bronchial veins and pulmonary veins, the thebesian circulation in the heart, and areas of low \dot{V}/\dot{Q} in the lungs (Figure 23-18). The venous admixture in normal individuals (physiological shunt) is typically less than 5%.

4. Effects of Anesthesia on Gas Exchange

Abnormalities in gas exchange during anesthesia are common. They include increased dead space, hypoventilation, and increased intrapulmonary shunting. There is increased scatter of \dot{V}/\dot{Q} ratios. Increases in alveolar dead space are most commonly seen during controlled ventilation, but may also

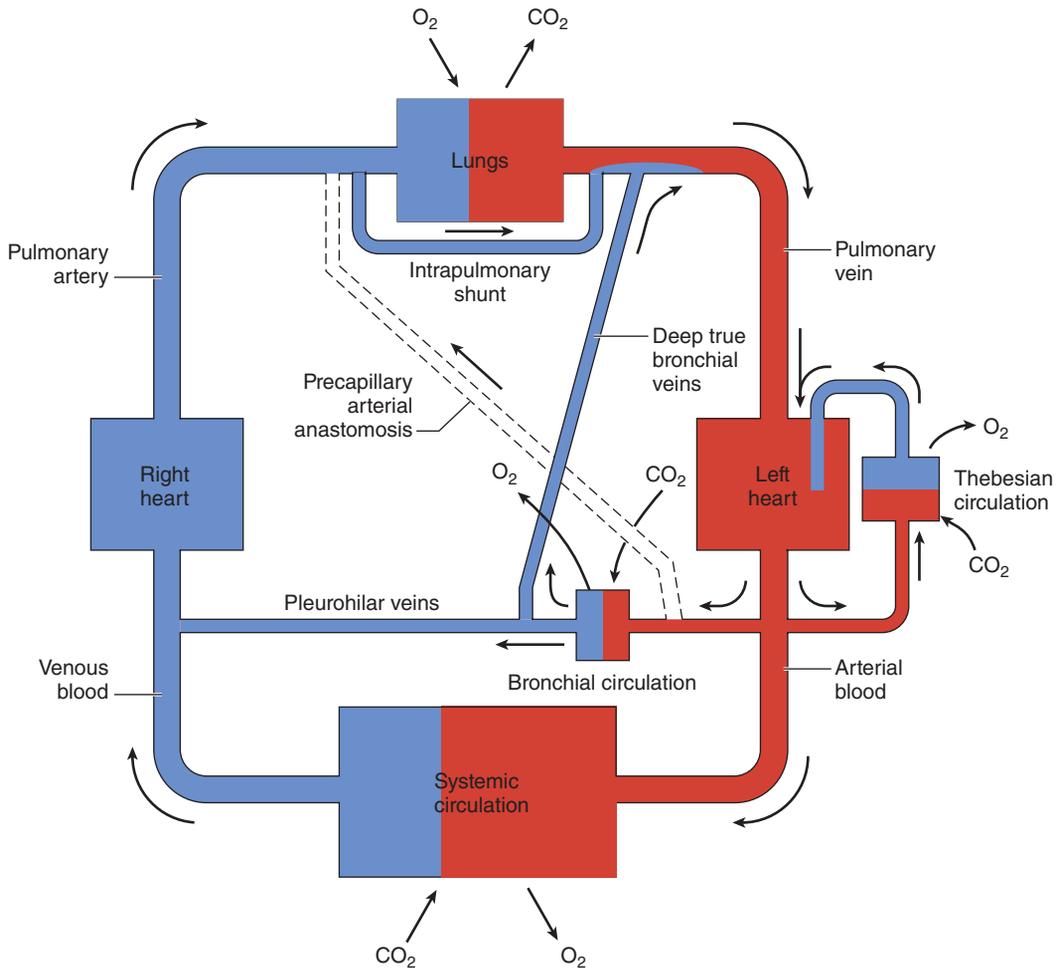

FIGURE 23-18 Components of the normal venous admixture. (Reproduced, with permission, from Nunn JF: *Nunn's Applied Physiology*, 4th ed. Butterworth, 2000.)

10 occur during spontaneous ventilation. General anesthesia commonly increases venous admixture to 5% to 10%, probably as a result of atelectasis and airway collapse in dependent areas of the lung. Inhalation agents, including nitrous oxide, also can inhibit **hypoxic pulmonary vasoconstriction** in high doses; for volatile agents, the ED_{50} is about 2 minimum alveolar concentration (MAC). Elderly patients seem to have the largest increases in \dot{Q}_S/\dot{Q}_T . Inspired O_2 tensions of 30% to 40% usually prevent hypoxemia, suggesting anesthesia increases relative shunt. PEEP is often effective in reducing venous

admixture and preventing hypoxemia during general anesthesia, as long as cardiac output is maintained. Prolonged administration of high inspired O_2 concentrations may be associated with atelectasis formation and increases in absolute shunt. Atelectasis in this situation is known as resorption atelectasis and appears in areas with a low \dot{V}/\dot{Q} ratio ventilated at an O_2 -inspired concentration close to 100%. Perfusion results in O_2 being transported out of the alveoli at a rate faster than it enters the alveoli, leading to an emptying of the alveoli and collapse.

ALVEOLAR, ARTERIAL, & VENOUS GAS TENSIONS

When dealing with gas mixtures, each gas is considered to contribute separately to total gas pressure, and its partial pressure is directly proportional to its concentration. Air has an O₂ concentration of approximately 21%; therefore, if the barometric pressure is 760 mm Hg (sea level), the partial pressure of O₂ (P_{O₂}) in air is normally 159.6 mm Hg:

$$760 \text{ mm Hg} \times 0.21 = 159.6 \text{ mm Hg}$$

In its general form, the equation may be written as follows:

$$P_{IO_2} = P_B \times F_{IO_2}$$

where P_B = barometric pressure and F_{IO₂} = the fraction of inspired O₂.

Two general rules can also be used:

- Partial pressure in millimeters of mercury approximates the percentage $\times 7$
- Partial pressure in kilopascals is approximately the same as the percentage.

1. Oxygen

Alveolar Oxygen Tension

With every breath, the inspired gas mixture is humidified at 37°C in the upper airway. The inspired tension of O₂ (P_{IO₂}) is therefore reduced by the added water vapor. Water vapor pressure is dependent only upon temperature and is 47 mm Hg at 37°C. In humidified air, the normal partial pressure of O₂ at sea level is 149.7 mm Hg:

$$(760 - 47) \times 0.21 = 149.1 \text{ mm Hg}$$

The general equation is

$$P_{IO_2} = (P_B - P_{H_2O}) \times F_{IO_2}$$

where P_{H₂O} = the vapor pressure of water at body temperature.

In alveoli, the inspired gases are mixed with residual alveolar gas from previous breaths, O₂ is taken up, and CO₂ is added. The final alveolar O₂ tension (P_{AO₂}) is therefore dependent on all of

these factors and can be estimated by the following equation:

$$P_{AO_2} = P_{IO_2} - \frac{P_{aCO_2}}{RQ}$$

where P_{aCO₂} = arterial CO₂ tension and RQ = respiratory quotient.

11 RQ is usually not measured. Note that large increases in P_{aCO₂} (>75 mm Hg) readily produce hypoxia (P_{aO₂} < 60 mm Hg) at room air, but not at high inspired O₂ concentrations.

A yet simpler method of approximating P_{AO₂} in millimeters of mercury is to multiply the percentage of inspired O₂ concentration by 6. Thus, at 40%, P_{AO₂} is 6 \times 40, or 240 mm Hg.

Pulmonary End-Capillary Oxygen Tension

For all practical purposes, pulmonary end-capillary O₂ tension (P_{c'O₂}) may be considered identical to P_{AO₂}; the P_{AO₂}-P_{c'O₂} gradient is normally minute. P_{c'O₂} is dependent on the rate of O₂ diffusion across the alveolar-capillary membrane, as well as on pulmonary capillary blood volume and transit time. The large capillary surface area in alveoli and the 0.4–0.5 μ m thickness of the alveolar-capillary membrane greatly facilitate O₂ diffusion. Enhanced O₂ binding to hemoglobin at saturations above 80% also augments O₂ diffusion (see below). Capillary transit time can be estimated by dividing pulmonary capillary blood volume by cardiac output (pulmonary blood flow); thus, normal capillary transit time is 70 mL \div 5000 mL/min (0.8 s). Maximum P_{c'O₂} is usually attained after only 0.3 sec, providing a large safety margin.

12 The binding of O₂ to hemoglobin seems to be the principal rate-limiting factor in the transfer of O₂ from alveolar gas to blood. Therefore, pulmonary diffusing capacity reflects not only the capacity and permeability of the alveolar-capillary membrane, but also pulmonary blood flow. Moreover, O₂ uptake is normally limited by pulmonary blood flow, not O₂ diffusion across the alveolar-capillary membrane; the latter may become significant during exercise in normal individuals at high altitudes and in patients with extensive destruction of the alveolar-capillary membrane.

O₂ transfer across the alveolar–capillary membrane is expressed as O₂ diffusing capacity (DLO₂):

$$DLO_2 = \frac{\text{Oxygen uptake}}{PAO_2 - Pc'O_2}$$

Because Pc'O₂ cannot be measured accurately, measurement of carbon monoxide diffusing capacity (DLCO) is used instead to assess gas transfer across the alveolar–capillary membrane. Because carbon monoxide has a very high affinity for hemoglobin, there is little or no CO in pulmonary capillary blood, so that even when it is administered at low concentration, Pc'CO can be considered zero. Therefore,

$$DLCO = \frac{\text{Carbon monoxide uptake}}{PACO}$$

Reductions in DLCO imply an impediment in gas transfer across the alveolar–capillary membrane. Such impediments may be due to abnormal \dot{V}/\dot{Q} ratios, extensive destruction of the gas alveolar–capillary membrane, or very short capillary transit times. Abnormalities are accentuated by increases in O₂ consumption and cardiac output, such as occurs during exercise.

Arterial Oxygen Tension

PaO₂ cannot be calculated like PAO₂ but must be measured at room air. The alveolar-to-arterial O₂ partial pressure gradient (A–a gradient) is normally less than 15 mm Hg, but progressively increases with age up to 20–30 mm Hg. Arterial O₂ tension can be approximated by the following formula (in mm Hg):

$$PaO_2 = 120 - \frac{\text{Age}}{3}$$

The range is 60–100 mm Hg (8–13 kPa). Decreases are probably the result of a progressive increase in closing capacity relative to FRC (see above). **Table 23–4** lists the mechanisms of hypoxemia (PaO₂ <60 mm Hg).

The most common mechanism for hypoxemia is an increased alveolar–arterial gradient. The A–a gradient for O₂ depends on the amount of right-to-left shunting, the amount of \dot{V}/\dot{Q} scatter, and the mixed venous O₂ tension (see below). The last

TABLE 23–4 Mechanisms of hypoxemia.

¹ \dot{V}/\dot{Q} , ventilation/perfusion.

depends on cardiac output, O₂ consumption, and hemoglobin concentration.

The A–a gradient for O₂ is directly proportional to shunt, but inversely proportional to mixed venous O₂ tension. The effect of each variable on PAO₂ (and consequently the A–a gradient) can be determined only when the other variables are held constant.

Figure 23–19 shows the effect of different degrees of **13** shunting on PaO₂. It should also be noted that the greater the shunt, the less likely the possibility that an increase in FIO₂ will prevent hypoxemia. Moreover, isoshunt lines seem to be most useful for O₂ concentrations between 35% and 100%. Lower O₂ concentrations require modification of isoshunt lines to account for the effect of \dot{V}/\dot{Q} scatter.

The effect of cardiac output on the A–a gradient (**Figure 23–20**) is due not only to its secondary effects on mixed venous O₂ tension but also to a direct relationship between cardiac output and intrapulmonary shunting. As can be seen, a low cardiac output tends to accentuate the effect of shunt on PaO₂. A reduction in venous admixture may be observed with low-normal cardiac outputs secondary to accentuated pulmonary vasoconstriction from a lower mixed venous O₂ tension. On the other hand, high cardiac outputs can increase venous admixture by elevating mixed venous O₂ tension, which in turn inhibits hypoxic pulmonary vasoconstriction.

O₂ consumption and hemoglobin concentration can also affect PaO₂ through their secondary effects on mixed venous O₂ tension (below). High O₂

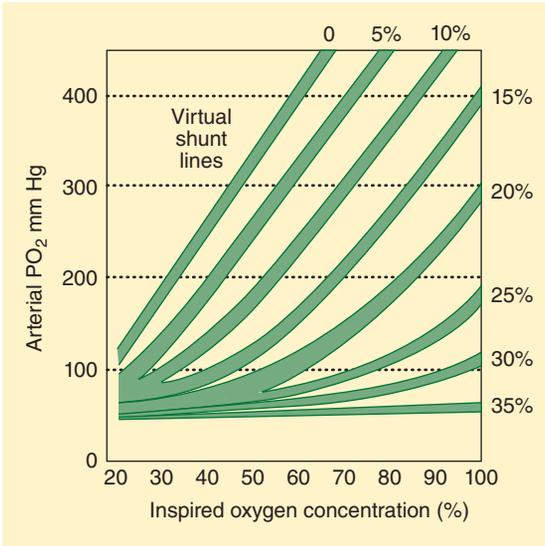

FIGURE 23-19 Isoshunt curves showing the effect of varying amounts of shunt on P_{aO_2} . Note that there is little benefit in increasing inspired oxygen concentration in patients with very large shunts. (Modified and reproduced, with permission, from Benatar SR, Hewlett AM, Nunn JF: The use of isoshunt lines for control of oxygen therapy. *Br J Anaesth* 1973;45:711.)

consumption rates and low hemoglobin concentrations can increase the A–a gradient and depress P_{aO_2} .

Mixed Venous Oxygen Tension

Normal mixed venous O_2 tension ($P\bar{v}O_2$) is about 40 mm Hg and represents the overall balance between O_2 consumption and O_2 delivery (Table 23-5). A true mixed venous blood sample

contains venous drainage from the superior vena cava, the inferior vena cava, and the heart; it must therefore be obtained from a pulmonary artery catheter.

2. Carbon Dioxide

Carbon dioxide is a by-product of aerobic metabolism in mitochondria. There are therefore small continuous gradients for CO_2 tension from mitochondria to cell cytoplasm, extracellular fluid, venous blood, and alveoli, where the CO_2 is finally eliminated.

Mixed Venous Carbon Dioxide Tension

Normal mixed venous CO_2 tension ($P\bar{v}CO_2$) is about 46 mm Hg and is the end result of mixing of blood from tissues of varying metabolic activity. Venous CO_2 tension is lower in tissues with low metabolic activity (eg, skin), but higher in blood from those with relatively high activity (eg, heart).

Alveolar Carbon Dioxide Tension

Alveolar CO_2 tension (P_{ACO_2}) is generally considered to represent the balance between total CO_2 production ($\dot{V}CO_2$) and alveolar ventilation (elimination):

$$P_{ACO_2} = \frac{\dot{V}CO_2}{\dot{V}_A}$$

where \dot{V}_A is alveolar ventilation (Figure 23-21). In reality, P_{ACO_2} is related to CO_2 elimination rather than production. Although the two are equal in a steady state, an imbalance occurs during periods

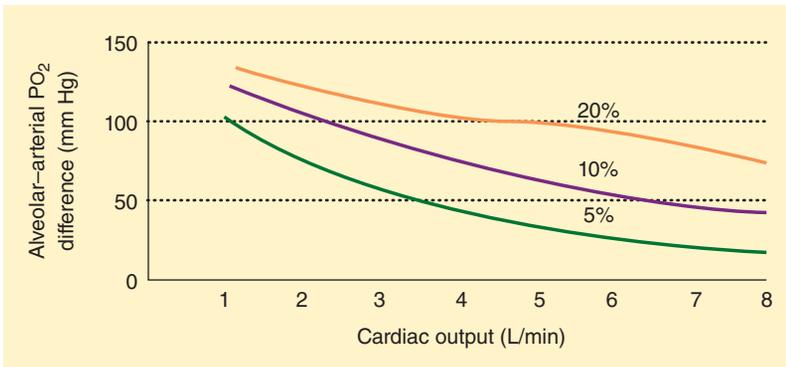

FIGURE 23-20 The effect of cardiac output on the alveolar–arterial P_{O_2} difference with varying degrees of shunting. $\dot{V}O_2 = 200$ mL/min and $P_{aO_2} = 180$ mm Hg. (Reproduced, with permission, from Nunn JF: *Nunn’s Applied Physiology*, 4th ed. Butterworth, 2000.)

of acute hypoventilation or hypoperfusion, and the excess CO_2 increases total body CO_2 content. Clinically, $PACO_2$ is more dependent on alveolar ventilation than is $\dot{V}CO_2$, because CO_2 output does

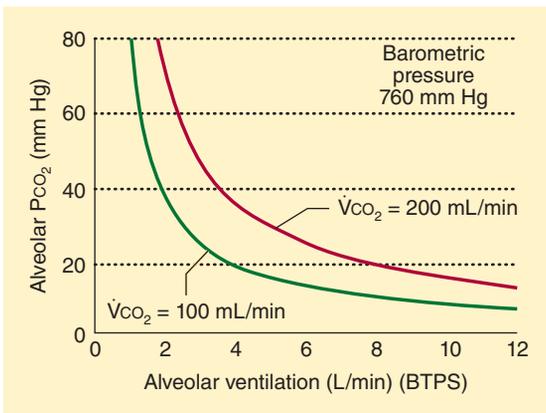

FIGURE 23-21 The effect of alveolar ventilation on alveolar P_{CO_2} at two rates of CO_2 production. (Reproduced, with permission, from Nunn JF: *Nunn's Applied Physiology*, 4th ed. Butterworth, 2000.)

not vary appreciably under most circumstances. Moreover, the body's large capacity to store CO_2 (see below) buffers acute changes in $\dot{V}CO_2$.

Pulmonary End-Capillary Carbon Dioxide Tension

Pulmonary end-capillary CO_2 tension ($Pc'CO_2$) is virtually identical to $PACO_2$ for the same reasons as those discussed in the section about O_2 . In addition, the diffusion rate for CO_2 across the alveolar-capillary membrane is 20 times that of O_2 .

Arterial Carbon Dioxide Tension

Arterial CO_2 tension ($Paco_2$), which is readily measurable, is identical to $Pc'CO_2$ and, necessarily, $PACO_2$. Normal $Paco_2$ is 38 ± 4 mm Hg (5.1 ± 0.5 kPa); in practice, 40 mm Hg is usually considered normal.

Although low \dot{V}/\dot{Q} ratios tend to increase $Paco_2$, whereas high \dot{V}/\dot{Q} ratios tend to decrease it (in contrast to the case for O_2 [see above]), significant arterial-to-alveolar gradients for CO_2 develop only in the presence of marked \dot{V}/\dot{Q} abnormalities (>30% venous admixture); even then the gradient is relatively small (2–3 mm Hg). Moreover, small increases in the gradient appreciably increase CO_2 output into alveoli with relatively normal \dot{V}/\dot{Q} . Even moderate to severe disturbances usually fail to appreciably alter arterial CO_2 because of a reflex increase in ventilation from concomitant hypoxemia.

End-Tidal Carbon Dioxide Tension

Because end-tidal gas is primarily alveolar gas and $PACO_2$ is virtually identical to $Paco_2$, end-tidal CO_2 tension ($P_{ET}CO_2$) is used clinically as an estimate of $PACO_2$. The $PACO_2$ – $P_{ET}CO_2$ gradient is normally less than 5 mm Hg and represents dilution of alveolar gas with CO_2 -free gas from nonperfused alveoli (alveolar dead space).

TRANSPORT OF RESPIRATORY GASES IN BLOOD

1. Oxygen

O_2 is carried in blood in two forms: dissolved in solution and in reversible association with hemoglobin.

Dissolved Oxygen

The amount of O_2 dissolved in blood can be derived from **Henry's law**, which states that the concentration of any gas in solution is proportional to its partial pressure. The mathematical expression is as follows:

$$\text{Gas concentration} = \alpha \times \text{Partial pressure}$$

where α = the gas solubility coefficient for a given solution at a given temperature.

The solubility coefficient for O_2 at normal body temperature is 0.003 mL/dL/mm Hg. Even with a P_{aO_2} of 100 mm Hg, the maximum amount of O_2 dissolved in blood is very small (0.3 mL/dL) compared with that bound to hemoglobin.

Hemoglobin

Hemoglobin is a complex molecule consisting of four heme and four protein subunits. Heme is an iron-porphyrin compound that is an essential part of the O_2 -binding sites; only the divalent form (+2 charge) of iron can bind O_2 . The normal

hemoglobin molecule (hemoglobin A_1) consists of two α and two β chains (subunits); the four subunits are held together by weak bonds between the amino acid residues. Each gram of hemoglobin can theoretically carry up to 1.39 mL of O_2 .

Hemoglobin Dissociation Curve

Each hemoglobin molecule binds up to four O_2 molecules. The complex interaction between the hemoglobin subunits results in nonlinear (an elongated S shape) binding with O_2 (Figure 23–22). Hemoglobin saturation is the amount of O_2 bound as a percentage of its total O_2 -binding capacity. Four separate chemical reactions are involved in binding each of the four O_2 molecules. The change in molecular conformation induced by the binding of the first three molecules greatly accelerates binding of the fourth O_2 molecule. The last reaction is responsible for the accelerated binding between 25% and 100% saturation. At about 90% saturation, the decrease in available O_2 receptors flattens the curve until full saturation is reached.

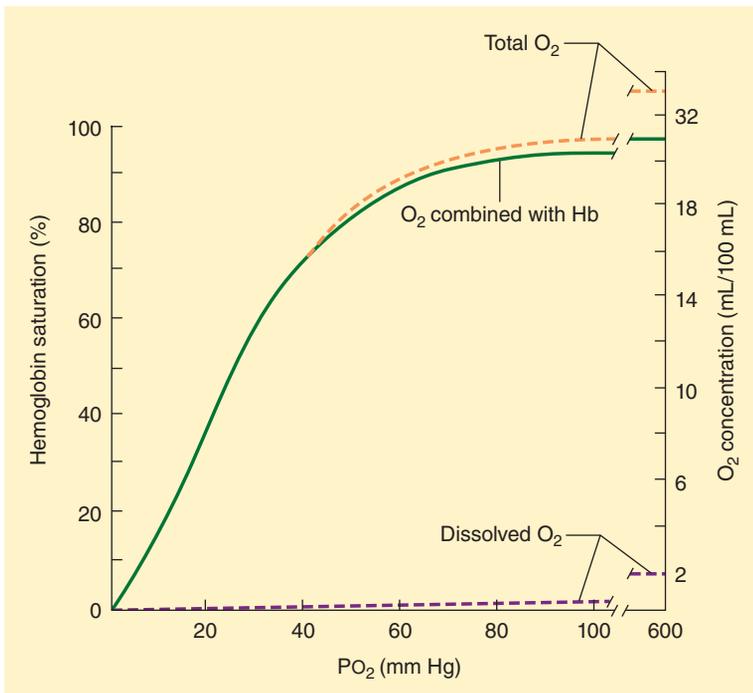

FIGURE 23–22 The normal adult hemoglobin–oxygen dissociation curve. (Modified and reproduced, with permission, from West JB: *Respiratory Physiology—The Essentials*, 6th ed. Williams & Wilkins, 2000.)

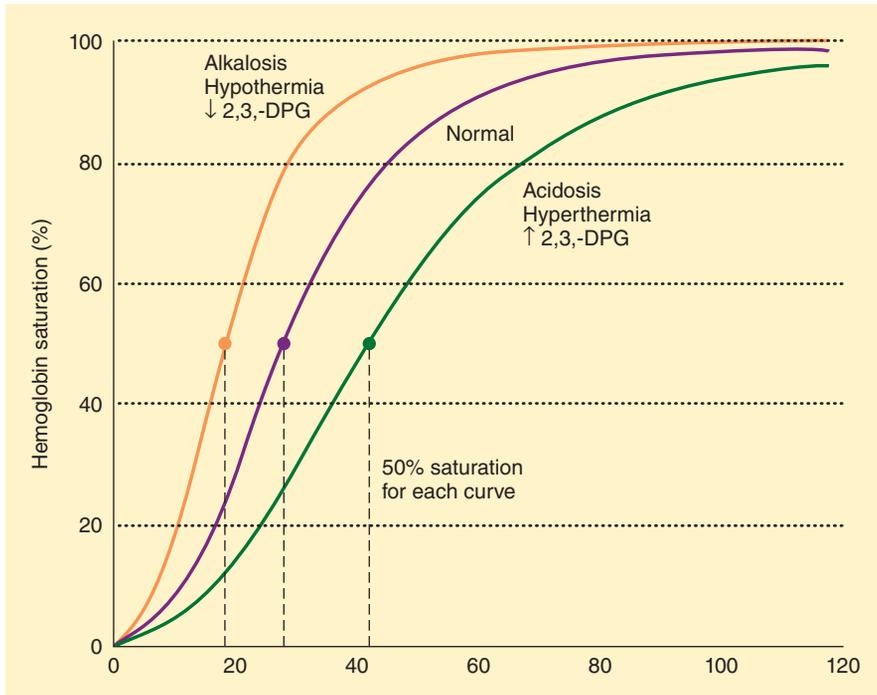

FIGURE 23-23 The effects of changes in acid–base status, body temperature, and 2,3-DPG concentration on the hemoglobin–oxygen dissociation curve.

Factors Influencing the Hemoglobin Dissociation Curve

Clinically important factors altering O_2 binding include hydrogen ion concentration, CO_2 tension, temperature, and 2,3-diphosphoglycerate (2,3-DPG) concentration. Their effect on hemoglobin– O_2 interaction can be expressed by P_{50} , the O_2 tension at which hemoglobin is 50% saturated (Figure 23-23). Each factor shifts the dissociation curve either to the right (increasing P_{50}) or to the left (decreasing P_{50}).

14 A rightward shift in the oxygen–hemoglobin dissociation curve lowers O_2 affinity, displaces O_2 from hemoglobin, and makes more O_2 available to tissues; a leftward shift increases hemoglobin’s affinity for O_2 , reducing its availability to tissues. The normal P_{50} in adults is 26.6 mm Hg (3.4 kPa).

An increase in blood hydrogen ion concentration reduces O_2 binding to hemoglobin (Bohr effect). Because of the shape of the **hemoglobin dissociation curve**, the effect is more important in

venous blood than arterial blood (Figure 23-23); the net result is facilitation of O_2 release to tissue with little impairment in O_2 uptake (unless severe hypoxia is present).

The influence of CO_2 tension on hemoglobin’s affinity for O_2 is important physiologically and is secondary to the associated rise in hydrogen ion concentration when CO_2 tension increases. The high CO_2 content of venous capillary blood, by decreasing hemoglobin’s affinity for O_2 , facilitates the release of O_2 to tissues; conversely, the lower CO_2 content in pulmonary capillaries increases hemoglobin’s affinity for O_2 again, facilitating O_2 uptake from alveoli.

2,3-DPG is a by-product of glycolysis (the Rapoport–Luebering shunt) and accumulates during anaerobic metabolism. Although its effects on hemoglobin under these conditions are theoretically beneficial, its physiological importance normally seems minor. 2,3-DPG levels may, however, play an important compensatory role in patients

with chronic anemia and may significantly affect the O₂-carrying capacity of blood transfusions.

Abnormal Ligands & Abnormal Forms of Hemoglobins

Carbon monoxide, cyanide, nitric acid, and ammonia can combine with hemoglobin at O₂-binding sites. They can displace O₂ and shift the saturation curve to the left. Carbon monoxide is particularly potent, having 200–300 times the affinity of O₂ for hemoglobin, combining with it to form carboxyhemoglobin. Carbon monoxide decreases hemoglobin's O₂-carrying capacity and impairs the release of O₂ to tissues.

Methemoglobin results when the iron in heme is oxidized to its trivalent (+3) form. Nitrates, nitrites, sulfonamides, and other drugs can rarely result in significant methemoglobinemia. Methemoglobin cannot combine with O₂ unless reconverted by the enzyme methemoglobin reductase; methemoglobin also shifts the normal hemoglobin saturation curve to the left. Methemoglobinemia, like carbon monoxide poisoning, therefore decreases the O₂-carrying capacity and impairs the release of O₂. Reduction of methemoglobin to normal hemoglobin is facilitated by such agents as methylene blue or ascorbic acid.

Abnormal hemoglobins can also result from variations in the protein subunit composition. Each variant has its own O₂-saturation characteristics. These include fetal hemoglobin, hemoglobin A₂, and sickle hemoglobin.

Oxygen Content

The total O₂ content of blood is the sum of that in solution plus that carried by hemoglobin. In reality, O₂ binding to hemoglobin never achieves the theoretical maximum (see above), but is closer to 1.31 mL O₂/dL blood per mm Hg. Total O₂ content is expressed by the following equation:

$$\text{O}_2 \text{ content} = ([0.003 \text{ mL O}_2/\text{dL blood per mm Hg}] \times \text{Po}_2) + (\text{So}_2 \times \text{Hb} \times 1.31 \text{ mL/dL blood})$$

where Hb is hemoglobin concentration in g/dL blood, and So₂ is hemoglobin saturation at the given Po₂.

Using the above formula and a hemoglobin of 15 g/dL, the normal O₂ content for both arterial and

mixed venous blood and the arteriovenous difference can be calculated as follows:

$$\begin{aligned} \text{CaO}_2 &= (0.003 \times 100) + (0.975 \times 15 \times 1.39) \\ &= 19.5 \text{ mL/dL blood} \end{aligned}$$

$$\begin{aligned} \text{C}\bar{\text{v}}\text{O}_2 &= (0.003 \times 40) + (0.75 \times 15 \times 1.31) \\ &= 14.8 \text{ mL/dL blood} \end{aligned}$$

$$\text{CaO}_2 - \text{C}\bar{\text{v}}\text{O}_2 = 4.7 \text{ mL/dL blood}$$

Oxygen Transport

O₂ transport is dependent on both respiratory and circulatory function. Total O₂ delivery ($\dot{D}\text{O}_2$) to tissues is the product of arterial O₂ content and cardiac output:

$$\dot{D}\text{O}_2 = \text{CaO}_2 \times \dot{Q}_T$$

Note that arterial O₂ content is dependent on PaO₂ as well as hemoglobin concentration. **As a result, deficiencies in O₂ delivery may be due to a low PaO₂, a low hemoglobin concentration, or an inadequate cardiac output.** Normal O₂ delivery can be calculated as follows:

$$\begin{aligned} \text{O}_2 \text{ delivery} &= 20 \text{ mL O}_2/\text{dL blood} \\ &\quad \times 50 \text{ dL per blood/min} \\ &= 1000 \text{ mL O}_2/\text{min} \end{aligned}$$

The Fick equation expresses the relationship between O₂ consumption, O₂ content, and cardiac output:

$$\text{O}_2 \text{ consumption} = \dot{V}\text{O}_2 = \dot{Q}_T \times (\text{CaO}_2 - \text{C}\bar{\text{v}}\text{O}_2)$$

Rearranging the equation:

$$\text{CaO}_2 = \frac{\dot{V}\text{O}_2}{\dot{Q}_T} + \text{C}\bar{\text{v}}\text{O}_2$$

Consequently, the arteriovenous difference is a good measure of the overall adequacy of O₂ delivery.

As calculated above, the arteriovenous difference (CaO₂ – C \bar{v} O₂) is about 5 mL O₂/dL blood (20 mL O₂/dL – 15 mL O₂/dL). Note that the normal extraction fraction for O₂ [(CaO₂ – C \bar{v} O₂)/CaO₂] is 5 mL ÷ 20 mL, or 25%; thus, the body normally consumes only 25% of the O₂ carried on hemoglobin. When O₂ demand exceeds supply, the extraction fraction exceeds 25%. Conversely, if O₂ supply exceeds demand, the extraction fraction falls below 25%.

When $\dot{D}O_2$ is even moderately reduced, $\dot{V}O_2$ usually remains normal because of increased O_2 extraction (mixed venous O_2 saturation decreases); $\dot{V}O_2$ remains independent of delivery. With further reductions in $\dot{D}O_2$, however, a critical point is reached beyond which $\dot{V}O_2$ becomes directly proportional to $\dot{D}O_2$. **This state of supply-dependent O_2 is typically associated with progressive lactic acidosis caused by cellular hypoxia.**

Oxygen Stores

The concept of O_2 stores is important in anesthesia. When the normal flux of O_2 is interrupted by apnea, existing O_2 stores are consumed by cellular metabolism; if stores are depleted, hypoxia and eventual cell death follow. Theoretically, normal O_2 stores in adults are about 1500 mL. This amount includes the O_2 remaining in the lungs, that bound to hemoglobin (and myoglobin), and that dissolved in body fluids. Unfortunately, the high affinity of hemoglobin for O_2 (the affinity of myoglobin is even higher), and the very limited quantity of O_2 in solution, restrict the availability of these stores. The O_2 contained within the lungs at FRC (initial lung volume during apnea), therefore, becomes the most important source of O_2 . Of that volume, however, probably only 80% is usable.

Apnea in a patient previously breathing room air leaves approximately 480 mL of O_2 in the lungs. (If $F_{IO_2} = 0.21$ and $FRC = 2300$ mL, O_2 content = $F_{IO_2} \times FRC$.) The metabolic activity of tissues rapidly depletes this reservoir (presumably at a rate equivalent to $\dot{V}O_2$); severe hypoxemia usually occurs within 90 sec. The onset of hypoxemia can be delayed by increasing the F_{IO_2} prior to the apnea. Following ventilation with 100% O_2 , FRC contains about 2300 mL of O_2 ; this delays hypoxemia following apnea for 4–5 min. This concept is the basis for preoxygenation prior to induction of anesthesia.

2. Carbon Dioxide

Carbon dioxide is transported in blood in three forms: dissolved in solution, as bicarbonate, and with proteins in the form of carbamino compounds (Table 23–6). The sum of all three forms is the total CO_2 content of blood (routinely reported with electrolyte measurements).

Dissolved Carbon Dioxide

Carbon dioxide is more soluble in blood than O_2 , with a solubility coefficient of 0.031 mmol/L/mm Hg (0.067 mL/dL/mm Hg) at 37°C.

TABLE 23–6 Contributions to carbon dioxide transport in 1 L of whole blood.^{1,2}

Form	Plasma	Erythrocytes	Combined	Contribution (%)
Mixed venous whole blood				
Dissolved CO_2	0.76	0.51	1.27	5.5
Bicarbonate	14.41	5.92	20.33	87.2

Total CO_2	14.08	7.42	21.50	

¹Data from Nunn JF: *Nunn's Applied Physiology*, 4th ed. Butterworth, 2000.

²Values are expressed in millimoles, except where indicated otherwise.

Bicarbonate

In aqueous solutions, CO₂ slowly combines with water to form carbonic acid and bicarbonate, according to the following reaction:

In plasma, although less than 1% of the dissolved CO₂ undergoes this reaction, the presence of the enzyme **carbonic anhydrase** within erythrocytes and endothelium greatly accelerates the reaction. As a result, bicarbonate represents the largest fraction of the CO₂ in blood (see Table 23–6). Administration of acetazolamide, a carbonic anhydrase inhibitor, can impair CO₂ transport between tissues and alveoli.

On the venous side of systemic capillaries, CO₂ enters red blood cells and is converted to bicarbonate, which diffuses out of red cells into plasma; chloride ions move from plasma into red cells to maintain electrical balance. In the pulmonary capillaries, the reverse occurs: chloride ions move out of red cells as bicarbonate ions reenter them for conversion back to CO₂, which diffuses out into alveoli. This sequence is referred to as the chloride or Hamburger shift.

Carbamino Compounds

Carbon dioxide can react with amino groups on proteins, as shown by the following equation:

At physiological pH, only a small amount of CO₂ is carried in this form, mainly as carbamino-hemoglobin. Deoxygenated hemoglobin (deoxy-hemoglobin) has a greater affinity (3.5 times) for CO₂ than does oxyhemoglobin. As a result, venous blood carries more CO₂ than does arterial blood (Haldane effect; see Table 23–6). P_{CO₂} normally has little effect on the fraction of CO₂ carried as carbamino-hemoglobin.

Effects of Hemoglobin Buffering on Carbon Dioxide Transport

The buffering action of hemoglobin also accounts for part of the Haldane effect. Hemoglobin can act as a buffer at physiological pH because of its

high content of histidine. Moreover, the acid–base behavior of hemoglobin is influenced by its oxygenation state:

Removal of O₂ from hemoglobin in tissue capillaries causes the hemoglobin molecule to behave more like a base; by taking up hydrogen ions, hemoglobin shifts the CO₂–bicarbonate equilibrium in favor of greater bicarbonate formation:

As a direct result, deoxyhemoglobin also increases the amount of CO₂ that is carried in venous blood as bicarbonate. As CO₂ is taken up from tissue and converted to bicarbonate, the total CO₂ content of blood increases (see Table 23–6).

In the lungs, the reverse is true. Oxygenation of hemoglobin favors its action as an acid, and the release of hydrogen ions shifts the equilibrium in favor of greater CO₂ formation:

Bicarbonate concentration decreases as CO₂ is formed and eliminated, so that the total CO₂ content of blood decreases in the lungs. Note that there is a difference between CO₂ content (concentration per liter) of whole blood (see Table 23–6) and plasma (Table 23–7).

Carbon Dioxide Dissociation Curve

A CO₂ dissociation curve can be constructed by plotting the total CO₂ content of blood against P_{CO₂}.

TABLE 23–7 Carbon dioxide content of plasma (mmol/L).^{1,2}

	Arterial	Venous
Dissolved CO ₂	1.2	1.4
Bicarbonate	24.4	26.2
Carbamino CO ₂	Negligible	Negligible
Total CO ₂	25.6	27.6

¹Data from Nunn JF: *Nunn's Applied Physiology*, 4th ed. Butterworth, 2000.

²Values are expressed in millimoles, except where indicated otherwise.

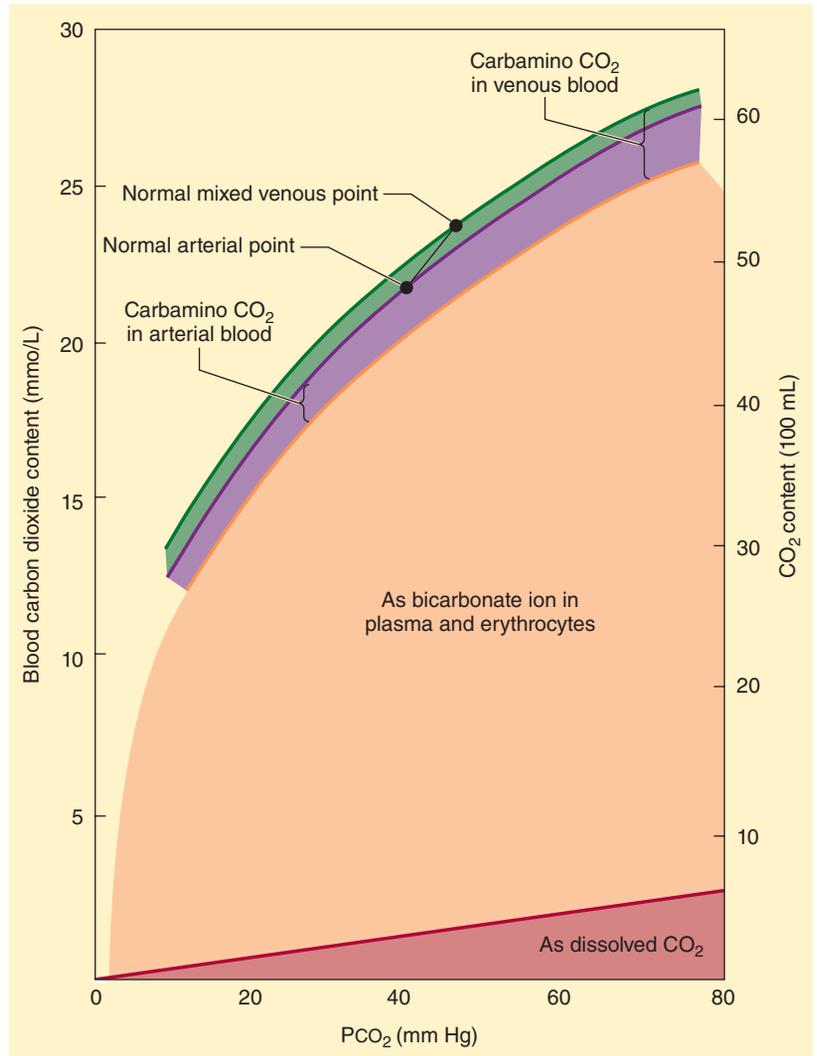

FIGURE 23-24 The CO_2 dissociation curve for whole blood. (Reproduced, with permission, from Nunn JF: *Nunn's Applied Physiology*, 4th ed. Butterworth, 2000.)

The contribution of each form of CO_2 can also be quantified in this manner (Figure 23-24).

Carbon Dioxide Stores

Carbon dioxide stores in the body are large (approximately 120 L in adults) and primarily in the form of dissolved CO_2 and bicarbonate. When an imbalance occurs between production and elimination, establishing a new CO_2 equilibrium requires 20–30 min (compared with less than 4–5 min for O_2 ; see above). Carbon dioxide is stored in the rapid-, intermediate-, and slow-equilibrating compartments. Because of the larger

capacity of the intermediate and slow compartments, the rate of rise in arterial CO_2 tension is generally slower than its fall following acute changes in ventilation.

CONTROL OF BREATHING

Spontaneous ventilation is the result of rhythmic neural activity in respiratory centers within the brainstem. This activity regulates respiratory muscles to maintain normal tensions of O_2 and CO_2 in the body. The basic neuronal activity is modified by inputs from other areas in the brain, volitional and

autonomic, as well as various central and peripheral receptors (sensors).

1. Central Respiratory Centers

The basic breathing rhythm originates in the medulla. Two medullary groups of neurons are generally recognized: a dorsal respiratory group, which is primarily active during inspiration, and a ventral respiratory group, which is active during expiration. The close association of the dorsal respiratory group of neurons with the tractus solitarius may explain reflex changes in breathing from vagal or glossopharyngeal nerve stimulation.

Two pontine areas influence the dorsal (inspiratory) medullary center. A lower pontine (apneustic) center is excitatory, whereas an upper pontine (pneumotaxic) center is inhibitory. The pontine centers appear to fine-tune respiratory rate and rhythm.

2. Central Sensors

The most important of these sensors are chemoreceptors that respond to changes in hydrogen ion concentration. Central chemoreceptors are thought to lie on the anterolateral surface of the medulla and respond primarily to changes in cerebrospinal fluid (CSF) $[H^+]$. This mechanism is effective in regulating $Paco_2$, because the blood-brain barrier is permeable to dissolved CO_2 , but not to bicarbonate ions. Acute changes in $Paco_2$, but not in arterial $[HCO_3^-]$, are reflected in CSF; thus, a change in CO_2 must result in a change in $[H^+]$:

Over the course of a few days, CSF $[HCO_3^-]$ can compensate to match any change in arterial $[HCO_3^-]$.

Increases in $Paco_2$ elevate CSF hydrogen ion concentration and activate the chemoreceptors. Secondary stimulation of the adjacent respiratory medullary centers increases alveolar ventilation (Figure 23–25) and reduces $Paco_2$ back to normal. Conversely, decreases in CSF hydrogen ion concentration secondary to reductions in $Paco_2$ reduce alveolar ventilation and elevate $Paco_2$. Note that the relationship between $Paco_2$ and minute volume is nearly linear. Also note that very high arterial $Paco_2$ tensions depress the ventilatory response (CO_2 narcosis). The $Paco_2$ at which ventilation is zero (x-intercept) is known as the apneic threshold. Spontaneous

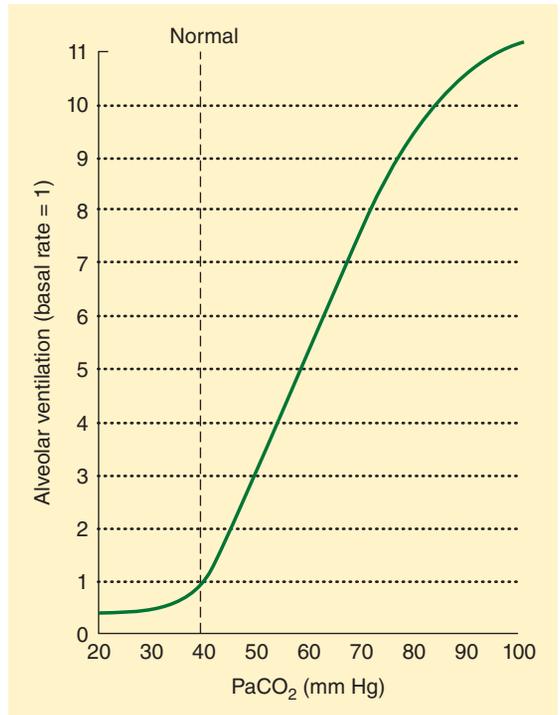

FIGURE 23–25 The normal relationship between $Paco_2$ and minute ventilation. (Reproduced, with permission, from Guyton AC: *Textbook of Medical Physiology*, 7th ed. W.B. Saunders, 1986.)

respirations are typically absent under anesthesia when $Paco_2$ falls below the apneic threshold. (In the awake state, cortical influences prevent apnea, so apneic thresholds are not ordinarily seen.) In contrast to peripheral chemoreceptors (see below), central chemoreceptor activity is depressed by hypoxia.

3. Peripheral Sensors

Peripheral Chemoreceptors

Peripheral chemoreceptors include the carotid bodies (at the bifurcation of the common carotid arteries) and the aortic bodies (surrounding the aortic arch). The carotid bodies are the principal peripheral chemoreceptors in humans and are sensitive to changes in PaO_2 , $Paco_2$, pH, and arterial perfusion pressure. They interact with central respiratory centers via the glossopharyngeal nerves, producing reflex increases in alveolar ventilation in response to reductions in PaO_2 , arterial perfusion, or elevations in $[H^+]$ and $Paco_2$. Peripheral chemoreceptors

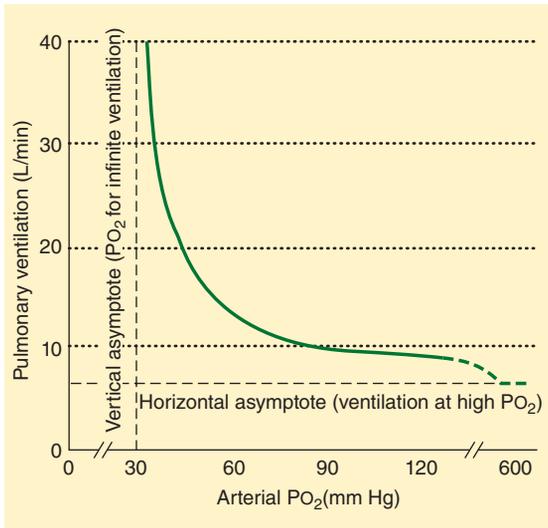

FIGURE 23-26 The relationship between P_{aO_2} and minute ventilation at rest and with a normal P_{aCO_2} . (Data from Weil JV, Byrne-Quinn E, Sodal IE, et al: Hypoxic ventilatory drive in normal man. *J Clin Invest* 1970;49:1061-1072; Dripps RD, Comroe JH: The effect of the inhalation of high and low oxygen concentration on respiration, pulse rate, ballistocardiogram and arterial oxygen saturation (oximeter) of normal individuals. *Am J Physiol* 1947;149:277-291; Cormac RS, Cunningham DJC, Gee JBL: The effect of carbon dioxide on the respiratory response to want of oxygen in man. *Q J Exp Physiol* 1957;42:303-316.)

are also stimulated by cyanide, doxapram, and large doses of nicotine. In contrast to central chemoreceptors, which respond primarily to P_{aCO_2} (really $[H^+]$), the carotid bodies are most sensitive to P_{aO_2} (Figure 23-26). Note that receptor activity does not appreciably increase until P_{aO_2} decreases below 50 mm Hg. Cells of the carotid body (glomus cells) are thought to be primarily dopaminergic neurons. Anti-dopaminergic drugs (such as phenothiazines), most commonly used anesthetics, and bilateral carotid surgery abolish the peripheral ventilatory response to hypoxemia.

Lung Receptors

Impulses from these receptors are carried centrally by the vagus nerve. Stretch receptors are distributed in the smooth muscle of airways; they are responsible for inhibition of inspiration when the lung is inflated to excessive volumes (Hering-Breuer inflation reflex) and shortening of exhalation when the lung is deflated (deflation reflex). Stretch receptors

normally play a minor role in humans. In fact, bilateral vagal nerve blocks have a minimal effect on the normal respiratory pattern.

Irritant receptors in the tracheobronchial mucosa react to noxious gases, smoke, dust, and cold gases; activation produces reflex increases in respiratory rate, bronchoconstriction, and coughing. J (juxta-capillary) receptors are located in the interstitial space within alveolar walls; these receptors induce dyspnea in response to expansion of interstitial space volume and various chemical mediators following tissue damage.

Other Receptors

These include various muscle and joint receptors on pulmonary muscles and the chest wall. Input from these sources is probably important during exercise and in pathological conditions associated with decreased lung or chest compliance.

4. Effects of Anesthesia on the Control of Breathing

The most important effect of most general anesthetics on breathing is a tendency to promote hypoventilation. The mechanism is probably dual: central depression of the chemoreceptor and depression of external intercostal muscle activity. The magnitude of the hypoventilation is generally proportional to **17** anesthetic depth. With increasing depth of anesthesia, the slope of the P_{aCO_2} /minute ventilation curve decreases, and the apneic threshold increases (Figure 23-27). This effect is at least partially reversed by surgical stimulation.

The peripheral response to hypoxemia is even more sensitive to anesthetics than the central CO_2 response and is nearly abolished by even subanesthetic doses of most inhalation agents (including nitrous oxide) and many intravenous agents.

NONRESPIRATORY FUNCTIONS OF THE LUNG

Filtration & Reservoir Function

A. Filtration

The unique in-series position of the pulmonary capillaries within the circulation allows them to act

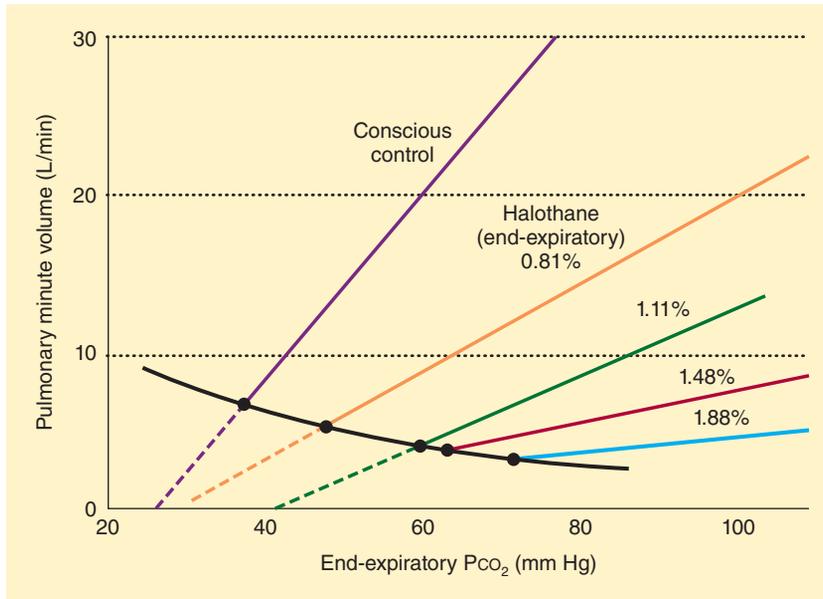

FIGURE 23-27 The effect of volatile agents (halothane) on the P_{ETCO_2} -ventilation response curve (see text). Data from Munson ES, Larson CP, Babad AA, et al: The effects of halothane, fluroxene and cyclopropane on ventilation: a comparative study in man. *Anesthesiology* 1966;27:716-728.

as a filter for debris in the bloodstream. The lungs' high content of heparin and plasminogen activator facilitates the breakdown of entrapped fibrin debris. Although pulmonary capillaries have an average diameter of 7 μm , larger particles have been shown to pass through to the left heart.

B. Reservoir Function

The role of the pulmonary circulation as a reservoir for the systemic circulation was discussed above.

Metabolism

The lungs are metabolically very active organs. In addition to surfactant synthesis, pneumocytes account for a major portion of extrahepatic mixed-function oxidation. Neutrophils and macrophages in the lung produce O_2 -derived free radicals in response to infection. The pulmonary endothelium metabolizes a variety of vasoactive compounds, including norepinephrine, serotonin, bradykinin, and a variety of prostaglandins and leukotrienes. Histamine and epinephrine are generally not metabolized in the lungs; in fact the lungs can be a major site of histamine synthesis and release during allergic reactions.

The lungs are also responsible for converting angiotensin I to its physiologically active form, angiotensin II. The enzyme responsible, angiotensin-converting enzyme, is bound on the surface of the pulmonary endothelium.

CASE DISCUSSION

Unilaterally Diminished Breath Sounds During General Anesthesia

A 67-year-old man with carcinoma is undergoing colon resection under general anesthesia. His history includes an old anterior myocardial infarction and compensated congestive heart failure. Arterial and central venous catheters are placed preoperatively for monitoring during surgery. Following a smooth induction and an atraumatic intubation, anesthesia is maintained with 60% nitrous oxide in O_2 , sevoflurane, and vecuronium. One-half hour into the operation, the surgeon asks for the Trendelenburg position to facilitate surgical exposure. The pulse

oximeter, which had been reading 99% saturation, suddenly drops and remains at 93%. The pulse oximeter's signal strength and waveform are unchanged. Auscultation of the lungs reveals diminished breath sounds over the left lung.

What is the most likely explanation?

Unilaterally diminished breath sounds under anesthesia are most commonly caused by accidental placement or migration of the tracheal tube into one of the two main bronchi. As a result, only one lung is ventilated. Other causes of unilaterally diminished breath sounds (such as pneumothorax, a large mucus plug, lobar atelectasis, or undiagnosed bullae) are less easily diagnosed, but are fortunately less common during anesthesia.

The Trendelenburg (head-down) position typically causes the tip of the tracheal tube to advance 1–2 cm relative to the carina. In this case, the tube was apparently placed just above the carina with the patient in the supine position, but migrated into the right bronchus when the Trendelenburg position was imposed. The diagnosis is confirmed by drawing the tube back 1–2 cm at a time as the chest is auscultated. Breath sounds will become equal again when the tip of the tube reenters the trachea. Following initial placement, tracheal tubes should be routinely checked for correct positioning by auscultating the chest, ascertaining depth of tube insertion by the markings on the tube (normally 20–24 cm at the teeth for an adult), and feeling for the cuff in the suprasternal notch. Tube position relative to the carina can also be quickly confirmed with a flexible fiberoptic bronchoscope.

Are tracheal tubes just as likely to enter either main bronchus?

In most cases of unintentional bronchial intubation, the tracheal tube enters the right bronchus because the latter diverges away from the trachea at a less acute angle than does the left bronchus.

Why did hemoglobin saturation decrease?

Failure to ventilate one lung as it continues to be perfused creates a large intrapulmonary shunt.

Venous admixture increases and tends to depress P_{aO_2} and hemoglobin saturation.

Does a saturation of 93% exclude bronchial intubation?

No; if both lungs continued to have equal blood flow, venous admixture should have theoretically increased to 50%, resulting in severe hypoxemia and very low hemoglobin saturation. Fortunately, hypoxic pulmonary vasoconstriction is a powerful compensatory response that tends to reduce flow to the hypoxic lung and reduces the expected venous admixture. In fact, if the patient has been receiving a higher inspired O_2 concentration (50% to 100%), the drop in arterial tension may not be detectable by the pulse oximeter due to the characteristics of the normal hemoglobin saturation curve. For example, bronchial intubation in a patient inspiring 50% O_2 might drop P_{AO_2} from 250 mm Hg to 95 mm Hg; the resulting change in pulse oximeter readings (100–99 to 98–97) would hardly be noticeable.

Arterial and mixed venous blood gas tensions are obtained with the following results:

$P_{aO_2} = 69$ mm Hg; $P_{aCO_2} = 42$ mm Hg; $S_{aO_2} = 93\%$; $P_{\bar{V}O_2} = 40$ mm Hg; and $S_{\bar{V}O_2} = 75\%$. Hemoglobin concentration is 15 g/dL.

What is the calculated venous admixture?

In this case, $Pc'_{O_2} = P_{aO_2} = ([760 - 47] \times 0.4) - 42 = 243$ mm Hg. Therefore, $Cc'_{O_2} = (15 \times 1.31 \times 1.0) + (243 \times 0.003) = 20.4$ mL/dL.

$C_{aO_2} = (15 \times 1.31 \times 0.93) + (69 \times 0.003) = 18.5$ mL/dL

$C_{\bar{V}O_2} = (15 \times 1.31 \times 0.75) + (40 \times 0.003) = 14.8$ mL/dL

$\dot{Q}_S/\dot{Q}_T = (20.4 - 18.5)/(20.4 - 14.8) = 34\%$

How does bronchial intubation affect arterial and end-tidal CO_2 tensions?

P_{aCO_2} is typically not appreciably altered as long as the same minute ventilation is maintained (see One-Lung Anesthesia, Chapter 25). Clinically, the $P_{aCO_2} - P_{ETCO_2}$ gradient often widens, possibly because of increased alveolar dead space (overdistension of the ventilated lung). Thus, P_{ETCO_2} may decrease or remain unchanged.

Anesthesia for Patients with Respiratory Disease

KEY CONCEPTS

- 1** In a patient with an acute asthma attack, a normal or high P_{aCO_2} indicates that the patient can no longer maintain the work of breathing and is often a sign of impending respiratory failure. A pulsus paradoxus and electrocardiographic signs of right ventricular strain (ST-segment changes, right axis deviation, and right bundle branch block) are also indicative of severe airway obstruction.
- 2** Asthmatic patients with active bronchospasm presenting for emergency surgery should be treated aggressively. Supplemental oxygen, aerosolized β_2 -agonists, and intravenous glucocorticoids can dramatically improve lung function in a few hours.
- 3** Intraoperative bronchospasm is usually manifested as wheezing, increasing peak airway pressures (plateau pressure may remain unchanged), decreasing exhaled tidal volumes, or a slowly rising waveform on the capnograph.
- 4** Other causes, such as obstruction of the tracheal tube from kinking, secretions, or an overinflated balloon; bronchial intubation; active expiratory efforts (straining); pulmonary edema or embolism; and pneumothorax, can simulate bronchospasm.
- 5** Chronic obstructive pulmonary disease (COPD) is currently defined as a disease state characterized by airflow limitation that is not fully reversible. The chronic airflow limitation of this disease is due to a mixture of small and large airway disease (chronic bronchitis/bronchiolitis) and parenchymal destruction (emphysema), with the representation of these two components varying from patient to patient.
- 6** Cessation of smoking is the long-term intervention that has been shown to reduce the rate of decline in lung function.
- 7** Preoperative interventions in patients with COPD aimed at correcting hypoxemia, relieving bronchospasm, mobilizing and reducing secretions, and treating infections may decrease the incidence of postoperative pulmonary complications. Patients at greatest risk of complications are those with preoperative pulmonary function measurements less than 50% of predicted.
- 8** Restrictive pulmonary diseases are characterized by decreased lung compliance. Lung volumes are typically reduced, with preservation of normal expiratory flow rates. Thus, both forced expiratory volume in 1 sec (FEV_1) and forced vital capacity (FVC) are reduced, but the FEV_1/FVC ratio is normal.
- 9** Intraoperative pulmonary embolism usually presents as unexplained cardiovascular collapse, hypoxemia, or bronchospasm. A decrease in end-tidal CO_2 concentration is also suggestive of pulmonary embolism, but is not specific.

The impact of preexisting pulmonary disease on respiratory function during anesthesia and in the postoperative period is predictable: Greater degrees of preoperative pulmonary impairment are associated with more marked intraoperative alterations in respiratory function and higher rates of postoperative pulmonary complications. Failure to recognize patients who are at increased risk is a frequent contributory factor leading to complications, as patients may not receive appropriate preoperative and intraoperative care. This chapter examines pulmonary risk in general and then reviews the anesthetic approach in patients with the most common types of respiratory disease.

PULMONARY RISK FACTORS

Certain risk factors (Table 24-1) may predispose patients to postoperative pulmonary complications. The incidence of atelectasis, pneumonia, pulmonary embolism, and respiratory failure following surgery is quite high, but varies widely (from 6% to 60%), depending on the patient population studied and the surgical procedures performed. The two strongest predictors of complications seem to be operative site and a history of dyspnea, which correlate with the degree of preexisting pulmonary disease.

The association between smoking and respiratory disease is well established; abnormalities in maximal midexpiratory flow (MMEF) rates are often demonstrable well before symptoms of COPD appear. Although abnormalities can be demonstrated on pulmonary function tests (PFTs), because most patients who smoke do not have PFTs performed preoperatively, it is best to assume that such patients have some degree of pulmonary compromise. Even in normal individuals, advancing age is associated with an increasing prevalence of pulmonary disease and an increase in closing capacity. Obesity decreases functional residual capacity (FRC), increases the work of breathing, and predisposes patients to deep venous thrombosis.

Thoracic and upper abdominal surgical procedures can have marked effects on pulmonary function. Operations near the diaphragm often result in diaphragmatic dysfunction and a restrictive

ventilatory defect (see below). Upper abdominal procedures consistently decrease FRC (60% to 70%); the effect is maximal on the first postoperative day and usually lasts 7–10 days. Rapid shallow breathing with an ineffective cough caused by pain (splinting), a decrease in the number of sighs, and impaired mucociliary clearance lead to microatelectasis and loss of lung volume. Intrapulmonary shunting promotes hypoxemia. Residual anesthetic effects, the recumbent position, sedation from opioids, abdominal distention, and restrictive dressings may also be contributory. Complete relief of pain with regional

TABLE 24–2 Recommendations of the American College of Physicians to reduce perioperative pulmonary complications in patients undergoing noncardiothoracic surgery.

<p>Recommendation 1:</p> <ul style="list-style-type: none"> • All patients undergoing noncardiothoracic surgery should be evaluated for the presence of the following significant risk factors for postoperative pulmonary complications in order to receive pre- and postoperative interventions to reduce pulmonary risk: chronic obstructive pulmonary disease, age older than 60 years, American Society of Anesthesiologists class of II or greater, functionally dependent, and congestive heart failure. • The following are not significant risk factors for postoperative pulmonary complications: obesity and mild or moderate asthma.
<p>Recommendation 2:</p> <ul style="list-style-type: none"> • Patients undergoing the following procedures are at higher risk for postoperative pulmonary complications and should be evaluated for other concomitant risk factors and receive pre- and postoperative interventions to reduce pulmonary complications: prolonged surgery (>3 hours), abdominal surgery, thoracic surgery, neurosurgery, head and neck surgery, vascular surgery, aortic aneurysm repair, emergency surgery, and general anesthesia.
<p>Recommendation 3:</p> <ul style="list-style-type: none"> • A low serum albumin level (<35 g/L) is a powerful marker of increased risk for postoperative pulmonary complications and should be measured in all patients who are clinically suspected of having hypoalbuminemia; measurement should be considered in patients with one or more risk factors for perioperative pulmonary complications.
<p>Recommendation 4:</p> <ul style="list-style-type: none"> • All patients who after preoperative evaluation are found to be at higher risk for postoperative pulmonary complications should receive the following postoperative procedures in order to reduce postoperative pulmonary complications: deep breathing exercises or incentive spirometry and the selective use of a nasogastric tube (as needed for postoperative nausea or vomiting, inability to tolerate oral intake, or symptomatic abdominal distention).
<p>Recommendation 5:</p> <ul style="list-style-type: none"> • Preoperative spirometry and chest radiography should not be used routinely for predicting risk for postoperative pulmonary complications. • Preoperative pulmonary function testing or chest radiography may be appropriate in patients with a previous diagnosis of chronic obstructive pulmonary disease or asthma.
<p>Recommendation 6:</p> <ul style="list-style-type: none"> • The following procedures should not be used solely for reducing postoperative pulmonary complication risk: right heart catheterization and total parenteral nutrition or total enteral nutrition (for patients who are malnourished or have low serum albumin levels).

Data from Qaseem A, Snow V, Fitterman N, et al: Risk assessment for and strategies to reduce perioperative pulmonary complication for patients undergoing noncardiothoracic surgery: a guideline from the American College of Physicians. *Ann Intern Med* 2006;144:576.

anesthesia can decrease, but does not completely reverse these abnormalities. Persistent microatelectasis and retention of secretions favor the development of postoperative pneumonia.

Although many adverse effects of general anesthesia on pulmonary function have been described, the superiority of regional over general anesthesia in patients with pulmonary impairment is not firmly established.

Because of the prevalence of smoking and obesity, many patients may be at increased risk of developing postoperative pulmonary dysfunction. The risk of complications increases if the patient is having a thoracotomy or laparotomy, even if the patient

has no risk factors. Patients with known disease should have their pulmonary function optimized preoperatively, with careful consideration given to the choice of general versus regional anesthesia.

The American College of Physicians has established guidelines to assist in the preoperative assessment of patients with pulmonary disease (see [Table 24–2](#)).

When patients with a history of dyspnea present without the benefit of a previous workup, the differential diagnosis can be quite broad and may include both primary pulmonary and cardiac pathologies. Diagnostic approaches to evaluating such patients are summarized in [Figure 24–1](#).

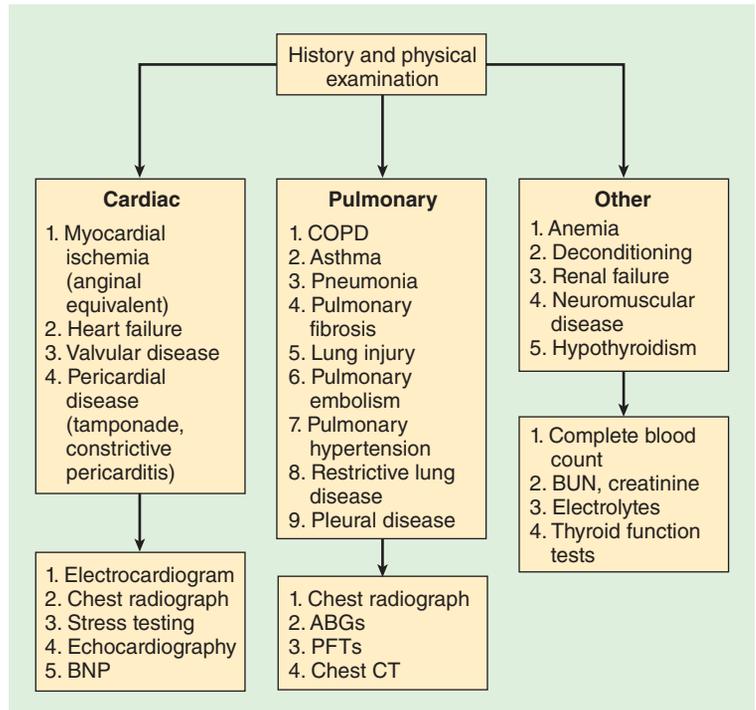

FIGURE 24-1 Evaluation of dyspnea. ABGs, arterial blood gases; BNP, brain natriuretic peptide; BUN, blood urea nitrogen; COPD, chronic obstructive pulmonary disease; CT, computed tomography; PFTs, pulmonary function tests. Obstructive Pulmonary Disease

Obstructive and restrictive breathing are the two most common abnormal patterns, as determined by PFTs. Obstructive lung diseases are the most common form of pulmonary dysfunction. They include asthma, emphysema, chronic bronchitis, cystic fibrosis, bronchiectasis, and bronchiolitis. The primary characteristic of these disorders is resistance to airflow. An MMEF of <70% (forced expiratory flow [FEF_{25-75%}]) is often the only abnormality early in the course of these disorders. Values for FEF_{25-75%} in adult males and females are normally >2.0 and >1.6 L/sec, respectively. As the disease progresses, both forced expiratory volume in 1 sec (FEV₁) and the FEV₁/FVC (forced vital capacity) ratio are less than 70% of the predicted values.

Elevated airway resistance and air trapping increase the work of breathing; respiratory gas exchange is impaired because of ventilation/perfusion (\dot{V}/\dot{Q}) imbalance. The predominance

of expiratory airflow resistance results in air trapping; residual volume and total lung capacity (TLC) increase. Wheezing is a common finding and represents turbulent airflow. It is often absent with mild obstruction that may be manifested initially only by prolonged exhalation. Progressive obstruction typically results first in expiratory wheezing only, and then in both inspiratory and expiratory wheezing. With marked obstruction, wheezing may be absent when airflow has nearly ceased.

ASTHMA

Preoperative Considerations

Asthma is a common disorder, affecting 5% to 7% of the population. Its primary characteristic is airway (bronchiolar) inflammation and hyperreactivity in response to a variety of stimuli. Clinically, asthma is manifested by episodic attacks of dyspnea, cough, and wheezing. Airway obstruction, which is generally reversible, is the result of bronchial smooth muscle constriction, edema, and increased secretions.

Classically, the obstruction is precipitated by a variety of airborne substances, including pollens, animal dander, dusts, pollutants, and various chemicals. Some patients also develop bronchospasm following ingestion of aspirin, nonsteroidal antiinflammatory agents, sulfites, or tartrazine and other dyes. Exercise, emotional excitement, and viral infections also precipitate bronchospasm in many patients. Asthma is classified as acute or chronic. Chronic asthma is further classified as intermittent (mild) and mild, moderate, and severe persistent disease.

The terms extrinsic (allergic) asthma (attacks related to environmental exposures) and intrinsic (idiosyncratic) asthma (attacks usually occurring without provocation) were used in the past, but these classifications were imperfect; many patients show features of both forms. Moreover, overlap with chronic bronchitis (see below) is common.

A. Pathophysiology

The pathophysiology of asthma involves the local release of various chemical mediators in the airway, and, possibly, overactivity of the parasympathetic nervous system. Inhaled substances can initiate bronchospasm through both specific and nonspecific immune mechanisms by degranulating bronchial mast cells. In classic allergic asthma, antigen binding to immunoglobulin E (IgE) on the surface of mast cells causes degranulation. Bronchoconstriction is the result of the subsequent release of histamine; bradykinin; leukotrienes C, D, and E; platelet-activating factor; prostaglandins (PG) PGE₂, PGF₂α, and PGD₂; and neutrophil and eosinophil chemotactic factors. The parasympathetic nervous system plays a major role in maintaining normal bronchial tone; a normal diurnal variation in tone is recognized in most individuals, with peak airway resistance occurring early in the morning (at about 6:00 AM). **Vagal afferents in the bronchi are sensitive to histamine and multiple noxious stimuli, including cold air, inhaled irritants, and instrumentation (eg, tracheal intubation).** Reflex vagal activation results in bronchoconstriction, which is mediated by an increase in intracellular cyclic guanosine monophosphate (cGMP).

During an asthma attack, bronchoconstriction, mucosal edema, and secretions increase resistance

to gas flow at all levels of the lower airways. As an attack resolves, airway resistance normalizes first in the larger airways (main-stem, lobar, segmental, and subsegmental bronchi), and then in more peripheral airways. Consequently, expiratory flow rates are initially decreased throughout an entire forced exhalation, but during resolution of the attack, the expiratory flow rate is reduced only at low lung volumes. TLC, residual volume (RV), and FRC are all increased. In acutely ill patients, RV and FRC are often increased by more than 400% and 100%, respectively. Prolonged or severe attacks markedly increase the work of breathing and can fatigue respiratory muscles. The number of alveolar units with low (\dot{V}/\dot{Q}) ratios increases, resulting in hypoxemia. Tachypnea is likely due to stimulation of bronchial receptors and typically produces hypoxemia. **1** capnia. A normal or high PaCO₂ indicates that the patient can no longer maintain the work of breathing and is often a sign of impending respiratory failure. A pulsus paradoxus and electrocardiographic signs of right ventricular strain (ST-segment changes, right axis deviation, and right bundle branch block) are also indicative of severe airway obstruction.

B. Treatment

Drugs used to treat asthma include β-adrenergic agonists, methylxanthines, glucocorticoids, anticholinergics, leukotriene blockers, and mast cell-stabilizing agents; with the exception of the last, these drugs may be used for either acute or chronic treatment of asthma. Although devoid of any bronchodilating properties, cromolyn sodium and nedocromil are effective in preventing bronchospasm by blocking the degranulation of mast cells.

Sympathomimetic agents ([Table 24-3](#)) are the most commonly used for acute exacerbations. They produce bronchodilation via β₂-agonist activity. Activation of β₂-adrenergic receptors on bronchiolar smooth muscle stimulates the activity of adenylate cyclase, which results in the formation of intracellular cyclic adenosine monophosphate (cAMP). These agents are usually administered via a metered-dose inhaler or by aerosol. Use of more selective β₂-agonists, such as terbutaline or albuterol, may decrease the incidence of undesirable β₁

TABLE 24-3 A comparison of commonly used bronchodilators.¹

Agent	Adrenergic Activity	
	β_1	β_2

Salmeterol (Serevent)	+	++++
Terbutaline (Brethaire)	+	+++

¹+ Indicates level of activity.

cardiac effects, but are often not particularly selective in high doses.

Traditionally, methylxanthines are thought to produce bronchodilation by inhibiting phosphodiesterase, the enzyme responsible for the breakdown of cAMP. Their pulmonary effects seem much more complex and include catecholamine release, blockade of histamine release, and diaphragmatic stimulation. Oral long-acting theophylline preparations are used for patients with nocturnal symptoms. Unfortunately, theophylline has a narrow therapeutic range; therapeutic blood levels are considered to be 10–20 mcg/mL. Lower levels, however, may be effective. Aminophylline is the only available intravenous theophylline preparation.

Glucocorticoids are used for both acute treatment and maintenance therapy of patients with asthma because of their antiinflammatory and membrane-stabilizing effects. Beclomethasone, triamcinolone, fluticasone, and budesonide are synthetic steroids commonly used in metered-dose inhalers for maintenance therapy. Although they are associated with a low incidence of undesirable

systemic effects, their use does not necessarily prevent adrenal suppression. Intravenous hydrocortisone or methylprednisolone is used acutely for severe attacks, followed by tapering doses of oral prednisone. Glucocorticoids usually require several hours to become effective.

Anticholinergic agents produce bronchodilation through their antimuscarinic action and may block reflex bronchoconstriction. Ipratropium, a congener of atropine that can be given by a metered-dose inhaler or aerosol, is a moderately effective bronchodilator without appreciable systemic anticholinergic effects.

Anesthetic Considerations

A. Preoperative Management

The emphasis in evaluating patients with asthma should be on determining the recent course of the disease and whether the patient has ever been hospitalized for an acute asthma attack, as well as on ascertaining that the patient is in optimal condition. Patients with poorly controlled asthma or wheezing at the time of anesthesia induction have a higher risk of perioperative complications. Conversely, well-controlled asthma has not been shown to be a risk factor for intraoperative or postoperative complications. A thorough history and physical examination are of critical importance. The patient should have no or minimal dyspnea, wheezing, or cough. Complete resolution of recent exacerbations should be confirmed by chest auscultation. Patients with frequent or chronic bronchospasm should be placed on an optimal bronchodilating regimen. A chest radiograph identifies air trapping; hyperinflation results in a flattened diaphragm, a small-appearing heart, and hyperlucent lung fields. PFTs—particularly expiratory airflow measurements such as FEV₁, FEV₁/FVC, FEF_{25-75%}, and peak expiratory flow rate—help in assessing the severity of airway obstruction and reversibility after bronchodilator treatment. Comparisons with previous measurements are invaluable.

2 Asthmatic patients with active bronchospasm presenting for emergency surgery should be treated aggressively. Supplemental oxygen, aerosolized β_2 -agonists, and intravenous glucocorticoids

can dramatically improve lung function in a few hours. Arterial blood gases may be useful in managing severe cases. Hypoxemia and hypercapnia are typical of moderate and severe disease; even slight hypercapnia is indicative of severe air trapping and may be a sign of impending respiratory failure.

Some degree of preoperative sedation may be desirable in asthmatic patients presenting for elective surgery—particularly in patients whose disease has an emotional component. In general, benzodiazepines are the most satisfactory agents for premedication. Anticholinergic agents are not customarily given unless very copious secretions are present or if ketamine is to be used for induction of anesthesia. In typical intramuscular doses, anticholinergics are not effective in preventing reflex bronchospasm following intubation. The use of an H_2 -blocking agent (such as cimetidine, ranitidine, or famotidine) is theoretically detrimental, since H_2 -receptor activation normally produces bronchodilation; in the event of histamine release, unopposed H_1 activation with H_2 blockade may accentuate bronchoconstriction.

Bronchodilators should be continued up to the time of surgery; in order of effectiveness, they are β -agonists, inhaled glucocorticoids, leukotriene blockers, mast-cell stabilizers, theophyllines, and anticholinergics. Patients who receive chronic glucocorticoid therapy with more than 5 mg/day of prednisone (or its equivalent) should receive a graduated supplementation schedule based on the severity of the illness and complexity of the surgical procedure. Supplemental doses should be tapered to baseline within 1–2 days.

B. Intraoperative Management

The most critical time for asthmatic patients undergoing anesthesia is during instrumentation of the airway. General anesthesia by mask or regional anesthesia will circumvent this problem, but neither eliminates the possibility of bronchospasm. In fact, some clinicians believe that high spinal or epidural anesthesia may aggravate bronchoconstriction by blocking sympathetic tone to the lower airways (T1–T4) and allowing unopposed parasympathetic activity. Pain, emotional stress, or stimulation during light general anesthesia can precipitate bronchospasm. Drugs often associated with histamine

release (eg, atracurium, morphine, and meperidine) should be avoided or given very slowly when used. The goal of any general anesthetic is a smooth induction and emergence, with anesthetic depth adjusted to stimulation.

The choice of induction agent is less important, if adequate depth of anesthesia is achieved before intubation or surgical stimulation. Thiopental may occasionally induce bronchospasm as a result of exaggerated histamine release. Propofol and etomidate are suitable induction agents; propofol may also produce bronchodilation. Ketamine has bronchodilating properties and is a good choice for patients with asthma who are also hemodynamically unstable. Ketamine should probably not be used in patients with high theophylline levels, as the combined actions of the two drugs can precipitate seizure activity. Halothane and sevoflurane usually provide the smoothest inhalation induction with bronchodilation in asthmatic children. Isoflurane and desflurane can provide equal bronchodilation, but are not normally used for inhalation induction. Desflurane is the most pungent of the volatile agents and may result in cough, laryngospasm, and bronchospasm.

Reflex bronchospasm can be blunted before intubation by an additional dose of the induction agent, ventilating the patient with a 2–3 minimum alveolar concentration (MAC) of a volatile agent for 5 min, or administering intravenous or intratracheal lidocaine (1–2 mg/kg). Note that intratracheal lidocaine itself can initiate bronchospasm if an inadequate dose of induction agent has been used. Administration of an anticholinergic agent may block reflex bronchospasm, but causes excessive tachycardia. Although succinylcholine may on occasion induce marked histamine release, it can generally be safely used in most asthmatic patients. In the absence of capnography, confirmation of correct tracheal placement by chest auscultation can be difficult in the presence of marked bronchospasm.

Volatile anesthetics are most often used for maintenance of anesthesia to take advantage of their potent bronchodilating properties. Ventilation should incorporate warmed humidified gases whenever possible. Airflow obstruction during expiration is apparent on capnography as a delayed rise of the end-tidal CO_2 value (**Figure 24–2**); the

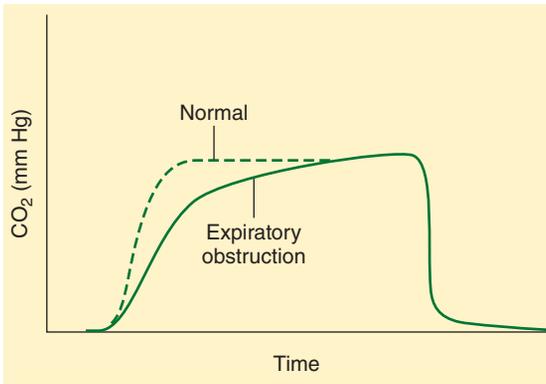

FIGURE 24-2 Capnograph of a patient with expiratory airway obstruction.

severity of obstruction is generally inversely related to the rate of rise in end-tidal CO_2 . Severe bronchospasm is manifested by rising peak inspiratory pressures and incomplete exhalation. Tidal volumes of 6–8 mL/kg, with prolongation of the expiratory time, may allow more uniform distribution of gas flow to both lungs and may help avoid air trapping. The PaCO_2 may increase, which is acceptable if there is no contraindication from a cardiovascular or neurologic perspective.

3 Intraoperative bronchospasm is usually manifested as wheezing, increasing peak airway pressures (plateau pressure may remain unchanged), decreasing exhaled tidal volumes, or a slowly rising **4** waveform on the capnograph. Other causes can simulate bronchospasm: obstruction of the tracheal tube from kinking, secretions, or an overinflated balloon; bronchial intubation; active expiratory efforts (straining); pulmonary edema or embolism; and pneumothorax. Bronchospasm should be treated by increasing the concentration of the volatile agent and administering an aerosolized bronchodilator. Infusion of low dose epinephrine may be needed if bronchospasm is refractory to other interventions.

Intravenous hydrocortisone can be given, particularly in patients with a history of glucocorticoid therapy.

At the completion of surgery, the patient should ideally be free of wheezing. Reversal of

nondepolarizing neuromuscular blocking agents with anticholinesterase agents does not precipitate bronchoconstriction, if preceded by the appropriate dose of an anticholinergic agent. Deep extubation (before airway reflexes return) reduces bronchospasm on emergence. Lidocaine as a bolus (1.5–2 mg/kg) may help obtund airway reflexes during emergence.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Preoperative Considerations

COPD is the most common pulmonary disorder encountered in anesthetic practice, and its prevalence increases with age. The disorder is strongly associated with cigarette smoking and has a male **5** predominance. COPD is currently defined as a disease state characterized by airflow limitation that is not fully reversible. The chronic airflow limitation of this disease is due to a mixture of small and large airway disease (chronic bronchitis/bronchiolitis) and parenchymal destruction (emphysema), with representation of these two components varying from patient to patient.

Most patients with COPD are asymptomatic or only mildly symptomatic, but show expiratory airflow obstruction upon PFTs. In many patients, the obstruction has an element of reversibility, presumably from bronchospasm (as shown by improvement in response to administration of a bronchodilator). With advancing disease, maldistribution of both ventilation and pulmonary blood flow results in areas of low (\dot{V}/\dot{Q}) ratios (intrapulmonary shunt), as well as areas of high (\dot{V}/\dot{Q}) ratios (dead space).

A. Chronic Bronchitis

The clinical diagnosis of chronic bronchitis is defined by the presence of a productive cough on most days of 3 consecutive months for at least 2 consecutive years. In addition to cigarette smoking, air pollutants, occupational exposure to dusts, recurrent pulmonary infections, and familial factors may be responsible. Secretions from hypertrophied bronchial mucous glands and mucosal edema from inflammation of the airways produce airflow obstruction. The term “chronic asthmatic

TABLE 24–4 Signs and symptoms of chronic obstructive pulmonary disease.

Feature	Chronic Bronchitis	Emphysema
Cough	Frequent	With exertion
Sputum	Copious	Scant
Hematocrit	Elevated	Normal
Paco ₂ (mm Hg)	Often elevated (>40)	Usually normal or <40
Chest radiograph	Increased lung markings	Hyperinflation
Elastic recoil	Normal	Decreased
Airway resistance	Increased	Normal to slightly increased
Cor pulmonale	Early	Late

bronchitis” may be used when bronchospasm is a major feature. Recurrent pulmonary infections (viral and bacterial) are common and often associated with bronchospasm. RV is increased, but TLC is often normal. Intrapulmonary shunting is prominent, and hypoxemia is common.

In patients with COPD, chronic hypoxemia leads to erythrocytosis, pulmonary hypertension, and eventually right ventricular failure (cor pulmonale); this combination of findings is often referred to as the blue bloater syndrome, but <5% of patients with COPD fit this description (Table 24–4). In the course of disease progression, patients gradually develop chronic CO₂ retention; the normal ventilatory drive becomes less sensitive to arterial CO₂ tension and may be depressed by oxygen administration (below).

B. Emphysema

Emphysema is a pathological disorder characterized by irreversible enlargement of the airways distal to terminal bronchioles and destruction of alveolar septa. The diagnosis can be reliably made with computed tomography (CT) of the chest. Mild apical emphysematous changes are a normal, but clinically insignificant, consequence of aging. Significant emphysema is more frequently related to cigarette

smoking. Less commonly, emphysema occurs at an early age and is associated with a homozygous deficiency of α_1 -antitrypsin. This is a protease inhibitor that prevents excessive activity of proteolytic enzymes (mainly elastase) in the lungs; these enzymes are produced by pulmonary neutrophils and macrophages in response to infection and pollutants. Emphysema associated with smoking may similarly be due to a relative imbalance between protease and antiprotease activities in susceptible individuals.

Emphysema may exist in a centrilobular or panlobular form. The centrilobular (or centriacinar) form results from dilatation or destruction of the respiratory bronchioles, is more closely associated with tobacco smoking, and has predominantly an upper lobe distribution. The panlobular (or panacinar) form results in a more even dilatation and destruction of the entire acinus, is associated with α_1 -antitrypsin deficiency, and has predominantly a lower lobe distribution.

Loss of the elastic recoil that normally supports small airways by radial traction allows premature collapse during exhalation, leading to expiratory flow limitation with air trapping and hyperinflation. Patients characteristically have increases in RV, FRC, TLC, and the RV/TLC ratio. The FRC is shifted rightward along the compliance curve of the lungs, toward the flat portion of the curve, in detriment of the pulmonary mechanics.

Disruption of the alveolar–capillary structure and loss of the acinar structure leads to decreased diffusion lung capacity (DLCO), \dot{V}/\dot{Q} mismatch, and impairment of gas exchange. Also, normal parenchyma may become compressed by the hyperinflated portions of the lung, resulting in a further increase in the \dot{V}/\dot{Q} mismatch. Due to the higher diffusibility of CO₂, its elimination is well preserved until \dot{V}/\dot{Q} abnormalities become severe. Chronic CO₂ retention occurs slowly and generally results in a compensated respiratory acidosis on blood gas analysis. Arterial oxygen tension is usually normal or slightly reduced. Acute CO₂ retention is a sign of impending respiratory failure.

Destruction of pulmonary capillaries in the alveolar septa leads to the development of pulmonary hypertension. However, the degree of

pulmonary hypertension is usually low to moderate, rarely exceeding 35–40 mm Hg.

When dyspneic, patients with emphysema often purse their lips to delay closure of the small airways, which accounts for the term “pink puffers” that is often used (Table 24–4). However, as mentioned above, most patients diagnosed with COPD have a combination of bronchitis and emphysema.

C. Treatment

Treatment for COPD is primarily supportive.

6 Cessation of smoking is the long-term intervention that has been shown to reduce the rate of decline in lung function. Patients demonstrating a reversible element in airway obstruction (>15% improvement in FEV₁ following administration of a bronchodilator) should be started on long-term bronchodilator therapy. Inhaled β_2 -adrenergic agonists, glucocorticoids, and ipratropium are very useful; ipratropium may play a more important role in the management of these patients than in patients with asthma. Even patients who do not show improvement in their PFTs from the use of bronchodilators may improve clinically with bronchodilator therapy. Treatment with systemic corticosteroids may be required in patients with acute exacerbations of COPD. However, systemic corticosteroids in patients with stable COPD is discouraged due to the lack of added benefit and the potential for systemic side effects. COPD exacerbations may be related to bouts of bronchitis, heralded by a change in sputum; frequent treatment with broad-spectrum antibiotics may be necessary. Hypoxemia should be treated carefully with supplemental oxygen. Patients with chronic hypoxemia ($\text{PaO}_2 < 55$ mm Hg) and pulmonary hypertension require low-flow oxygen therapy (1–2 L/min). Oxygen treatment during acute COPD exacerbations to a PaO_2 above 60 mm Hg may lead to CO_2 retention, most likely due to an inhibition of the hypoxic vasoconstriction in areas with low \dot{V}/\dot{Q} and the Haldane effect.

When cor pulmonale is present, diuretics are used to control peripheral edema; beneficial effects from vasodilators are inconsistent. Pulmonary rehabilitation may improve the functional status of the patient by improving physical symptoms and exercise capacity. Some studies suggest that the ability

to increase oxygen consumption during exercise is inversely related to postoperative complications.

Anesthetic Considerations

A. Preoperative Management

Patients with COPD should be prepared prior to elective surgical procedures in the same way as patients with asthma (above). They should be questioned about recent changes in dyspnea, sputum, and wheezing. Patients with an FEV₁ less than 50% of predicted (1.2–1.5 L) usually have dyspnea on exertion, whereas those with an FEV₁ less than 25% (<1 L in men) typically have dyspnea with minimal activity. The latter finding, in patients with predominantly chronic bronchitis, is also often associated with CO_2 retention and pulmonary hypertension. PFTs, chest radiographs, and arterial blood gas measurements, if available, should be reviewed carefully. The presence of bullous changes on the radiograph should be noted. Many patients have concomitant cardiac disease and should also receive a careful cardiovascular evaluation.

In contrast to asthma, only limited improvement in respiratory function may be seen after a short period of intensive preoperative preparation.

7 Nonetheless, preoperative interventions in patients with COPD aimed at correcting hypoxemia, relieving bronchospasm, mobilizing and reducing secretions, and treating infections may decrease the incidence of postoperative pulmonary complications. Patients at greatest risk of complications are those with preoperative pulmonary function measurements less than 50% of predicted. The possibility that postoperative ventilation may be necessary in high-risk patients should be discussed with both the patient and the surgeon.

Smoking should be discontinued for at least 6–8 weeks before the operation to decrease secretions and to reduce pulmonary complications. Cigarette smoking increases mucus production and decreases clearance. Both gaseous and particulate phases of cigarette smoke can deplete glutathione and vitamin C and may promote oxidative injury to tissues. Cessation of smoking for as little as 24 hr has theoretical beneficial effects on the oxygen-carrying capacity of hemoglobin; acute inhalation of cigarette smoke releases carbon monoxide, which increases

carboxyhemoglobin levels, as well as nitric oxide, and nitrogen dioxide, which can lead to formation of methemoglobin.

Long-acting bronchodilators and mucolytics should be continued, including on the day of surgery. COPD exacerbations should be treated aggressively.

Preoperative chest physiotherapy and lung expansion interventions with incentive spirometry, deep breathing exercises, cough, chest percussion, and postural drainage may be beneficial in decreasing postoperative pulmonary complications.

B. Intraoperative Management

Although regional anesthesia is often considered preferable to general anesthesia, high spinal or epidural anesthesia can decrease lung volumes, restrict the use of accessory respiratory muscles, and produce an ineffective cough, leading to dyspnea and retention of secretions. Loss of proprioception from the chest and positions such as lithotomy or lateral decubitus may accentuate dyspnea in awake patients.

Concerns about diaphragmatic paralysis may make interscalene blocks a less attractive option in the lung disease patient.

Preoxygenation prior to induction of general anesthesia prevents the rapid oxygen desaturation often seen in these patients. The selection of anesthetic agents and general intraoperative management must be tailored to the specific needs and goals of every patient. Unfortunately, the use of bronchodilating anesthetics improves only the reversible component of airflow obstruction; significant expiratory obstruction may still present, even under deep anesthesia. Expiratory airflow limitation, especially under positive pressure ventilation, may lead to air trapping, dynamic hyperinflation, and elevated intrinsic positive end-expiratory pressure (iPEEP). Dynamic hyperinflation may result in volutrauma to the lungs, hemodynamic instability, hypercapnia, and acidosis. Interventions to mitigate air trapping include: (1) allowing more time to exhale by decreasing both the respiratory rate and I:E ratio; (2) allowing permissive hypercapnia; (3) applying low levels of extrinsic PEEP; and (4) aggressively treating bronchospasm.

Intraoperative causes of hypotension include pneumothorax, and right heart failure due to

hypercapnia and acidosis. A pneumothorax may manifest as hypoxemia, increased peak airway pressures, decreasing tidal volumes, and abrupt cardiovascular collapse unresponsive to fluid and vasopressor administration.

Nitrous oxide should be avoided in patients with bullae and pulmonary hypertension. Inhibition of hypoxic pulmonary vasoconstriction by inhalation anesthetics is usually not clinically significant at the usual doses. However, due to increased dead space, patients with severe COPD have unpredictable uptake and distribution of inhalational agents, and the end-tidal volatile anesthetic concentration is inaccurate.

Measurement of arterial blood gases is desirable for extensive intraabdominal and thoracic procedures. Although pulse oximetry accurately detects significant arterial desaturation, direct measurement of arterial oxygen tensions may be necessary to detect more subtle changes in intrapulmonary shunting. Moreover, arterial CO₂ measurements should be used to guide ventilation because increased dead space widens the normal arterial-to-end-tidal CO₂ gradient. Moderate hypercapnia with a PaCO₂ of up to 70 mm Hg may be well tolerated in the short term, assuming a reasonable cardiovascular reserve. Hemodynamic support with inotropic agents may be required in more compromised patients. Hemodynamic monitoring should be dictated by any underlying cardiac dysfunction, as well as the extent of the surgery. In patients with pulmonary hypertension, measurements of central venous pressure reflect right ventricular function rather than intravascular volume.

At the end of surgery, the timing of extubation should balance the risk of bronchospasm with that of respiratory failure, but evidence suggests that early extubation (in the operating room) is beneficial. Successful extubation at the end of the procedure depends on multiple factors: adequate pain control, reversal of neuromuscular blockade, absence of significant bronchospasm and secretions, absence of significant hypercapnia and acidosis, and absence of respiratory depression due to residual anesthetic agents. Patients with an FEV₁ below 50% may require a period of postoperative ventilation, particularly following upper abdominal and thoracic operations.

Restrictive Pulmonary Disease

8 Restrictive pulmonary diseases are characterized by decreased lung compliance. Lung volumes are typically reduced, with preservation of normal expiratory flow rates. Thus, both FEV₁ and FVC are reduced, but the FEV₁/FVC ratio is normal.

Restrictive pulmonary diseases include many acute and chronic intrinsic pulmonary disorders, as well as extrinsic (extrapulmonary) disorders involving the pleura, chest wall, diaphragm, or neuromuscular function. Reduced lung compliance increases the work of breathing, resulting in a characteristic rapid, but shallow, breathing pattern. Respiratory gas exchange is usually maintained until the disease process is advanced.

ACUTE INTRINSIC PULMONARY DISORDERS

Acute intrinsic pulmonary disorders include pulmonary edema (including the acute respiratory distress syndrome [ARDS]), infectious pneumonia, and aspiration pneumonitis.

Preoperative Considerations

Reduced lung compliance in these disorders is primarily due to an increase in extravascular lung water, from either an increase in pulmonary capillary pressure or pulmonary capillary permeability. Increased pressure occurs with left ventricular failure, whereas fluid overload and increased permeability are present with ARDS. Localized or generalized increases in permeability also occur following aspiration or infectious pneumonitis.

Anesthetic Considerations

A. Preoperative Management

Patients with acute pulmonary disease should be spared elective surgery. In preparation for emergency procedures, oxygenation and ventilation should be optimized preoperatively to the greatest extent possible. Fluid overload should be treated with diuretics; heart failure may also require vasodilators and inotropes. Drainage of large pleural effusions should be considered. Similarly, massive

abdominal distention should be relieved by nasogastric compression or drainage of ascites. Persistent hypoxemia may require mechanical ventilation.

B. Intraoperative Management

Selection of anesthetic agents should be tailored to each patient. Surgical patients with acute pulmonary disorders, such as ARDS, cardiogenic pulmonary edema, or pneumonia, are critically ill; anesthetic management should be a continuation of their preoperative intensive care. Anesthesia is most often provided with a combination of intravenous and inhalation agents, together with a neuromuscular blocking agent. High inspired oxygen concentrations and PEEP may be required. The decreased lung compliance results in high peak inspiratory pressures during positive-pressure ventilation and increases the risk of barotrauma and volutrauma. Tidal volumes for these patients should be reduced to 4–6 mL/kg, with a compensatory increase in the ventilatory rate (14–18 breaths/min), even if the result is an increase in end-tidal CO₂. Airway pressure should generally not exceed 30 cm H₂O. Airway pressure release ventilation may improve oxygenation in the ARDS patient. The ventilator on the anesthesia machine may prove inadequate for patients with severe ARDS because of its limited gas flow capabilities, low pressure-limiting settings, and the absence of certain ventilatory modes. A more sophisticated intensive care unit ventilator should be used in such instances. Aggressive hemodynamic monitoring is recommended.

CHRONIC INTRINSIC PULMONARY DISORDERS

Chronic intrinsic pulmonary disorders are also often referred to as interstitial lung diseases. Regardless of etiology, the disease process is generally characterized by an insidious onset, chronic inflammation of alveolar walls and perialveolar tissue, and progressive pulmonary fibrosis. The latter can eventually interfere with gas exchange and ventilatory function. The inflammatory process may be primarily confined to the lungs or may be part of a generalized multiorgan process. Causes include hypersensitivity pneumonitis from occupational and environmental

pollutants, drug toxicity (bleomycin and nitrofurantoin), radiation pneumonitis, idiopathic pulmonary fibrosis, autoimmune diseases, and sarcoidosis. Chronic pulmonary aspiration, oxygen toxicity, and severe ARDS can also produce chronic fibrosis.

Preoperative Considerations

Patients typically present with dyspnea on exertion and sometimes a nonproductive cough. Symptoms of cor pulmonale are present only with advanced disease. Physical examination may reveal fine (dry) crackles over the lung bases, and, in late stages, evidence of right ventricular failure. The chest radiograph progresses from a “ground-glass” appearance to prominent reticulonodular markings, and, finally, to a “honeycomb” appearance. Arterial blood gases usually show mild hypoxemia with normocarbia. PFTs are typical of a restrictive ventilatory defect (see above), and carbon monoxide diffusing capacity is reduced.

Treatment is directed at abating the disease process and preventing further exposure to the causative agent (if known). Glucocorticoid and immunosuppressive therapy may be used for idiopathic pulmonary fibrosis, autoimmune disorders, and sarcoidosis. If the patient has chronic hypoxemia, oxygen therapy may be started to prevent, or attenuate, right ventricular failure.

Anesthetic Considerations

A. Preoperative Management

Preoperative evaluation should focus on determining the degree of pulmonary impairment as well as the underlying disease process. The latter is important in determining the potential involvement of other organs. A history of dyspnea on exertion (or at rest) should be evaluated further with PFTs and arterial blood gas analysis. A vital capacity of less than 15 mL/kg is indicative of severe dysfunction (normal is >70 mL/kg). A chest radiograph is helpful in assessing disease severity.

B. Intraoperative Management

The management of these patients is complicated by a predisposition to hypoxemia and the need to control ventilation to ensure optimum gas exchange;

anesthetic drug selection is generally not critical. The reduction in FRC (and oxygen stores) predisposes these patients to rapid hypoxemia following induction of anesthesia. Because these patients may be more susceptible to oxygen-induced toxicity, particularly patients who have received bleomycin, the inspired fractional concentration of oxygen should be kept to the minimum concentration compatible with acceptable oxygenation (SpO_2 of >88% to 92%). High peak inspiratory pressures during mechanical ventilation increase the risk of pneumothorax and should prompt adjustment of the ventilatory parameters. In patients with severe restrictive disease, using an I:E ratio of 1:1 (or even an inverse ratio ventilation) and dividing the minute ventilation to a higher respiratory rate (10–15 breaths/minute) may help to maximize the inspiratory time per tidal volume and minimize the peak and plateau ventilatory pressures.

EXTRINSIC RESTRICTIVE PULMONARY DISORDERS

Extrinsic restrictive pulmonary disorders alter gas exchange by interfering with normal lung expansion. They include pleural effusions, pneumothorax, mediastinal masses, kyphoscoliosis, pectus excavatum, neuromuscular disorders, and increased intraabdominal pressure from ascites, pregnancy, or bleeding. Marked obesity also produces a restrictive ventilatory defect. Anesthetic considerations are similar to those discussed for intrinsic restrictive disorders.

Pulmonary Embolism

Preoperative Considerations

Pulmonary embolism results from the entry of blood clots, fat, tumor cells, air, amniotic fluid, or foreign material into the venous system. Clots from the lower extremities, pelvic veins, or, less commonly, the right side of the heart are usually responsible. Venous stasis or hypercoagulability is often contributory in such cases ([Table 24–5](#)). Pulmonary embolism can also occur intraoperatively in normal individuals undergoing certain procedures.

TABLE 24-5 Factors associated with deep venous thrombosis and pulmonary embolism.

Prolonged bed rest
Postpartum state
Fracture of the lower extremities
Surgery on the lower extremities
Carcinoma
Heart failure
Obesity
Surgery lasting more than 30 min
Hypercoagulability
Antithrombin III deficiency
Protein C deficiency
Protein S deficiency
Plasminogen-activator deficiency

A. Pathophysiology

Embolus occlusions in the pulmonary circulation increase dead space, and, if minute ventilation does not change, this increase in dead space should theoretically increase P_{aCO_2} . However, in practice, hypoxemia is more often seen. Pulmonary emboli acutely increase pulmonary vascular resistance by reducing the cross-sectional area of the pulmonary vasculature, causing reflex and humoral vasoconstriction. Localized or generalized reflex bronchoconstriction further increases areas with low (\dot{V}/\dot{Q}) ratios. The net effect is an increase in \dot{V}/\dot{Q} mismatch and hypoxemia. The affected area loses its surfactant within hours and may become atelectatic within 24–48 hr. Pulmonary infarction occurs if the embolus involves a large vessel and collateral blood flow from the bronchial circulation is insufficient for that part of the lung (incidence <10%). In previously healthy persons, occlusion of more than 50% of the pulmonary circulation (massive pulmonary embolism) is necessary before sustained pulmonary hypertension is seen. Patients with preexisting cardiac or pulmonary disease can develop acute pulmonary hypertension with occlusions of lesser magnitude. A sustained increase in right ventricular afterload can precipitate acute right ventricular failure. If the patient survives acute pulmonary thromboembolism, the thrombus usually begins to resolve within 1–2 weeks.

B. Diagnosis

Clinical manifestations of pulmonary embolism include sudden tachypnea, dyspnea, chest pain,

or hemoptysis. The latter generally implies lung infarction. Symptoms are often absent or mild and nonspecific unless massive embolism has occurred. Wheezing may be present on auscultation. Arterial blood gas analysis typically shows mild hypoxemia with respiratory alkalosis (the latter due to an increase in ventilation). The chest radiograph is commonly normal, but may show an area of oligemia (radiolucency), a wedge-shaped density with an infarct, atelectasis with an elevated diaphragm, or an asymmetrically enlarged proximal pulmonary artery with acute pulmonary hypertension. Cardiac signs include tachycardia and wide fixed splitting of the S_2 heart sound; hypotension with elevated central venous pressure is usually indicative of right ventricular failure. The electrocardiogram frequently shows tachycardia and may show signs of acute cor pulmonale, such as new right axis deviation, right bundle branch block, and tall peaked T waves. Ultrasound studies of the lower extremities also may be helpful in demonstrating deep venous thrombosis. The diagnosis of embolism is more difficult to make intraoperatively (see below).

Pulmonary angiography is still the gold standard criterion for diagnosing a pulmonary embolism, but it is invasive and difficult to perform. Therefore, the less invasive spiral computed tomography angiography (CTA) is the initial imaging of choice in stable patients with suspected pulmonary embolism. Ventilation-perfusion (\dot{V}/\dot{Q}) scanning may also be used when CTA cannot be performed. High-, intermediate-, and low-probability criteria have been established for the diagnosis of pulmonary embolism by \dot{V}/\dot{Q} scan.

C. Treatment and Prevention

The best treatment for pulmonary embolism is prevention. Heparin (unfractionated heparin 5000 U subcutaneously every 12 h begun preoperatively or immediately postoperatively in high-risk patients), enoxaparin or other related compounds, oral anticoagulation (warfarin), aspirin, or dextran therapy, together with early ambulation, can all be used to reduce the incidence of deep vein thrombosis. The use of high elastic stockings and pneumatic compression of the legs may also decrease the incidence

of venous thrombosis in the legs, but not in the pelvis or the heart.

After a pulmonary embolism, systemic anticoagulation prevents the formation of new blood clots or the extension of existing clots. Heparin therapy is begun with the goal of achieving an activated partial thromboplastin time of 1.5–2.4 times normal. Low molecular-weight heparin (LMWH) is as effective and is given subcutaneously at a fixed dose (based on body weight) without laboratory monitoring. In high-risk patients, LMWH is started either 12 hr before surgery, 12–24 hr after surgery, or at 50% the usual dose 4–6 hr after surgery. All patients should start warfarin therapy concurrent with starting heparin therapy, and the two should overlap for 4–5 days. The international normalized ratio should be within the therapeutic range on two consecutive measurements, at least 24 hr apart, before the heparin is stopped. Warfarin should be continued for 3–12 months. Thrombolytic therapy with tissue plasminogen activator or streptokinase is indicated in patients with massive pulmonary embolism or circulatory collapse. Recent surgery and active bleeding are contraindications to anticoagulation and thrombolytic therapy. In these cases, an inferior vena cava umbrella filter may be placed to prevent recurrent pulmonary emboli. Pulmonary embolectomy may be indicated for patients with massive embolism in whom thrombolytic therapy is contraindicated.

Anesthetic Considerations

A. Preoperative Management

Patients with acute pulmonary embolism may present in the operating room for placement of an IVC filter, or, rarely, for pulmonary embolectomy. In most instances, the patient will have a history of pulmonary embolism and presents for unrelated surgery; in this group of patients, the risk of interrupting anticoagulant therapy perioperatively is unknown. If the acute episode is more than 1 year old, the risk of temporarily stopping anticoagulant therapy is probably small. Moreover, except in the case of chronic recurrent pulmonary emboli, pulmonary function has usually returned to normal. The emphasis in the perioperative management of

these patients should be in preventing new episodes of embolism (see above).

B. Intraoperative Management

Vena cava filters are usually placed percutaneously under local anesthesia with sedation.

Patients presenting for pulmonary embolectomy are critically ill. They are usually already intubated, but tolerate positive-pressure ventilation poorly. Inotropic support is necessary until the clot is removed. They also tolerate all anesthetic agents very poorly. Small doses of an opioid, etomidate, or ketamine may be used, but the latter can theoretically increase pulmonary artery pressures. Cardiopulmonary bypass is required.

C. Intraoperative Pulmonary Embolism

Significant pulmonary embolism is a rare occurrence during anesthesia. Diagnosis requires a high index of suspicion. Air emboli are common, but are often overlooked unless large amounts are entrained. Fat embolism can occur during orthopedic procedures; amniotic fluid embolism is a rare, unpredictable, and often fatal, complication of obstetrical delivery. Thromboembolism may occur intraoperatively during prolonged procedures. The clot may have been present prior to surgery or may form intraoperatively; surgical manipulations or a change in the patient's position may then dislodge the venous thrombus. Manipulation of tumors with intravascular extension can similarly produce pulmonary embolism.

9 Intraoperative pulmonary embolism usually presents as sudden cardiovascular collapse, hypoxemia, or bronchospasm. A decrease in end-tidal CO₂ concentration is also suggestive of pulmonary embolism, but is not specific. Invasive monitoring may reveal elevated central venous and pulmonary arterial pressures. Depending on the type and location of an embolism, a transesophageal echocardiogram may be helpful. TEE may not reveal the embolus but will often demonstrate right heart distention and dysfunction. **If air is identified in the right atrium, or if it is suspected, emergent central vein cannulation and aspiration of the air may be lifesaving.** For all other emboli, treatment is supportive, with intravenous fluids and inotropes. Placement of a vena cava filter should be considered postoperatively.

CASE DISCUSSION

Laparoscopic Surgery

A 45-year-old woman is scheduled for a laparoscopic cholecystectomy. Known medical problems include obesity and a history of smoking.

What are the advantages of laparoscopic cholecystectomy compared with open cholecystectomy?

Laparoscopic techniques have rapidly increased in popularity because of the multiple benefits associated with much smaller incisions than with traditional open techniques. These benefits include decreased postoperative pain, less postoperative pulmonary impairment, a reduction in postoperative ileus, shorter hospital stays, earlier ambulation, and smaller surgical scars. Thus, laparoscopic surgery can provide substantial medical and economic advantages.

How does laparoscopic surgery affect intraoperative pulmonary function?

The hallmark of laparoscopy is the creation of a pneumoperitoneum with pressurized CO₂. The resulting increase in intraabdominal pressure displaces the diaphragm cephalad, causing a decrease in lung compliance and an increase in peak inspiratory pressure. **Atelectasis, diminished FRC, ventilation/perfusion mismatch, and pulmonary shunting contribute to a decrease in arterial oxygenation.** These changes should be exaggerated in this obese patient with a long history of tobacco use.

The high solubility of CO₂ increases systemic absorption by the vasculature of the peritoneum. This, combined with smaller tidal volumes because of poor lung compliance, leads to increased arterial CO₂ levels and decreased pH.

Why does patient position affect oxygenation?

A head-down (Trendelenburg) position is commonly requested during insertion of the Veress needle and cannula. This position causes a cephalad shift in abdominal viscera and the diaphragm. FRC, total lung volume, and pulmonary compliance

will be decreased. Although these changes are usually well tolerated by healthy patients, this patient's obesity and presumed preexisting lung disease increase the likelihood for hypoxemia. A head-down position also tends to shift the trachea upward, so that a tracheal tube anchored at the mouth may migrate into the right mainstem bronchus. This tracheobronchial shift may be exacerbated during insufflation of the abdomen.

After insufflation, the patient's position is usually changed to a steep head-up position (reverse Trendelenburg) to facilitate surgical dissection. The respiratory effects of the head-up position are the opposite of the head-down position.

Does laparoscopic surgery affect cardiac function?

Moderate insufflation pressures usually leave heart rate, central venous pressure, and cardiac output unchanged or slightly elevated. This seems to result from increased effective cardiac filling because blood tends to be forced out of the abdomen and into the chest. **Higher insufflation pressures (>25 cm H₂O or 18 mm Hg), however, tend to collapse the major abdominal veins (particularly the inferior vena cava), which decreases venous return and leads to a drop in preload and cardiac output in some patients.**

Hypercarbia, if allowed to develop, will stimulate the sympathetic nervous system and thus increase blood pressure, heart rate, and the risk of arrhythmias. Attempting to compensate by increasing the tidal volume or respiratory rate will increase the mean intrathoracic pressure, further hindering venous return and increasing mean pulmonary artery pressures. These effects can prove particularly challenging in patients with restrictive lung disease, impaired cardiac function, or intravascular volume depletion.

Although the Trendelenburg position increases preload, mean arterial pressure and cardiac output usually either remain unchanged or decrease. These seemingly paradoxical responses may be explained by carotid and aortic baroreceptor-mediated reflexes. The reverse Trendelenburg position decreases preload, cardiac output, and mean arterial pressure.

Describe the advantages and disadvantages of alternative anesthetic techniques for this patient.

Anesthetic approaches to laparoscopic surgery include infiltration of local anesthetic with an intravenous sedative, epidural or spinal anesthesia, or general anesthesia. Experience with local anesthesia has been largely limited to brief gynecologic procedures (laparoscopic tubal sterilization, intrafallopian transfers) in young, healthy, and motivated patients. Although postoperative recovery is rapid, patient discomfort and suboptimal visualization of intraabdominal organs preclude the use of this local anesthesia technique for laparoscopic cholecystectomy.

Epidural or spinal anesthesia represents another alternative for laparoscopic surgery. A high level is required for complete muscle relaxation and to prevent diaphragmatic irritation caused by gas insufflation and surgical manipulations. An obese patient with lung disease may not be able to increase spontaneous ventilation to maintain normocarbina in the face of a T2 level regional block during insufflation and a 20° Trendelenburg position. Another disadvantage of a regional technique is the occasional occurrence of referred shoulder pain from diaphragmatic irritation. General anesthesia would therefore be the preferred technique in this patient.

Does a general anesthetic technique require tracheal intubation?

Tracheal intubation with positive-pressure ventilation is usually favored for many reasons: the risk of regurgitation from increased intraabdominal pressure during insufflation; the necessity for controlled ventilation to prevent hypercapnia; the relatively high peak inspiratory pressures required because of the pneumoperitoneum; the need for neuromuscular blockade during surgery to allow lower insufflation pressures, provide better visualization, and prevent unexpected patient movement; and the placement of a nasogastric tube and gastric decompression to minimize the risk of visceral perforation during trocar introduction and optimize visualization. The obese patient presented here would benefit from intubation to

decrease the likelihood of hypoxemia, hypercarbia, and aspiration.

What special monitoring should be considered for this patient?

Monitoring end-tidal CO₂ normally provides an adequate guide for determining the minute ventilation required to maintain normocarbina. This assumes a constant gradient between arterial CO₂ and end-tidal CO₂, which is generally valid in healthy patients undergoing laparoscopy. This assumption would not apply if alveolar dead space changes during surgery. For example, any significant reduction in lung perfusion increases alveolar dead space and therefore increases the gradient between arterial and end-tidal CO₂. This may occur during laparoscopy if cardiac output drops because of high inflation pressures, the reverse Trendelenburg position, or gas embolism. Furthermore, abdominal distention lowers pulmonary compliance. Large tidal volumes are usually avoided because they are associated with high peak inspiratory pressures and can cause considerable movement of the surgical field. The resulting choice of lower tidal volumes and higher respiratory rates may lead to poor alveolar gas sampling and erroneous end-tidal CO₂ measurements. In fact, end-tidal CO₂ values have been found to be particularly unreliable in patients with significant cardiac or pulmonary disease undergoing laparoscopy. Thus, placement of an arterial catheter should be considered in patients with cardiopulmonary disease.

What are some possible complications of laparoscopic surgery?

Surgical complications include hemorrhage, if a major abdominal vessel is lacerated, or peritonitis, if a viscus is perforated during trocar introduction. Significant intraoperative hemorrhage may go unrecognized because of the limitations of laparoscopic visualization. Fulguration has been associated with bowel burns and bowel gas explosions. The use of pressurized gas introduces the possibility of extravasation of CO₂ along tissue planes, resulting in subcutaneous emphysema,

pneumomediastinum, or pneumothorax. Nitrous oxide should be discontinued and insufflating pressures decreased as much as possible. Patients with this complication may benefit from the continuation of mechanical ventilation into the immediate postoperative period.

Venous CO₂ embolism resulting from unintentional insufflation of gas into an open vein may lead to hypoxemia, pulmonary hypertension, pulmonary edema, and cardiovascular collapse. Unlike air embolism, end-tidal CO₂ may transiently increase during CO₂ gas embolism. Treatment includes immediate release of the pneumoperitoneum, discontinuation of nitrous oxide, insertion of a central venous catheter for gas aspiration, and placement of the patient in a head-down left lateral decubitus position.

Vagal stimulation during trocar insertion, peritoneal insufflation, or manipulation of viscera can result in bradycardia and even sinus arrest. Although this usually resolves spontaneously, elimination of the stimulus (eg, deflation of the peritoneum) and administration of a vagolytic drug (eg, atropine sulfate) should be considered. Intraoperative hypotension may be more common during laparoscopic cholecystectomy than during cholecystectomy by laparotomy. Preoperative fluid loading has been recommended to avoid this complication.

Even though laparoscopic procedures are associated with less muscle trauma and incisional pain than open surgery, pulmonary dysfunction can persist for at least 24 hr postoperatively. For example, forced expiratory volume, forced vital

capacity, and forced expiratory flow are reduced by approximately 25% following laparoscopic cholecystectomy, compared with a 50% reduction following open cholecystectomy. The cause of this dysfunction may be related to diaphragmatic tension during the pneumoperitoneum.

Nausea and vomiting are common following laparoscopic procedures, despite routine emptying of the stomach with a nasogastric tube. Pharmacological prophylaxis is recommended.

Anesthesia for Thoracic Surgery

KEY CONCEPTS

- 1 During one-lung ventilation, the mixing of unoxygenated blood from the collapsed upper lung with oxygenated blood from the still-ventilated dependent lung widens the alveolar-to-arterial (A-a) O_2 gradient and often results in hypoxemia.
- 2 There are certain clinical situations in which the use of a right-sided double-lumen tube is recommended: (1) distorted anatomy of the left main bronchus by an intrabronchial or extrabronchial mass; (2) compression of the left main bronchus due to a descending thoracic aortic aneurysm; (3) left-sided pneumonectomy; (4) left-sided single lung transplantation; and (5) left-sided sleeve resection.
- 3 If epidural opioids are to be used postoperatively, their intravenous use should be limited during surgery to prevent excessive postoperative respiratory depression.
- 4 Postoperative hemorrhage complicates about 3% of thoracotomies and may be associated with up to 20% mortality. Signs of hemorrhage include increased chest tube drainage (>200 mL/h), hypotension, tachycardia, and a falling hematocrit.
- 5 Bronchopleural fistula presents as a sudden large air leak from the chest tube that may be associated with an increasing pneumothorax and partial lung collapse.
- 6 Acute herniation of the heart into the operative hemithorax can occur through the pericardial defect that is left following a radical pneumonectomy.
- 7 Nitrous oxide is contraindicated in patients with cysts or bullae because it can expand the air space and cause rupture. The latter may be signaled by sudden hypotension, bronchospasm, or an abrupt rise in peak inflation pressure and requires immediate placement of a chest tube.
- 8 Following transplantation, peak inspiratory pressures should be maintained at the minimum pressure compatible with good lung expansion, and the inspired oxygen concentration should be maintained as close to room air as allowed by a $Pao_2 >60$ mm Hg.
- 9 Regardless of the procedure, a common anesthetic concern for patients with esophageal disease is the risk of pulmonary aspiration.

Indications and techniques for thoracic surgery continually evolve. Common indications now include thoracic malignancies (mainly of the lungs and esophagus), chest trauma, esophageal disease, and mediastinal tumors. Diagnostic procedures such as

bronchoscopy, mediastinoscopy, and open-lung biopsies are also common. Anesthetic techniques for providing lung separation have allowed the refinement of surgical techniques to the point that many procedures are increasingly performed thoracoscopically.

Physiological Considerations During Thoracic Anesthesia

Thoracic surgery presents a unique set of physiological problems for the anesthesiologist. These include physiological derangements caused by placing the patient in the lateral decubitus position, opening the chest (**open pneumothorax**), and the need for one-lung ventilation.

THE LATERAL DECUBITUS POSITION

The lateral decubitus position provides optimal access for most operations on the lungs, pleura, esophagus, the great vessels, other mediastinal structures, and vertebrae. Unfortunately, this position may significantly alter the normal pulmonary ventilation/perfusion relationships. These derangements are further accentuated by induction of anesthesia, initiation of mechanical ventilation, neuromuscular blockade, opening the chest, and surgical

retraction. Although perfusion continues to favor the dependent (lower) lung, ventilation progressively favors the less perfused upper lung. The resulting mismatch increases the risk of hypoxemia.

The Awake State

When a supine patient assumes the lateral decubitus position, ventilation/perfusion matching is preserved during spontaneous ventilation. The dependent (lower) lung receives more perfusion than does the upper lung due to gravitational influences on blood flow distribution in the pulmonary circulation. The dependent lung also receives more ventilation because: (1) contraction of the dependent hemidiaphragm is more efficient compared with the nondependent [upper] hemidiaphragm and (2) the dependent lung is on a more favorable part of the compliance curve (**Figure 25-1**).

Induction of Anesthesia

The decrease in functional residual capacity (FRC) with induction of general anesthesia moves the upper lung to a more favorable part of the compliance

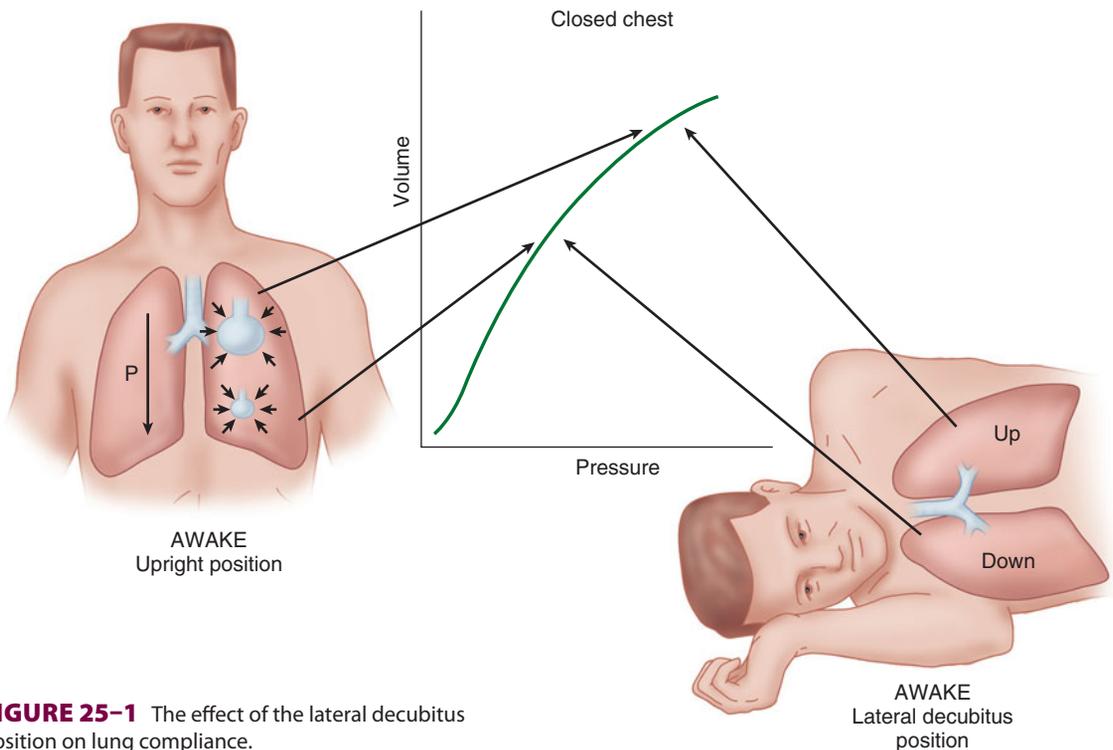

FIGURE 25-1 The effect of the lateral decubitus position on lung compliance.

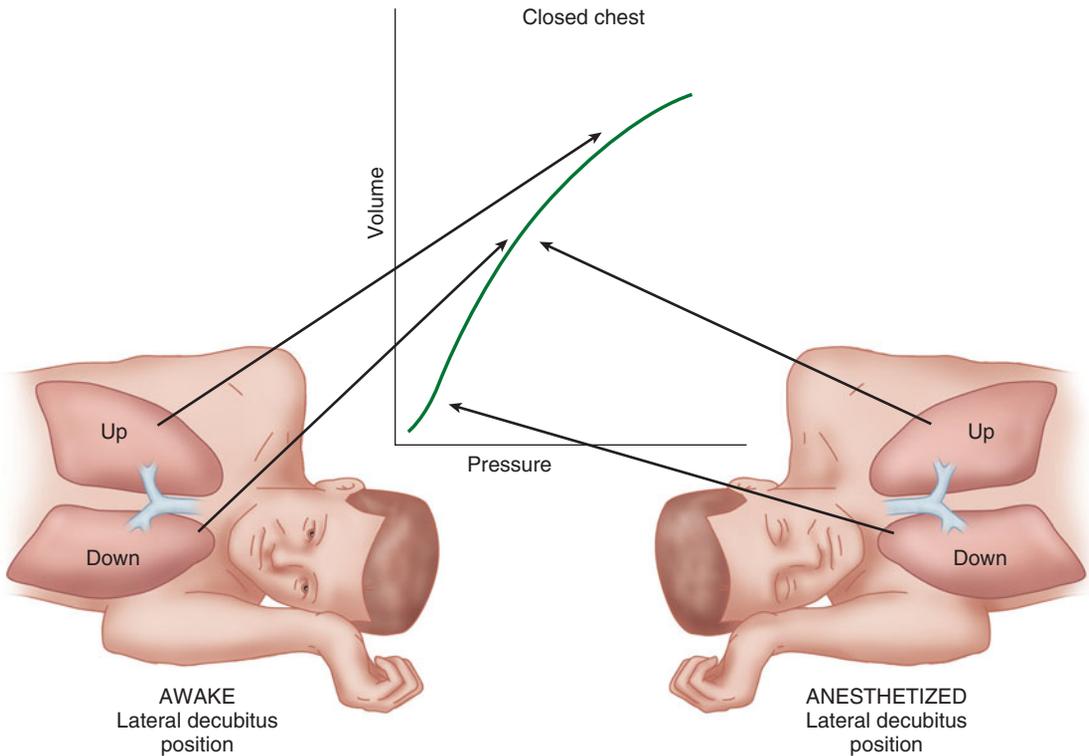

FIGURE 25-2 The effect of anesthesia on lung compliance in the lateral decubitus position. The upper lung assumes a more favorable position, and the lower lung becomes less compliant.

curve, but moves the lower lung to a less favorable position (Figure 25-2). As a result, the upper lung is ventilated more than the dependent lower lung; ventilation/perfusion mismatching occurs because the dependent lung continues to have greater perfusion.

Positive-Pressure Ventilation

Controlled positive-pressure ventilation favors the upper lung in the lateral position because it is more compliant than the lower lung. Neuromuscular blockade enhances this effect by allowing the abdominal contents to rise up further against the dependent hemidiaphragm and impede ventilation of the lower lung. Using a rigid “bean bag” to maintain the patient in the lateral decubitus position further restricts movement of the dependent hemithorax. Finally, opening the nondependent side of the chest further accentuates differences in compliance between the two sides because the upper lung is now less restricted in movement. All of these effects

worsen ventilation/perfusion mismatching and predispose the patient to hypoxemia.

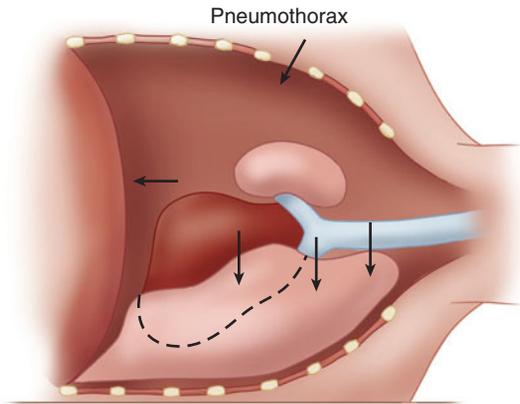

THE OPEN PNEUMOTHORAX

The lungs are normally kept expanded by a negative pleural pressure—the net result of the tendency of the lung to collapse and the chest wall to expand. When one side of the chest is opened, the negative pleural pressure is lost, and the elastic recoil of the lung on that side tends to collapse it. Spontaneous ventilation with an open pneumothorax in the lateral position results in paradoxical respirations and mediastinal shift. These two phenomena can cause progressive hypoxemia and hypercapnia, but, fortunately, their effects are overcome by the use of positive-pressure ventilation during general anesthesia and thoracotomy.

Mediastinal Shift

During spontaneous ventilation in the lateral position, inspiration causes pleural pressure to become

INSPIRATION

EXPIRATION

more negative on the dependent side, but not on the side of the open pneumothorax. This results in a downward shift of the mediastinum during inspiration and an upward shift during expiration (Figure 25-3). The major effect of the mediastinal shift is to decrease the contribution of the dependent lung to the tidal volume.

Paradoxical Respiration

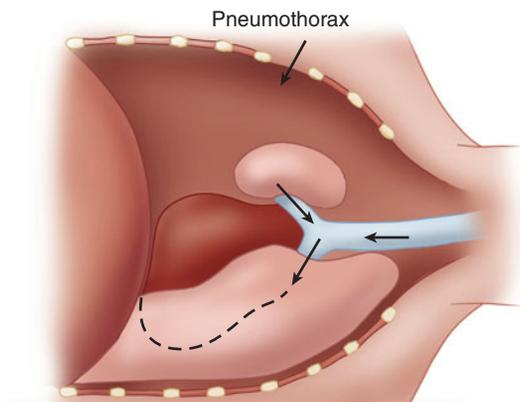

Spontaneous ventilation in a patient with an open pneumothorax also results in to-and-fro gas flow between the dependent and nondependent lung

(paradoxical respiration [pendeluft]). During inspiration, the pneumothorax increases, and gas flows from the upper lung across the carina to the dependent lung. During expiration, the gas flow reverses and moves from the dependent to the upper lung (Figure 25-4).

ONE-LUNG VENTILATION

Intentional collapse of the lung on the operative side facilitates most thoracic procedures, but greatly complicates anesthetic management. Because the

INSPIRATION

EXPIRATION

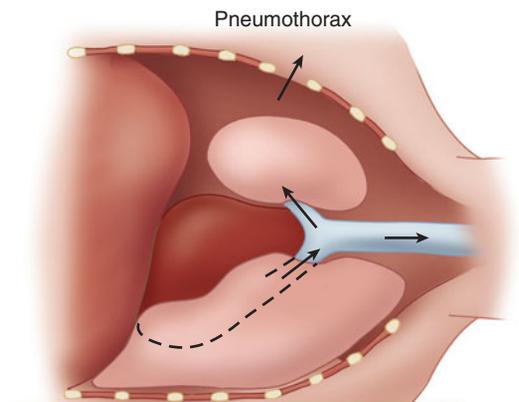

FIGURE 25-4 Paradoxical respiration in spontaneously breathing patients on their side. (Reproduced, with permission, from Tarhan S, Moffitt EA: Principles of thoracic anesthesia. Surg Clin North Am 1973;53:813.)

collapsed lung continues to be perfused and is deliberately no longer ventilated, the patient develops a large right-to-left intrapulmonary shunt (20% to 30%). During one-lung ventilation, the mixing of unoxygenated blood from the collapsed upper lung with oxygenated blood from the still-ventilated dependent lung widens the alveolar-to-arterial (A-a) O_2 gradient and often results in hypoxemia. Fortunately, blood flow to the nonventilated lung is decreased by hypoxic pulmonary vasoconstriction (HPV) and possibly surgical compression of the upper lung.

Factors known to inhibit HPV (increasing venous admixture), and thus worsen the right-to-left shunting, include (1) very high or very low pulmonary artery pressures; (2) hypocapnia; (3) high or very low mixed venous PO_2 ; (4) vasodilators such as nitroglycerin, nitroprusside, phosphodiesterase inhibitors (milrinone and inamrinone), β -adrenergic agonists, calcium channel blockers; (5) pulmonary infection; and (6) inhalation anesthetics.

Factors that decrease blood flow to the ventilated lung can be equally detrimental; they counteract the effect of HPV by indirectly increasing blood flow to the collapsed lung. Such factors include (1) high mean airway pressures in the ventilated lung due to high positive end-expiratory pressure (PEEP), hyperventilation, or high peak inspiratory pressures; (2) a low FIO_2 , which produces hypoxic pulmonary vasoconstriction in the ventilated lung; (3) vasoconstrictors that may have a greater effect on normoxic vessels than hypoxic ones; and (4) intrinsic PEEP that develops due to inadequate expiratory times.

Elimination of CO_2 is usually unchanged by one-lung ventilation, provided that minute ventilation is unchanged and that preexisting CO_2 retention was not present while ventilating both lungs; arterial CO_2 tension is usually not appreciably altered.

Techniques for One-Lung Ventilation

One-lung ventilation can also be utilized to isolate a lung or to facilitate ventilatory management under certain conditions (Table 25-1). Three techniques can be employed: (1) placement of a double-lumen

bronchial tube; (2) use of a single-lumen tracheal tube in conjunction with a bronchial blocker; or (3) insertion of a conventional endotracheal tube into a mainstem bronchus. Double-lumen tubes are most often used.

DOUBLE-LUMEN BRONCHIAL TUBES

The principal advantages of double-lumen tubes are relative ease of placement, the ability to ventilate one or both lungs, and the ability to suction either lung.

All double-lumen tubes share the following characteristics:

- A longer bronchial lumen that enters either the right or left main bronchus and another shorter tracheal lumen that terminates in the lower trachea
- A preformed curve that when properly “aimed” allows preferential entry into a bronchus
- A bronchial cuff
- A tracheal cuff

Ventilation can be delivered to only one lung by clamping either the bronchial or tracheal lumen with both cuffs inflated; opening the port on the

appropriate connector allows the ipsilateral lung to collapse. Because of differences in bronchial anatomy between the two sides, tubes are designed specifically for either the right or left bronchus. A right-sided double-lumen tube incorporates a modified cuff and a proximal portal on the endobronchial side for ventilation of the right upper lobe. The most commonly used double-lumen tube are available in several sizes: 35, 37, 39, and 41F.

Anatomic Considerations

On average, the adult trachea is 11–13 cm long. It begins at the level of the cricoid cartilage (C6) and bifurcates at the level of the carina behind the sternomanubrial joint (T5). Major differences between the right and left main bronchi are as follows: (1) the larger diameter right bronchus diverges away from the trachea at a less acute angle in relation to the trachea, whereas the left bronchus diverges at a more horizontal angle (Figure 25-5); (2) the

right bronchus has upper, middle, and lower lobe branches, whereas the left bronchus divides into only upper and lower lobe branches; and (3) the orifice of the right upper lobe bronchus is typically about 1–2.5 cm from the carina, whereas the bifurcation of the left main bronchus is typically about 5 cm distal to the carina. There is considerable anatomic variation: for example, the right upper lobe bronchus will occasionally arise from the trachea itself.

As previously noted, right-sided double-lumen tubes must have a portal through the bronchial cuff for ventilating the right upper lobe (Figure 25-6). Anatomic variations among individuals in the distance between the carina and the right upper lobe orifice will occasionally result in difficulty ventilating that lobe with right-sided tubes. A left-sided double-lumen tube can be used in most surgical procedures, **2** irrespective of the operative side. There are certain clinical situations in which the use of a right-sided double-lumen tube is recommended:

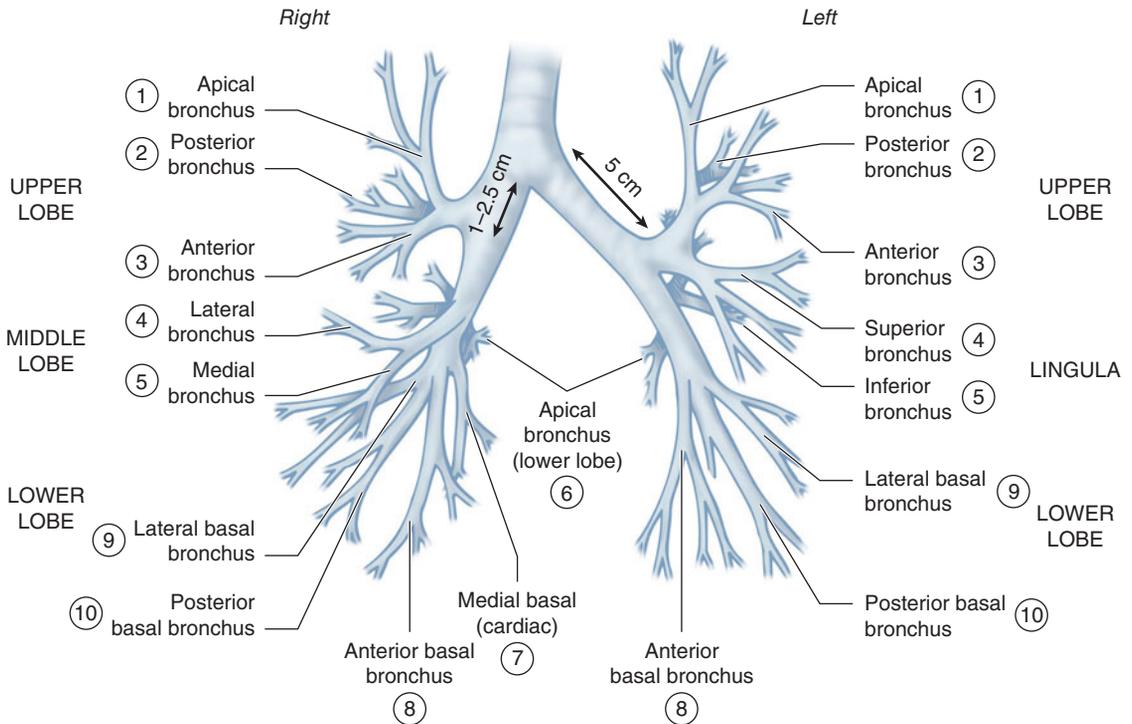

FIGURE 25-5 Anatomy of the tracheobronchial tree. Note bronchopulmonary segments (1–10) as numbered. (Adapted and reproduced, with permission, from Gothard JWW, Branthwaite MA: *Anesthesia for Thoracic Surgery*. Blackwell, 1982.)

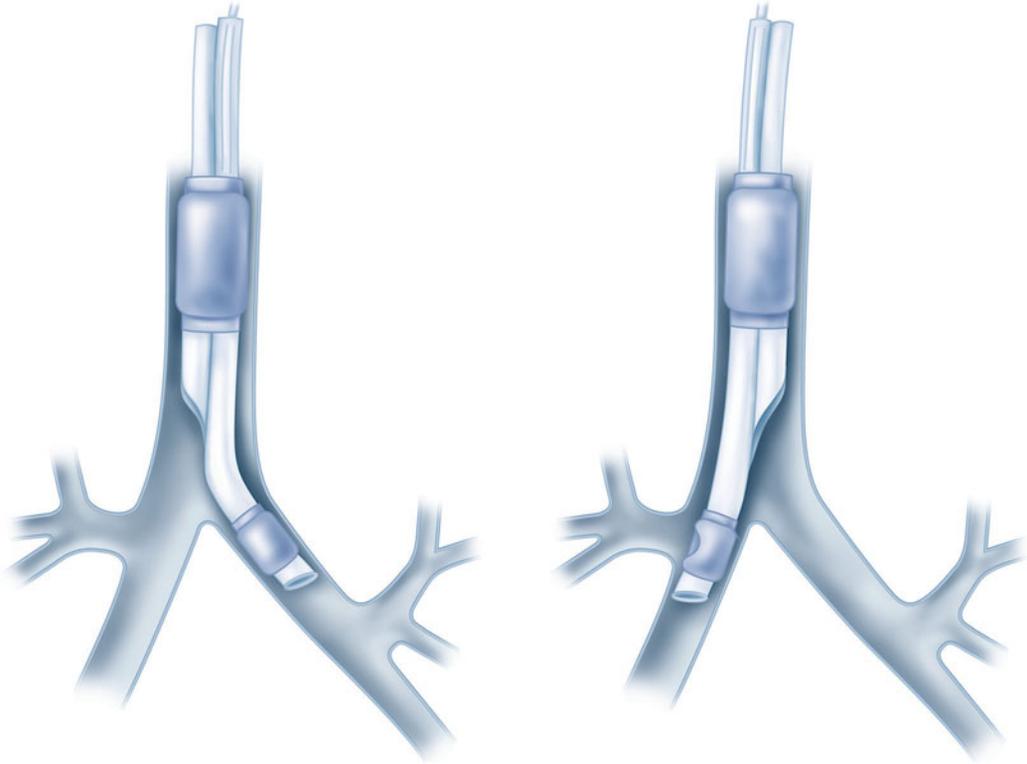

FIGURE 25-6 Correct position of a left- and right-sided double-lumen tube.

(1) distorted anatomy of the left main bronchus by an intrabronchial or extrabronchial mass; (2) compression of the left main bronchus due to a descending thoracic aortic aneurysm; (3) left-sided pneumonectomy; (4) left-sided single lung transplantation; and (5) left-sided sleeve resection. Finally, despite concerns about right upper lobe atelectasis and potentially difficult placement, studies have failed to detect differences in clinical performance of right- and left-sided double-lumen tubes when used clinically.

Placement of Double-Lumen Tubes

Laryngoscopy with a curved (MacIntosh) blade usually provides better intubating conditions than does a straight blade because the curved blade typically provides more room for manipulation of the large double-lumen tube. Video laryngoscopy can also be employed to facilitate tube placement. The double-lumen tube is passed with the distal curvature concave anteriorly

and is rotated 90° (toward the side of the bronchus to be intubated) after the tip passes the vocal cords and enters the larynx (Figure 25-7). At this point, the operator has two options: the tube can be advanced until resistance is felt (the average depth of insertion is about 29 cm [at the teeth]), or alternatively, the fiberoptic bronchoscope can be inserted through the bronchial limb and advanced into the desired bronchus. The double-lumen tube can be advanced over the bronchoscope into the desired bronchus. Correct tube placement should be established using a preset protocol (Figure 25-8 and Table 25-2) and confirmed by flexible fiberoptic bronchoscopy. When problems are encountered in intubating the patient with the double-lumen tube, placement of a single-lumen endotracheal tube should be attempted; once positioned in the trachea, the latter can be exchanged for the double-lumen tube by using a specially designed catheter guide (“tube exchanger”).

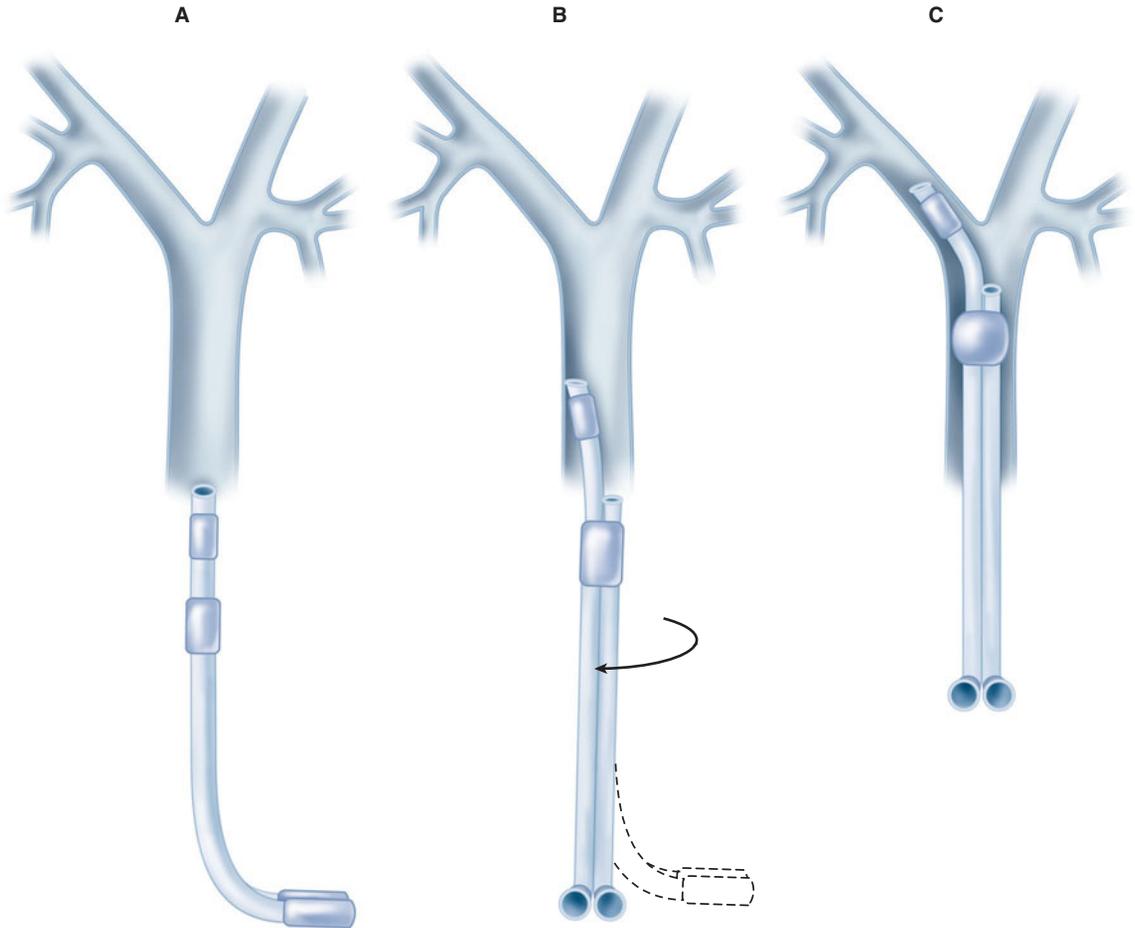

FIGURE 25-7 Placement of a left-sided double-lumen tube. Note that the tube is turned 90° as soon as it enters the larynx. **A:** Initial position. **B:** Rotated 90° . **C:** Final position.

Most double-lumen tubes easily accommodate bronchoscopes with a 3.6- to 4.2-mm outer diameter. When the bronchoscope is introduced into the tracheal lumen and advanced through the tracheal orifice, the carina should be visible (Figure 25-9), and the bronchial limb of the tube should be seen entering the respective bronchus; additionally, the top of the bronchial cuff (usually colored blue) should be visible, but should not extend above the carina. If the bronchial cuff of a left-sided double-lumen tube is not visible, the bronchial limb may have been inserted sufficiently far to allow the bronchial cuff to obstruct the orifice of the left upper or lower lobe; the tube should be withdrawn until the

cuff can be identified distal to the carina. The optimal position of a right-sided double-lumen tube is confirmed by placing the fiberoptic scope through the endobronchial lumen, which should show alignment of the endobronchial side portal with the opening of the right upper lobe bronchus. The bronchial cuff should be inflated only to the point at which the audible leak from the open tracheal lumen disappears while ventilating only through the bronchial lumen. Tube position should be reconfirmed after the patient is positioned for surgery because the tube may move relative to the carina as the patient is turned into the lateral decubitus position. Malpositioning of a double-lumen tube is usually

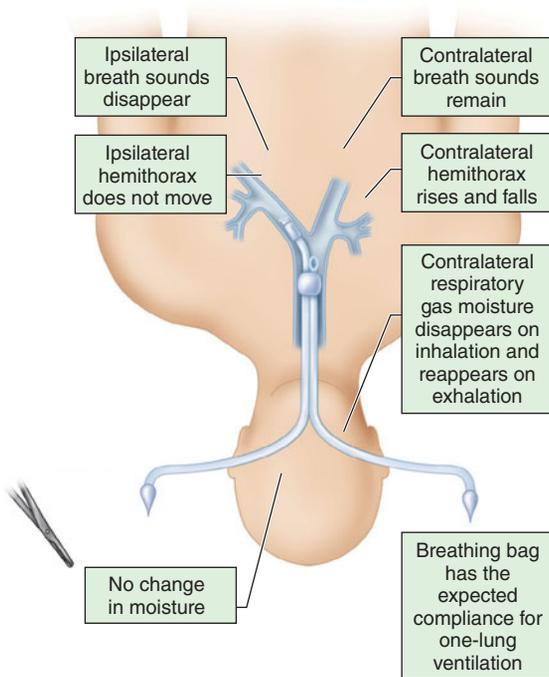

FIGURE 25-8 Results of unilateral clamping of the bronchial lumen tube when the double-lumen tube is in the correct position.

indicated by failure of the operative lung to collapse, poor lung compliance, and low exhaled tidal volume. Problems with left-sided double-lumen tubes are usually related to one of three possibilities: (1) the tube tip is too distal; (2) the tube tip is too proximal; or (3) the tube is in the right bronchus (the wrong side). If the tube tip is located too distally, the bronchial cuff can obstruct the left upper or the left lower lobe orifice, and the bronchial lumen can be inserted into the orifice of the left lower or left upper lobe bronchus, respectively. When the tube is not advanced distally enough, the inflated bronchial cuff may be above the carina and also occlude the tracheal lumen. In both instances, deflation of the bronchial cuff improves ventilation to the lung and helps to identify the problem. In some patients, the bronchial lumen may be within the left upper or left lower lobe bronchus but with the tracheal opening remaining above the carina; this situation is suggested by collapse of only one of the left lobes

TABLE 25-2 Protocol for checking placement of a left-sided double-lumen tube.

1. Inflate the tracheal cuff (5–10 mL of air).
2. Check for bilateral breath sounds. Unilateral breath sounds indicate that the tube is too far down (tracheal opening is bronchial).
3. Inflate the bronchial cuff (1–2 mL).
4. Clamp the tracheal lumen.
5. Check for unilateral left-sided breath sounds.
 - a. Persistence of right-sided breath sounds indicates that the bronchial opening is still in the trachea (tube should be advanced).
 - b. Unilateral right-sided breath sounds indicate incorrect entry of the tube in the right bronchus.
 - c. Absence of breath sounds over the entire right lung and the left upper lobe indicates that the tube is too far down the left bronchus.
6. Unclamp the tracheal lumen and clamp the bronchial lumen.
7. Check for unilateral right-sided breath sounds. Absence or diminution of breath sounds indicates that the tube is not far enough down and that the bronchial cuff is occluding the distal trachea.

when the bronchial lumen is clamped. In the same situation, if the surgical procedure is in the right thorax, clamping of the tracheal lumen will lead to ventilation of only the left upper or left lower lobe; hypoxia usually develops rapidly.

Right-sided double-lumen tubes can be accidentally inserted into the left main stem bronchus, inserted too distally or too proximally, or have

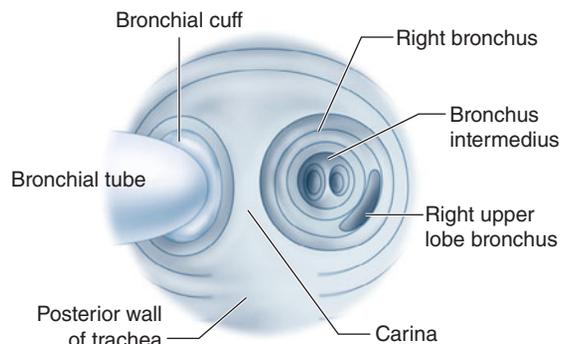

FIGURE 25-9 The view of the carina looking down the tracheal lumen of a properly positioned left double-lumen bronchial tube.

misalignment of the endobronchial side portal with the opening of the right upper lobe bronchus. If the tube inadvertently enters the wrong bronchus, the fiberoptic bronchoscope can be used to direct it into the correct side: (1) the bronchoscope is passed through the bronchial lumen to the tip of the tube; (2) under direct vision, the tube and the bronchoscope are withdrawn together into the trachea just above the carina; (3) the bronchoscope alone is then advanced into the correct bronchus; and (4) the double-lumen tube is gently advanced over the bronchoscope, which functions as a stylet to guide the bronchial lumen into the correct bronchus.

Complications of Double-Lumen Tubes

Major complications of double-lumen tubes include: (1) hypoxemia due to tube malplacement, tube occlusion, or excessive degrees of venous admixture with one-lung ventilation; (2) traumatic laryngitis; (3) tracheobronchial rupture resulting from traumatic placement or overinflation of the bronchial cuff; and (4) inadvertent suturing of the tube to a bronchus during surgery (detected as the inability to withdraw the tube during attempted extubation).

SINGLE-LUMEN TRACHEAL TUBES WITH A BRONCHIAL BLOCKER

Bronchial blockers are inflatable devices that are passed alongside or through a single-lumen tracheal tube to selectively occlude a bronchial orifice. A single-lumen tracheal tube with a built-in side channel for a retractable bronchial blocker is available. The tube is placed with the blocker fully retracted; its natural curve is such that turning the tube with the curve concave toward the right preferentially directs the bronchial blocker toward the right bronchus. Turning the tube with the curve concave toward the left usually directs the blocker toward the left bronchus. The bronchial blocker must be advanced, positioned, and inflated under direct visualization via a flexible bronchoscope.

The major advantage of a tube with an incorporated bronchial blocker is that, unlike a double-lumen

tube, it does not need to be replaced with a conventional tracheal tube if the patient remains intubated postoperatively (below). Its major disadvantage is that the “blocked” lung collapses slowly (and sometimes incompletely) because of the small size of the channel within the blocker.

Another way to achieve lung separation is by using an independent bronchial blocker passed through a single-lumen endotracheal tube. There are several types of independent bronchial blockers. They come in different sizes (7Fr and 9Fr) and have a 1.4-mm diameter inner lumen. Bronchial blockers have a high-volume low-pressure cuff with either an elliptical or spherical shape. The spherical shape of the cuff facilitates adequate blockade of the right mainstem bronchus. The spherical or the elliptical cuff can be used for the left main stem bronchus. The inner lumen contains a nylon wire, which exits the distal end as a wireloop. The placement of the bronchial blocker involves inserting the endobronchial blocker through the endotracheal tube and using the fiberoptic bronchoscope and the distal loop of the guidewire to direct the blocker into a mainstem bronchus. The fiberoptic bronchoscope must be advanced beyond the bronchus opening so that the blocker enters the bronchus while it is being advanced. When the deflated cuff is beyond the entrance of the bronchus, the fiberoptic bronchoscope is withdrawn, and the blocker is secured in position. In order to obtain bronchial blockade, the cuff is fully inflated under fiberoptic visualization with 4 to 8 mL of air. The placement must be reconfirmed when the patient is placed in the lateral position. Bronchial blockers may be good choices for lung separation in intubated critically ill patients who require one-lung ventilation, patients who are difficult to intubate using direct laryngoscopy, patients with prior tracheostomies, and patients who may require postoperative mechanical ventilation. However, because bronchial blockers are more prone to dislodgement compared with double-lumen endotracheal tubes, and their small central lumens do not allow efficient suctioning of secretions or rapid collapse of the lung, some clinicians prefer not to use them.

In smaller children, an inflatable embolectomy (Fogarty) catheter can be used as a bronchial

blocker in conjunction with a conventional tracheal tube (with the embolectomy catheter placed either inside or alongside the tracheal tube); a guidewire in the catheter can be used to facilitate placement. This technique is occasionally used to collapse one lung when other techniques do not work. As the embolectomy catheter does not have a communicating channel in the center, it also does not allow suctioning or ventilation of the isolated lung, and the catheter can be easily dislodged. Nonetheless, such bronchial blockers may be useful for one-lung anesthesia in pediatric patients and for tamponading bronchial bleeding in adult patients (see below).

Anesthesia for Lung Resection

PREOPERATIVE CONSIDERATIONS

Lung resections are usually carried out for the diagnosis and treatment of pulmonary tumors, and, less commonly, for complications of necrotizing pulmonary infections and bronchiectasis.

1. Tumors

Pulmonary tumors can be either benign or malignant, and, with the widespread use of bronchoscopic sampling, the diagnosis is usually available prior to surgery. Hamartomas account for 90% of benign pulmonary tumors; they are usually peripheral pulmonary lesions and represent disorganized normal pulmonary tissue. Bronchial adenomas are usually central pulmonary lesions that are typically benign, but occasionally may be locally invasive and rarely metastasize. These tumors include pulmonary carcinoids, cylindromas, and mucoepidermoid adenomas. They often obstruct the bronchial lumen and cause recurrent pneumonia distal to the obstruction in the same area. Primary pulmonary carcinoids may secrete multiple hormones, including adrenocorticotropic hormone (ACTH) and arginine vasopressin; however, manifestations of the carcinoid syndrome are uncommon and are more likely with metastases.

Malignant pulmonary tumors are divided into small (“oat”) cell and non-small cell carcinomas.

The latter group includes squamous cell (epidermoid) tumors, adenocarcinomas, and large cell (anaplastic) carcinomas. All types are more commonly encountered in smokers, but more “never smokers” die of lung cancer each year in the United States than the total number of people who die of ovarian cancer. Epidermoid and small cell carcinomas usually present as central masses with bronchial lesions; adenocarcinoma and large cell carcinomas are more typically peripheral lesions that often involve the pleura.

Clinical Manifestations

Symptoms may include cough, hemoptysis, wheezing, weight loss, productive sputum, dyspnea, or fever. Pleuritic chest pain or pleural effusion suggests pleural extension. Involvement of mediastinal structures is suggested by hoarseness that results from compression of the recurrent laryngeal nerve, Horner’s syndrome caused by involvement of the sympathetic chain, an elevated hemidiaphragm caused by compression of the phrenic nerve, dysphagia caused by compression of the esophagus, or the superior vena cava syndrome caused by compression or invasion of the superior vena cava. Pericardial effusion or cardiomegaly suggests cardiac involvement. Extension of apical (superior sulcus) tumors can result in either shoulder or arm pain, or both, because of involvement of the C7–T2 roots of the brachial plexus (Pancoast syndrome). Distant metastases most commonly involve the brain, bone, liver, and adrenal glands.

Lung carcinomas—particularly small cell—can produce remote effects that are not related to malignant spread (paraneoplastic syndromes). Mechanisms include ectopic hormone production and immunologic cross-reactivity between the tumor and normal tissues. Cushing’s syndrome, hyponatremia, and hypercalcemia may be encountered, resulting from secretion of ACTH, arginine vasopressin, and parathyroid hormone, respectively. Lambert–Eaton (myasthenic) syndrome is characterized by a proximal myopathy in which muscle strength increases with repeated effort (in contrast to myasthenia gravis). Other paraneoplastic syndromes include peripheral neuropathy and migratory thrombophlebitis.

Treatment

Surgery is the treatment of choice to reduce the tumor burden in nonmetastatic lung cancer. Various chemotherapy and radiation treatments are likewise employed, but there is wide variation among tissue types in their sensitivity to chemotherapy and radiation.

Resectability & Operability

Resectability is determined by the anatomic stage of the tumor, whereas operability is dependent on the interaction between the extent of the procedure required for cure and the physiological status of the patient. Anatomic staging is accomplished using chest radiography, computed tomography (CT) or magnetic resonance imaging (MRI), bronchoscopy, and (sometimes) mediastinoscopy. The extent of the surgery should maximize the chances for a cure but still allow for adequate residual pulmonary function postoperatively. Lobectomy via a posterior thoracotomy, through the fifth or sixth intercostal space, or thorough video assisted thoracoscopic surgery (VATS), is the procedure of choice for most lesions. Segmental or wedge resections may be performed in patients with small peripheral lesions and poor pulmonary reserve. Pneumonectomy is necessary for curative treatment of lesions involving the left or right main bronchus or when the tumor extends toward the hilum. A sleeve resection may be employed for patients with proximal lesions and limited pulmonary reserve as an alternative to pneumonectomy; in such instances, the involved lobar bronchus, together with part of the right or left main bronchus, is resected, and the distal bronchus is reanastomosed to the proximal bronchus or the trachea. Sleeve pneumonectomy may be considered for tumors involving the trachea.

The incidence of pulmonary complications after thoracotomy and lung resection is about 30% and is related not only to the amount of lung tissue resected, but also to the disruption of chest wall mechanics due to the thoracotomy. Postoperative pulmonary dysfunction seems to be less after VATS than “open” thoracotomy. The mortality rate for pneumonectomy is generally more than twice that of for a lobectomy. Mortality is greater for right-sided than left-sided pneumonectomy, possibly because of greater loss of lung tissue.

Evaluation for Lung Resection

A comprehensive preoperative pulmonary assessment is necessary to assess the operative risk, minimize perioperative complications, and achieve better outcomes. Preoperative assessment of respiratory function includes determinations of respiratory mechanics, gas exchange, and cardiorespiratory interaction.

Respiratory mechanics are assessed by pulmonary function tests. Of these parameters, the most useful is the predicted postoperative forced expiratory volume in one sec (FEV_1), which is calculated as follows:

$$\text{Postoperative } FEV_1 = \text{preoperative } FEV_1 \times (1 - \frac{\text{percentage of functional lung tissue removed}}{100})$$

Removal of extensively diseased lung (nonventilated but perfused) does not necessarily adversely affect pulmonary function and may actually improve oxygenation. Mortality and morbidity are significantly increased if postoperative FEV_1 is less than 40% of normative FEV_1 , and patients with predicted postoperative FEV_1 of less than 30% may need postoperative mechanical ventilatory support.

Gas exchange will sometimes be characterized by diffusion lung capacity for carbon monoxide (DLCO). DLCO correlates with the total functioning surface area of the alveolar-capillary interface. Predictive postoperative DLCO can be calculated in the same fashion as postoperative FEV_1 . A predicted postoperative DLCO of less than 40% also correlates with increased postoperative respiratory and cardiac complications. Adequacy of gas exchange is more commonly assessed by arterial blood gas data such as $P_{aO_2} > 60$ mm Hg and a $P_{aCO_2} < 45$ mm Hg.

Ventilation-perfusion (\dot{V}/\dot{Q}) scintigraphy provides the relative contribution of each lobe to overall pulmonary function and may further refine the assessment of predicted postoperative lung function, in patients where pneumonectomy is the indicated surgical procedure and there is concern whether a single lung will be adequate to support life.

Patients considered at greater risk of perioperative complications based on standard spirometry testing and calculation of postoperative function should undergo exercise testing for evaluation of

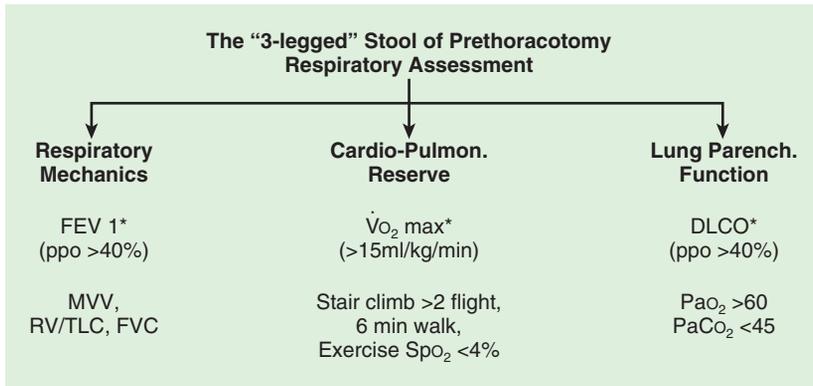

FIGURE 25–10 The “three-legged” stool of prethoracotomy respiratory assessment. *Most valid test. (Reproduced, with permission, from Slinger PD, Johnston MR: Preoperative assessment: an anesthesiologist’s perspective. *Thorac Surg Clin* 2005;15:11.)

cardiopulmonary interaction. Stair climbing is the easiest way to assess exercise capacity and cardiopulmonary reserve. Patients capable of climbing two or three flights of stairs have decreased mortality and morbidity. On the other hand, the ability to climb less than two flights of stairs is associated with increased perioperative risk. The gold standard for evaluating cardiopulmonary interaction is by laboratory exercise testing and measurement of maximal minute oxygen consumption. A $\dot{V}O_2 >20$ mL/kg is not associated with a significant increase in perioperative mortality or morbidity, whereas a minute consumption of less than 10 mL/kg is associated with an increased perioperative risk.

A combination of tests to evaluate the three components of the respiratory function (ie, respiratory mechanics, gas exchange, and cardiopulmonary interaction) has been summarized in the so-called “three-legged” stool of respiratory assessment (Figure 25–10).

2. Infection

Pulmonary infections may present as a solitary nodule or cavitory lesion (necrotizing pneumonitis). An exploratory thoracotomy may be carried out to exclude malignancy and diagnose the infectious agent. Lung resection is also indicated for cavitory lesions that are refractory to antibiotic treatment, are associated with refractory empyema, or result in

massive hemoptysis. Responsible organisms include both bacteria and fungi.

3. Bronchiectasis

Bronchiectasis is a permanent dilation of bronchi. It is usually the end result of severe or recurrent inflammation and obstruction of bronchi. Causes include a variety of viral, bacterial, and fungal pathogens, as well as inhalation of toxic gases, aspiration of gastric acid, and defective mucociliary clearance (cystic fibrosis and disorders of ciliary dysfunction). Bronchial muscle and elastic tissue are typically replaced by very vascular fibrous tissue. The latter predisposes to bouts of hemoptysis. Pulmonary resection is usually indicated for massive hemoptysis when conservative measures have failed and the disease is localized. Patients with diffuse bronchiectasis have a chronic obstructive ventilatory defect.

ANESTHETIC CONSIDERATIONS

1. Preoperative Management

The majority of patients undergoing pulmonary resections have underlying lung disease. It should be emphasized that smoking is a risk factor for both chronic obstructive pulmonary disease and coronary artery disease; both disorders commonly coexist in patients presenting for thoracotomy.

Echocardiography is useful for assessing baseline cardiac function and may suggest evidence of cor pulmonale (right ventricular enlargement or hypertrophy) in patients with poor exercise tolerance. Stress echocardiography (exercise or dobutamine) may be useful in diagnosing coronary artery disease in patients with suggestive signs and symptoms.

Patients with tumors should be evaluated for complications related to local extension of the tumor and paraneoplastic syndromes (above). Preoperative chest radiographs and CT or MR images should be reviewed. Tracheal or bronchial deviation can make tracheal intubation and proper positioning of bronchial tubes much more difficult. Moreover, airway compression can lead to difficulty in ventilating the patient following induction of anesthesia. Pulmonary consolidation, atelectasis, and large pleural effusions predispose to hypoxemia. The location of any bullous cysts or abscesses should be noted.

Patients undergoing thoracic procedures are at increased risk of postoperative pulmonary and cardiac complications. Perioperative arrhythmias, particularly supraventricular tachycardias, are thought to result from surgical manipulations or distention of the right atrium following reduction of the pulmonary vascular bed. The incidence of arrhythmias increases with age and the amount of pulmonary resection.

2. Intraoperative Management

Preparation

As with anesthesia for cardiac surgery, optimal preparation may help to prevent potentially catastrophic problems. The frequent presence of poor pulmonary reserve, anatomic abnormalities, or compromise of the airways, and the need for one-lung ventilation predispose these patients to the rapid onset of hypoxemia. A well thought-out plan to deal with potential difficulties is necessary. Moreover, in addition to items for basic airway management, specialized and properly functioning equipment—such as multiple sizes of single- and double-lumen tubes, a flexible (pediatric) fiberoptic bronchoscope, a small-diameter “tube exchanger” of adequate length to accommodate a double lumen tube, a continuous positive airway pressure (CPAP) delivery system,

and an anesthesia circuit adapter for administering bronchodilators—should be immediately available.

Patients undergoing open-lung resections (segmentectomy, lobectomy, pneumonectomy) often receive postoperative thoracic epidural analgesia, unless there is a contraindication. However, patients are increasingly being treated with numerous antiplatelet and anticoagulant medications, which may preclude epidural catheter placement.

Venous Access

At least one large-bore (14- or 16-gauge) intravenous line is mandatory for all open thoracic surgical procedures. Central venous access (preferably on the side of the thoracotomy to avoid the risk of pneumothorax on the side that will be ventilated intraoperatively), a blood warmer, and a rapid infusion device are also desirable if extensive blood loss is anticipated.

Monitoring

Direct monitoring of arterial pressure is indicated for resections of large tumors (particularly those with mediastinal or chest wall extension), and any procedure performed in patients who have limited pulmonary reserve or significant cardiovascular disease. Central venous access with monitoring of central venous pressure (CVP) is desirable for pneumonectomies and resections of large tumors. Less invasive measures of cardiac output through use of pulse contour analysis and transpulmonary thermodilution provide better estimates of cardiac function and volume responsiveness (See Chapter 5). Pulmonary artery catheters are very rarely used. Measurement of pulmonary artery pressures may also not be accurate due to intrinsic and extrinsic PEEP, lateral decubitus, and open chest. In patients with significant coronary artery disease or pulmonary hypertension, intraoperative monitoring can be enhanced by the use of transesophageal echocardiography.

Induction of Anesthesia

After adequate preoxygenation, an intravenous anesthetic is used for induction of most patients. The selection of an induction agent should be based on the patient's preoperative status. Direct

laryngoscopy should generally be performed only after adequate depth of anesthesia has been achieved to prevent reflex bronchospasm and to obtund the cardiovascular pressor response. This may be accomplished by incremental doses of the induction agent, an opioid, or deepening the anesthesia with a volatile inhalation agent (the latter is particularly useful in patients with reactive airways).

Tracheal intubation with a single-lumen tracheal tube (or with a laryngeal mask airway [LMA]) may be necessary, if the surgeon performs diagnostic bronchoscopy (below) prior to surgery. Once the bronchoscopy is completed, the single-lumen tracheal tube (or LMA) can be replaced with a double-lumen bronchial tube (above). Controlled positive-pressure ventilation helps prevent atelectasis, paradoxical breathing, and mediastinal shift; it also allows control of the operative field to facilitate the surgery.

Positioning

Following induction, intubation, and confirmation of correct tracheal or bronchial tube position, additional venous access and monitoring may be obtained before the patient is positioned for surgery. Most lung resections are performed with the patient in the lateral decubitus position. Proper positioning avoids injuries and facilitates surgical exposure. The lower arm is flexed and the upper arm is extended in front of the head, pulling the scapula away from the operative field (Figure 25-11). Pillows are placed between the arms and legs, and an axillary (chest) roll may be positioned just beneath the dependent axilla to reduce pressure on the inferior shoulder (it is assumed that this helps to protect the brachial plexus); care is taken to avoid pressure on the eyes and the dependent ear.

Maintenance of Anesthesia

All current anesthetic techniques have been successfully used for thoracic surgery, but the combination of a potent halogenated agent (isoflurane, sevoflurane, or desflurane) and an opioid is preferred by most clinicians. Advantages of the halogenated agents include: (1) potent dose-related bronchodilation; (2) depression of airway reflexes; (3) the ability to use a high inspired oxygen concentration (F_{IO_2}), if necessary; (4) the ability to make relatively rapid adjustments in anesthetic depth; and (5) minimal effects on hypoxic pulmonary vasoconstriction (see below). Halogenated agents generally have minimal effects on HPV in doses <1 minimum alveolar concentration (MAC). Advantages of an opioid include: (1) generally minimal hemodynamic effects; (2) depression of airway reflexes; and (3) residual postoperative analgesia. If epidural opioids are used postoperatively, intravenous opioids should be limited during surgery to prevent excessive postoperative respiratory depression. Maintenance of neuromuscular blockade with a nondepolarizing neuromuscular blocker (NMB) during surgery facilitates rib spreading as well as anesthetic management. Intravenous fluids should generally be restricted in patients undergoing pulmonary resections. Excessive fluid administration in thoracic surgical patients has been associated with acute lung injury in the postoperative period. No fluid replacement for estimated “third space” losses should be administered during lung resection. Excessive fluid administration in the lateral decubitus position may promote a “lower lung syndrome” (ie, gravity-dependent transudation of fluid into the dependent lung). The latter increases intrapulmonary shunting and promotes hypoxemia, particularly

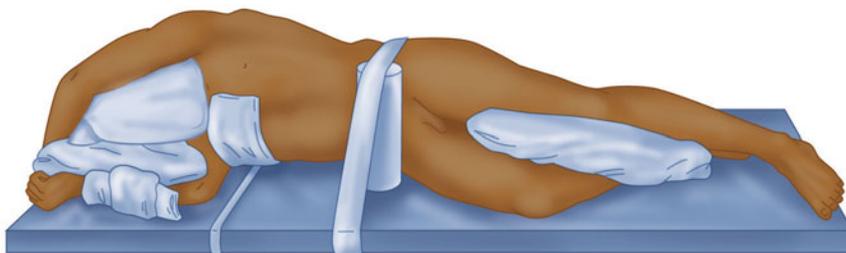

FIGURE 25-11 Proper positioning for a lateral thoracotomy. (Reproduced, with permission, from Gothard JWW, Branthwaite MA: *Anesthesia for Thoracic Surgery*. Blackwell, 1982.)

during one-lung ventilation. Moreover, the collapsed lung may be prone to acute lung injury due to surgical retraction during the procedure and possible ischemia–reperfusion injury. During lung resections, the bronchus (or remaining lung tissue) is usually divided with an automated stapling device. The bronchial stump is then tested for an air leak under water by transiently sustaining 30 cm of positive pressure to the airway. Prior to completion of chest closure, all remaining lung segments should be fully expanded manually under direct vision. Controlled mechanical ventilation is then resumed and continued until chest tubes are connected to suction.

Management of One-Lung Ventilation

Although still an intraoperative problem, hypoxemia has become less frequent due to better lung isolation methods, ventilation techniques, and the use of anesthetic agents with less detrimental effects on hypoxic pulmonary vasoconstriction. Attention has currently shifted toward avoidance of acute lung injury (ALI). Fortunately, ALI occurs infrequently, with an incidence of 2.5 % of all lung resections combined, and an incidence of 7.9% after pneumonectomy. However, when it occurs, ALI is associated with a risk of mortality or major morbidity of about 40%.

Based on current data, it seems that protective lung ventilation strategies may minimize the risk of acute lung injury *after* lung resection. This ventilatory strategy includes the use of lower tidal volumes (6–8 mL/kg), routine use of PEEP (5–10 cm H₂O), lower F_{IO₂} (50% to 80%), lower ventilatory pressures (plateau pressure <25 cm H₂O; peak airway pressure <35 cm H₂O) through the use of pressure-controlled ventilation and permissive hypercapnia. The use of lower tidal volumes may lead to lung derecruitment, atelectasis, and hypoxemia. Lung derecruitment may be avoided by application of external PEEP and frequent recruitment maneuvers. Although PEEP may prevent alveolar collapse and development of atelectasis, it may cause a decrease in Pao₂ due to diversion of blood flow away from the dependent, ventilated lung and an increase in total shunt. Thus, PEEP must be customized to the underlying disease of each patient, and a new application of PEEP will almost never be the appropriate

way to treat hypoxemia that occurs immediately after the onset of one-lung ventilation. Patients with obstructive pathology may develop intrinsic PEEP. In these patients, the application of external PEEP may lead to unpredictable levels of total PEEP. Although the management of one-lung ventilation has long included the use of 100% oxygen, evidence of oxygen toxicity has accumulated both experimentally and clinically. Although there is no convincing evidence that outcomes are worsened with the use of 100% oxygen, some clinicians recommend titrating F_{IO₂} to maintain the oxygen saturation above 90%, especially in patients who have undergone adjuvant therapy and are at risk of developing ALI. Although there is no unequivocal evidence that one mode of ventilation may be more beneficial than the other, pressure-controlled ventilation may diminish the risk of barotrauma by limiting peak and plateau airway pressures, and the flow pattern results in a more homogenous distribution of the tidal volume and improved dead space ventilation.

At the end of the procedure, the operative lung is inflated gradually to a peak inspiratory pressure of less than 30 cm H₂O to prevent disruption of the staple line. During reinflation of the operative lung, it may be helpful to clamp the lumen serving the dependent lung to limit overdistension.

Periodic arterial blood gas analysis is helpful to ensure adequate ventilation. End-tidal CO₂ measurement may not be reliable due to increased dead-space and an unpredictable gradient between the arterial and end-tidal CO₂ partial pressure.

Management of Hypoxia

Hypoxemia during one-lung anesthesia requires one or more of the following interventions:

1. Adequate position of the bronchial tube (or bronchial blocker) must be confirmed, as its position relative to the carina can change as a result of surgical manipulations or traction; repeat fiberoptic bronchoscopy through the tracheal lumen can quickly detect this problem. Both lumens of the tube should also be suctioned to exclude excessive secretions or obstruction as a factor.
2. Increase F_{IO₂} to 1.0

3. Recruitment maneuvers on the dependent, ventilated lung may eliminate atelectasis and improve shunt.
4. Optimize PEEP to the dependent, nonoperative lung.
5. Ensure adequate cardiac output and adequate oxygen carrying capacity.
6. CPAP or blow-by oxygen to the operative lung will decrease shunting and improve oxygenation. However, inflation of the operative lung during VATS will make identification and visualization of the lung structures difficult for the surgeon; therefore, such maneuvers should be applied carefully and cautiously.
7. Two-lung ventilation should be instituted for severe hypoxemia. If possible, pulmonary artery clamp can also be placed during pneumonectomy to eliminate shunt.
8. In patients with chronic obstructive lung disease, one should always be suspicious of pneumothorax on the dependent, ventilated side as a cause of severe hypoxemia. This complication requires immediate detection and treatment by aborting the surgical procedure, reexpanding the operative lung, and immediately inserting a chest tube in the contralateral chest.

Alternatives to One-Lung Ventilation

Ventilation can be stopped for short periods if 100% oxygen is insufflated at a rate greater than oxygen consumption (**apneic oxygenation**) into an **unobstructed tracheal tube**. Adequate oxygenation can often be maintained for prolonged periods, but progressive respiratory acidosis limits the use of this technique to 10–20 min in most patients. Arterial PCO_2 rises 6 mm Hg in the first minute, followed by a rise of 3–4 mm Hg during each subsequent minute.

High-frequency positive-pressure ventilation and high-frequency jet ventilation have been used during thoracic procedures as alternatives to one-lung ventilation. A standard tracheal tube may be used with either technique. Small tidal volumes (<2 mL/kg) allow decreased lung excursion, which may facilitate the surgery but still allow ventilation of

both lungs. Unfortunately, mediastinal “bounce”—a to-and-fro movement—often interferes with the surgery.

3. Postoperative Management

General Care

Most patients are extubated shortly after surgery to decrease the risk of pulmonary barotrauma (particularly “blowout” [rupture] of the bronchial suture line). Patients with marginal pulmonary reserve should remain intubated until standard extubation criteria are met; if a double-lumen tube was used for one-lung ventilation, it should be replaced with a regular single-lumen tube at the end of surgery. A catheter guide (“tube exchanger”) should be used if the original laryngoscopy was difficult (above).

Patients are observed in the postanesthesia care unit, and, in most instances, at least overnight or longer in an intensive care unit or intermediate care unit. Postoperative hypoxemia and respiratory acidosis are common. These effects are largely caused by atelectasis and “shallow breathing (‘splinting’)” due to incisional pain. Gravity-dependent transudation of fluid into the intraoperative dependent lung may also be contributory. Reexpansion edema of the collapsed nondependent lung can also occur.

4 Postoperative hemorrhage complicates about 3% of thoracotomies and may be associated with up to 20% mortality. Signs of hemorrhage include increased chest tube drainage (>200 mL/h), hypotension, tachycardia, and a falling hematocrit. Postoperative supraventricular tachyarrhythmias are common and usually require immediate treatment. Routine postoperative care should include maintenance of a semiupright (>30°) position, supplemental oxygen (40% to 50%), incentive spirometry, electrocardiographic and hemodynamic monitoring, a postoperative chest radiograph (to confirm proper position of all thoracostomy tube drains and central lines and to confirm expansion of both lung fields), and adequate pain relief.

Postoperative Analgesia

The importance of adequate pain management in the thoracic surgical patient cannot be overstated. Inadequate pain control in these high-risk patients

will result in splinting; poor respiratory effort; and the inability to cough and clear secretions, with an end result of airway closure, atelectasis, shunting, and hypoxemia. Irrespective of the modality used, there must be a comprehensive plan for pain management.

A balance between comfort and respiratory depression in patients with marginal lung function is difficult to achieve with parenteral opioids alone. Patients who have undergone thoracotomy clearly benefit from the use of other techniques (described below) that may reduce the need for parenteral opioids. If parenteral opioids are used alone, they are best administered via a patient-controlled analgesia device.

In the absence of an epidural catheter, intercostal or paravertebral nerve blocks with long-acting local anesthetics may facilitate extubation, but have a limited duration of action, so alternative means of pain management must be employed. Alternatively, a cryoanalgesia probe may be used intraoperatively to freeze the intercostal nerves (cryoneurolysis) and produce long-lasting anesthesia; unfortunately, maximum analgesia may not be achieved until 24–48 hr after the cryoanalgesia procedure. Nerve regeneration is reported to occur approximately 1 month after the cryoneurolysis. Infusion of local anesthetic through a catheter placed in the surgical wound during closure will markedly reduce the requirement for parenteral opioids and improve the overall quality of analgesia relative to parenteral opioids alone.

Epidural analgesia is the current optimal method for acute pain control following thoracic surgical procedures. It provides excellent pain relief, continuous therapy, and avoidance of the side effects associated with administration of systemic opioids. On the other hand, epidural techniques require attention from the acute pain team for the duration of the infusion and subject the patient to the long list of epidural-related side effects and complications. However, there is still much debate over the level of placement of the epidural catheter (thoracic versus lumbar), type of medication administered (opioid and/or local anesthetic), and timing of medication administration (before surgical incision vs before end of surgery). Most practitioners use a combination of opioid (fentanyl, morphine, hydromorphone) and local anesthetic (bupivacaine

or ropivacaine), with the epidural catheter placed at a thoracic level.

Postoperative Complications

Postoperative complications following thoracotomy are relatively common, but fortunately most are minor and resolve uneventfully. Blood clots and thick secretions may obstruct the airways and result in atelectasis; suctioning may be necessary. Atelectasis is suggested by tracheal deviation and shifting of the mediastinum to the operative side following segmental or lobar resections. Therapeutic bronchoscopy should be considered for persistent atelectasis, particularly when associated with thick secretions. Air leaks from the operative hemithorax are common following segmental and lobar resections. Most air leaks stop after a few days.

5 Bronchopleural fistulae present as a sudden large air leak from the chest tube that may be associated with an increasing pneumothorax and partial lung collapse. When they occur within the first 24–72 hr, they are usually the result of inadequate surgical closure of the bronchial stump. Delayed presentation is usually due to necrosis of the suture line associated with inadequate blood flow or infection.

Some complications are rare, but deserve special consideration because they can be life-threatening and require immediate exploratory thoracotomy. Postoperative bleeding was discussed above. Torsion of a lobe or segment can occur as the remaining lung on the operative side expands to occupy the hemithorax. The torsion usually occludes the pulmonary vein to that part of the lung, causing venous outflow obstruction. Hemoptysis and infarction can rapidly follow. The diagnosis is suggested by an enlarging homogeneous density on the chest radiograph and a closed lobar orifice on bronchoscopy.

6 Acute herniation of the heart into the operative hemithorax can occur through the pericardial defect that may remain following a pneumonectomy. A large pressure differential between the two hemithoraces is thought to trigger this catastrophic event. Cardiac herniation into the right hemithorax results in sudden severe hypotension with an elevated CVP because of torsion of the central veins. Cardiac herniation into the left

hemithorax following left pneumonectomy results in sudden compression of the myocardium, resulting in hypotension, ischemia, and infarction. A chest radiograph shows a shift of the cardiac shadow into the operative hemithorax.

Extensive mediastinal dissections can injure the phrenic, vagus, and left recurrent laryngeal nerves. Postoperative phrenic nerve palsy presents as elevation of the ipsilateral hemidiaphragm together with difficulty in weaning the patient from the ventilator. Large chest wall resections may include part of the diaphragm, causing a similar problem, in addition to a flail chest. Paraplegia rarely follows thoracotomy for lung resection. There are reports of cellulose gauze and other debris migrating from the thoracic gutter into the spinal canal, resulting in spinal cord compression. If an epidural catheter has been placed, any loss of motor function or unexplained back pain should immediately trigger imaging to rule out epidural hematoma.

SPECIAL CONSIDERATIONS FOR PATIENTS UNDERGOING LUNG RESECTION

Massive Pulmonary Hemorrhage

Massive hemoptysis is usually defined as >500–600 mL of blood loss from the tracheobronchial tree within 24 hr. The etiology is usually tuberculosis, bronchiectasis, or a neoplasm, or complication of transbronchial biopsies. Emergency surgical management with lung resection is reserved for “potentially lethal” massive hemoptysis. In most cases, surgery is usually carried out on an urgent rather than on a true emergent basis whenever possible; even then, operative mortality may exceed 20% (compared with > 50% for medical management). Embolization of the involved bronchial arteries may be attempted. The most common cause of death is asphyxia secondary to blood in the airway. Patients may be brought to the operating room for rigid bronchoscopy when localization is not possible with fiberoptic flexible bronchoscopy. A bronchial blocker or Fogarty catheter (above) may be placed to tamponade the bleeding, or laser coagulation may be attempted.

Multiple large-bore intravenous catheters should be placed. Sedating drugs should not be given to awake, nonintubated, spontaneously ventilating patients because they are usually already hypoxic; 100% oxygen should be given continuously. If the patient is already intubated and has bronchial blockers in place, sedation is helpful to prevent coughing. The bronchial blocker should be left in position until the lung is resected. When the patient is not intubated, a rapid sequence induction (ketamine or etomidate with succinylcholine) is used. Patients usually swallow a large amount of blood and should be considered to have a full stomach. A large double-lumen bronchial tube is ideal for protecting the normal lung from blood and for suctioning each lung separately. If any difficulty is encountered in placing the double-lumen tube, or its relatively small lumens occlude easily, a large (>8.0-mm inner diameter) single-lumen tube may be used with a bronchial blocker to provide lung isolation.

Pulmonary Cyst & Bulla

Pulmonary cysts or bullae may be congenital or acquired as a result of emphysema. Large bullae can impair ventilation by compressing the surrounding lung. These air cavities often behave as if they have a one-way valve, predisposing them to progressively enlarge. Lung resection may be undertaken for progressive dyspnea or recurrent pneumothorax. The greatest risk of anesthesia is rupture of the air cavity during positive-pressure ventilation, resulting in tension pneumothorax; the latter may occur on either side prior to thoracotomy or on the nonoperative side during the lung resection. Induction of anesthesia with maintenance of spontaneous ventilation is desirable until the side with the cyst or bullae is isolated with a double-lumen tube, or until a chest tube is placed; most patients have a large increase in dead space, so assisted ventilation is necessary to avoid excessive hypercarbia. The use of N_2O is contraindicated in patients with cysts or bullae because it can expand the air space and cause rupture. The latter may be signaled by sudden hypotension, bronchospasm, or an abrupt rise in peak inflation pressure and requires immediate placement of a chest tube.

Lung Abscess

Lung abscesses result from primary pulmonary infections, obstructing pulmonary neoplasms (above), or, rarely, hematogenous spread of systemic infections. The two lungs should be isolated to prevent contamination of the healthy lung. A rapid-sequence intravenous induction with tracheal intubation with a double-lumen tube is generally recommended, with the affected lung in a dependent position. As soon as the double-lumen tube is placed, both bronchial and tracheal cuffs should be inflated. The bronchial cuff should make a tight seal before the patient is turned into the lateral decubitus position, with the diseased lung in a nondependent position. The diseased lung should be frequently suctioned during the procedure to decrease the likelihood of contaminating the healthy lung.

Bronchopleural Fistula

Bronchopleural fistulas occur following lung resection (usually pneumonectomy), rupture of a pulmonary abscess into a pleural cavity, pulmonary barotrauma, or spontaneous rupture of bullae. The majority of patients are treated (and cured) conservatively; patients come to surgery when chest tube drainage has failed. **Anesthetic management may be complicated by the inability to effectively ventilate the patient with positive pressure because of a large air leak, the potential for a tension pneumothorax, and the risk of contaminating the other lung if an empyema is present.** The empyema is usually drained, prior to closure of the fistula.

A correctly placed double-lumen tube greatly simplifies anesthetic management by isolating the fistula and allowing one-lung ventilation to the normal lung. The patient should be extubated as soon as possible after the repair.

Anesthesia for Tracheal Resection

Preoperative Considerations

Tracheal resection is most commonly performed for tracheal stenosis, tumors, or, less commonly, congenital abnormalities. Tracheal stenosis can result from penetrating or blunt trauma, as well as tracheal

intubation and tracheostomy. Squamous cell and adenoid cystic carcinomas account for the majority of tumors. Compromise of the tracheal lumen results in progressive dyspnea. Wheezing or stridor may be evident only with exertion. The dyspnea may be worse when the patient is lying down, with progressive airway obstruction. Hemoptysis can also complicate tracheal tumors. CT is valuable in localizing the lesion. **Measurement of flow–volume loops confirms the location of the obstruction and aids the clinician in evaluating the severity of the lesion (Figure 25–12).**

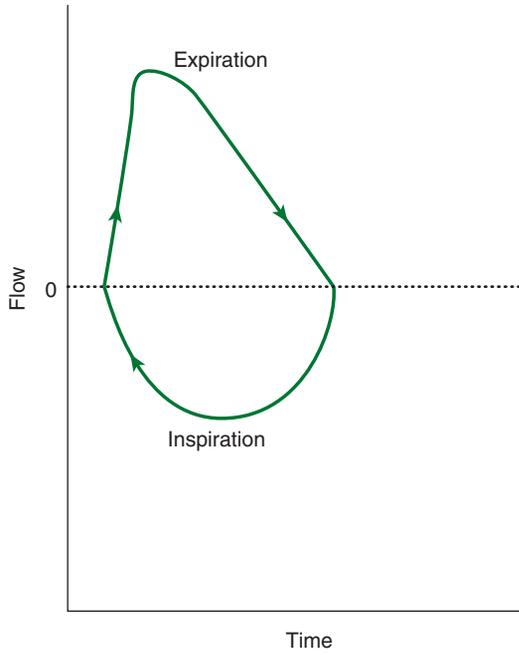

Anesthetic Considerations

Little premedication is given, as most patients presenting for tracheal resection have moderate to severe airway obstruction. Use of an anticholinergic agent to dry secretions is controversial because of the theoretical risk of inspissation. Monitoring should include direct arterial pressure measurements.

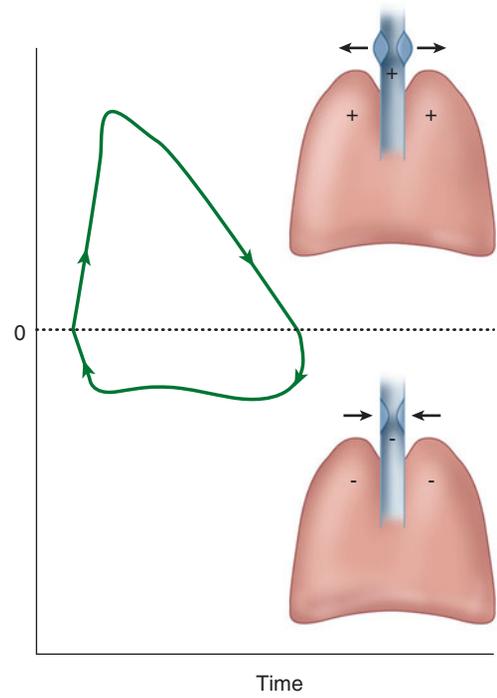

An inhalation induction (in 100% oxygen) is carried out in patients with severe obstruction. Sevoflurane is preferred because it is the potent anesthetic that is least irritating to the airway. Spontaneous ventilation is maintained throughout induction. NMBs are generally avoided because of the potential for complete airway obstruction following neuromuscular blockade. Laryngoscopy is performed only when the patient is judged to be under deep anesthesia. Intravenous lidocaine (1–2 mg/kg) can deepen the anesthesia without depressing respirations. The surgeon may then perform rigid bronchoscopy to evaluate and possibly dilate the lesion. Following bronchoscopy, the patient is intubated with a tracheal tube small enough to be passed distal to the obstruction whenever possible.

A collar incision is utilized for high tracheal lesions. The surgeon divides the trachea in the neck and advances a sterile armored tube into the distal trachea, passing off a sterile connecting breathing circuit to the anesthesiologist for ventilation during the resection. Following the resection and completion of the posterior part of the reanastomosis, the armored tube is removed, and the original tracheal tube is advanced distally, past the anastomosis (Figure 25–13). Alternatively, high-frequency jet ventilation may be employed during the anastomosis

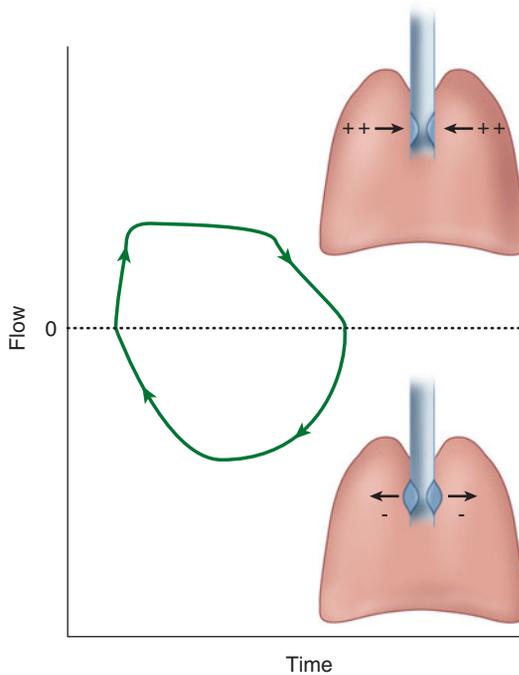

A NORMAL

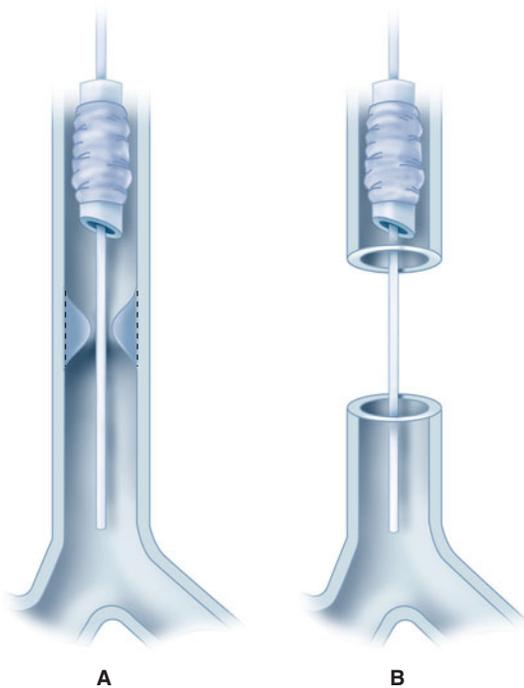

FIGURE 25-14 Tracheal resection using high-frequency jet ventilation. **A:** The catheter is advanced past the obstruction, and the cuff is deflated when jet ventilation is initiated. **B:** The catheter is advanced distally by the surgeon. Jet ventilation can be continued without interruption during resection and reanastomosis.

by passing the jet cannula past the obstruction and into the distal trachea (Figure 25-14). Return of spontaneous ventilation and early extubation at the end of the procedure are desirable. Patients should be positioned with the neck flexed immediately after the operation to minimize tension on the suture line (Figure 25-15).

Surgical management of low tracheal lesions requires a median sternotomy or right posterior thoracotomy. Anesthetic management is similar, but more regularly requires more complicated techniques, such as high-frequency ventilation or even cardiopulmonary bypass (CPB) in complex congenital cases.

Anesthesia for Video-Assisted Thoracoscopic Surgery (VATS)

VATS is now used for most lung resections that previously required open thoracotomy. The list of procedures that can be accomplished during VATS includes lung biopsy, segmental and lobar resections, pleurodesis, esophageal procedures, and pericardectomy. Most procedures are performed through three or more small incisions in the chest, with the patient in the lateral decubitus position.

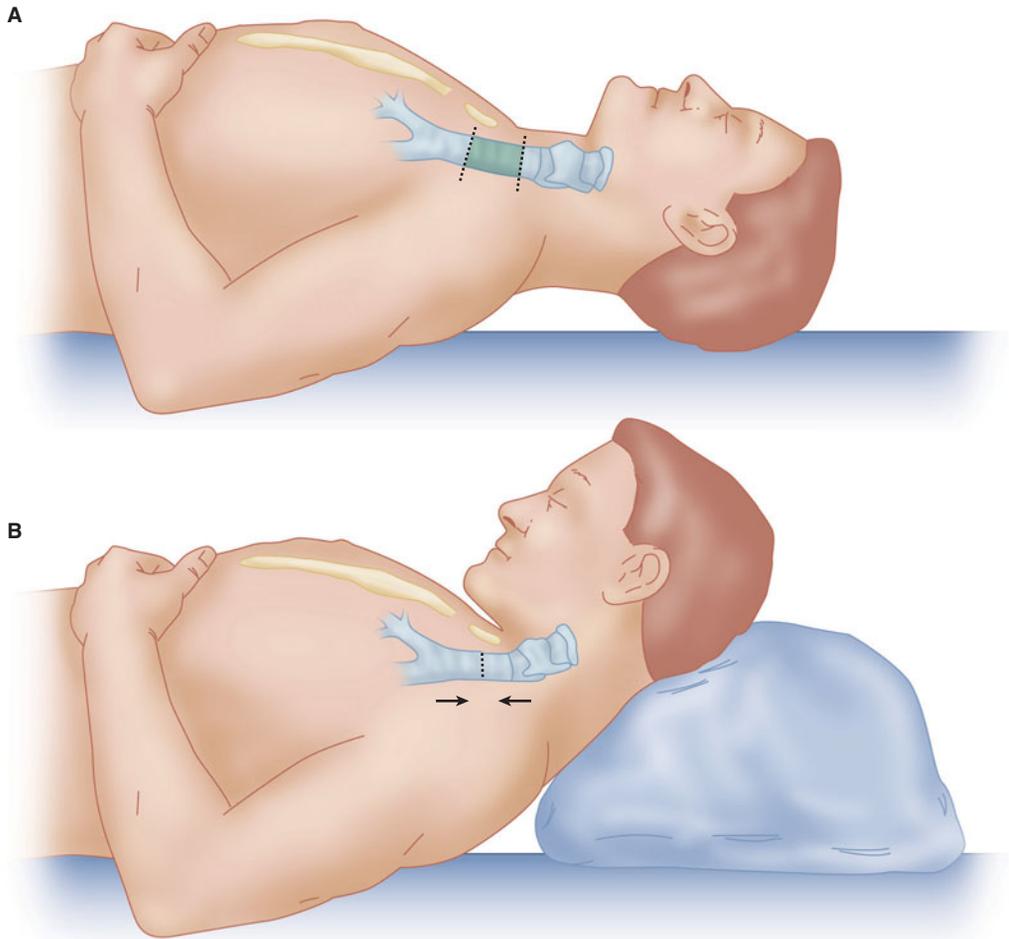

FIGURE 25-15 Position of the patient before (A) and after (B) tracheal resection and reanastomosis with the patient's neck flexed for the first 24–48 hr.

Anesthetic management is similar to that for open procedures, except that one-lung ventilation is required (as opposed to being desirable) for nearly all procedures.

Anesthesia for Diagnostic Thoracic Procedures

Bronchoscopy

Rigid bronchoscopy for removal of foreign bodies or tracheal dilatation is usually performed under general anesthesia. These procedures are complicated

by the need to share the airway with the surgeon or pulmonologist; fortunately, they are often of short duration. After a standard intravenous induction, anesthesia is often maintained with total intravenous anesthesia, and a short- or intermediate-acting NMB. Brief airway procedures are among the few remaining indications for a succinylcholine infusion. One of three techniques can then be used during rigid bronchoscopy: (1) apneic oxygenation using a small catheter positioned alongside the bronchoscope to insufflate oxygen (above); (2) conventional ventilation through the side arm of a ventilating bronchoscope (when the proximal window of this

instrument is opened for suctioning or biopsies, ventilation must be interrupted); or (3) jet ventilation through an injector-type bronchoscope.

Mediastinoscopy

Mediastinoscopy, much more commonly employed in the past than at present, provides access to the mediastinal lymph nodes and is used to establish either the diagnosis or the resectability of intrathoracic malignancies (above). Preoperative CT or MR imaging is useful for evaluating tracheal distortion or compression.

Mediastinoscopy is performed under general tracheal anesthesia with neuromuscular paralysis. Venous access with a large-bore (14- to 16-gauge) intravenous catheter is mandatory because of the risk of bleeding and the difficulty in controlling bleeding when it occurs. Because the innominate artery may be compressed during the procedure, blood pressure should be measured in the left arm.

Complications associated with mediastinoscopy include: (1) vagally mediated reflex bradycardia from compression of the trachea or the great vessels; (2) excessive hemorrhage (see above); (3) cerebral ischemia from compression of the innominate artery (detected with a right radial arterial line or pulse oximeter on the right hand); (4) pneumothorax (usually presents postoperatively); (5) air embolism (because of a 30° head elevation, the risk is greatest during spontaneous ventilation); (6) recurrent laryngeal nerve damage; and (7) phrenic nerve injury.

Bronchoalveolar Lavage

Bronchoalveolar lavage may be employed for patients with pulmonary alveolar proteinosis. These patients produce excessive quantities of surfactant and fail to clear it. They present with dyspnea and bilateral consolidation on the chest radiograph. In such patients, bronchoalveolar lavage may be indicated for severe hypoxemia or worsening dyspnea. Often, one lung is lavaged, allowing the patient to recover for a few days before the other lung is lavaged; the “sicker” lung is therefore lavaged first. Increasingly, both lungs are lavaged during the same procedure, creating unique challenges to ensure adequate oxygenation during lavage of the second lung.

Unilateral bronchoalveolar lavage is performed under general anesthesia with a double-lumen bronchial tube. The cuffs on the tube should be properly positioned and should make a watertight seal to prevent spillage of fluid into the other side. The procedure is normally done in the supine position; although lavage with the lung in a dependent position helps to minimize contamination of the other lung, this position can cause severe ventilation/perfusion mismatch. Warm normal saline is infused into the lung to be treated and is drained by gravity; treatment continues until the fluid returning is clear (about 10–20 L). At the end of the procedure, both lungs are well suctioned, and the double-lumen tracheal tube is replaced with a single-lumen tracheal tube.

Anesthesia for Lung Transplantation

PREOPERATIVE CONSIDERATIONS

Lung transplantation is indicated for end-stage pulmonary parenchymal disease or pulmonary hypertension. Candidates are functionally incapacitated by dyspnea and have a poor prognosis. Criteria vary according to the primary disease process. Common etiologies are listed in [Table 25–3](#). Lung transplantation (as is true for all solid organ transplants) is limited by the availability of suitable organs, not by the availability of recipients. Patients typically have dyspnea at rest or with minimal activity and resting

hypoxemia ($\text{PaO}_2 < 50$ mm Hg) with increasing oxygen requirements. Progressive CO_2 retention is also very common. Patients may be ventilator dependent. Cor pulmonale does not necessarily require combined heart–lung transplantation because right ventricular function may recover when pulmonary artery pressures normalize. Patients should have normal left ventricular function and be free of coronary artery disease, as well as other serious health problems.

Single-lung transplantation may be performed in selected patients with idiopathic pulmonary fibrosis, whereas double-lung transplantation is typically performed in patients with cystic fibrosis, bullous emphysema, or vascular diseases. Patients with Eisenmenger syndrome require combined heart–lung transplantation.

ANESTHETIC CONSIDERATIONS

1. Preoperative Management

Effective coordination between the organ-retrieval team and the transplant team minimizes graft ischemia time and avoids unnecessary prolongation of pretransplant anesthesia time. These procedures are performed on an emergency basis; therefore, patients may have little time to fast for surgery. Oral cyclosporine also may be given preoperatively. Administration of a clear antacid, an H_2 blocker, or metoclopramide should be considered. Patients are very sensitive to sedatives, so premedication is usually administered only in the operating room when the patient is directly attended. Immunosuppressants and antibiotics are also administered after induction and prior to surgical incision.

2. Intraoperative Management

Monitoring

Strict asepsis should be observed for invasive monitoring procedures. Central venous access might be accomplished only after induction of anesthesia because patients may not be able to lie flat while awake. Patients with a patent foramen ovale are at risk of paradoxical embolism because of high right atrial pressures.

Induction & Maintenance of Anesthesia

A rapid-sequence induction is utilized. Induction with ketamine, etomidate, an opioid, or a combination of these agents is employed, avoiding precipitous drops in blood pressure. An NMB is used to facilitate laryngoscopy. Hypoxemia and hypercarbia must be avoided to prevent further increases in pulmonary artery pressure. Hypotension should be treated with vasopressors instead of large fluid boluses (see below).

Anesthesia is usually maintained with total intravenous anesthesia or a volatile agent. Intraoperative difficulties in ventilation are not uncommon. Progressive retention of CO_2 can also be a problem intraoperatively. Ventilation should be adjusted to maintain a PaCO_2 as close to the patient's baseline as possible. However, in the presence of a reasonable cardiovascular reserve and normal right heart function, higher levels of PaCO_2 can be tolerated for short periods of time. Hypercarbia and acidosis may lead to pulmonary vasoconstriction and acute right heart failure, and hemodynamic support with inotropes may be required for these patients. Patients with cystic fibrosis have copious secretions and require frequent suctioning.

Single-Lung Transplantation

Single-lung transplantation is often attempted without CPB. The procedure is performed through a posterior thoracotomy. Whether to employ CPB during transplantation of one lung is based on the patient's response to collapsing the lung to be replaced and clamping its pulmonary artery. Persistent arterial hypoxemia ($\text{SpO}_2 < 88\%$) or a sudden increase in pulmonary artery pressures necessitates CPB. Prostaglandin E_1 , milrinone, nitroglycerin, and dobutamine may be utilized to reduce pulmonary hypertension and prevent right ventricular failure. Inotropic support may be necessary. After the recipient lung is removed, the pulmonary artery, left atrial cuff (with the pulmonary veins), and bronchus of the donor lung are anastomosed. Flexible bronchoscopy is used to examine the bronchial suture line after its completion.

Double-Lung Transplantation

A “clamshell” transverse sternotomy can be used for double-lung transplantation. The procedure is occasionally performed with CPB; sequential thoracotomies for double-lung transplantation can also be performed. Heart lung transplantation is performed through median sternotomy with CPB.

Posttransplantation Management

After anastomosis of the donor organ or organs, ventilation to both lungs is resumed. Following **8** transplantation, peak inspiratory pressures should be maintained at the minimum pressure compatible with good lung expansion, and the inspired oxygen concentration should be maintained as close to room air as allowed by a $\text{PaO}_2 > 60$ mm Hg. Methylprednisolone and mannitol are usually administered prior to the release of vascular clamps. Hyperkalemia may occur as the preservative fluid is washed out of the donor organ. If transplantation has been performed on CPB, the patient is separated from CPB. Pulmonary vasodilators, inhaled nitric oxide, and inotropes (above) may be necessary. Transesophageal echocardiography is helpful in differentiating right and left ventricular dysfunction, as well as in evaluating blood flow in the pulmonary vessels, particularly after transplantation.

Transplantation disrupts the neural innervation, lymphatic drainage, and bronchial circulation of the transplanted lung. The respiratory pattern is unaffected, but the cough reflex is abolished below the carina. Bronchial hyperreactivity is observed in some patients. Hypoxic pulmonary vasoconstriction remains normal. Loss of lymphatic drainage increases extravascular lung water and predisposes the transplanted lung to pulmonary edema. Intraoperative fluid replacement must therefore be kept to a minimum. Loss of the bronchial circulation predisposes to ischemic breakdown of the bronchial suture line.

3. Postoperative Management

Patients are extubated after surgery as soon as is feasible. A thoracic epidural catheter may be employed for postoperative analgesia when coagulation studies are normal. The postoperative course may be complicated by acute rejection, infections,

and renal and hepatic dysfunction. Deteriorating lung function may result from rejection or reperfusion injury. Occasionally, temporary extracorporeal membrane oxygenation may be necessary. Frequent bronchoscopy with transbronchial biopsies and lavage are necessary to differentiate between rejection and infection. Nosocomial Gram-negative bacteria, cytomegalovirus, *Candida*, *Aspergillus*, and *Pneumocystis carinii* are common pathogens. Other postoperative surgical complications include damage to the phrenic, vagus, and left recurrent laryngeal nerves.

Anesthesia for Esophageal Surgery

PREOPERATIVE CONSIDERATIONS

Common indications for esophageal surgery include tumors, gastroesophageal reflux, and motility disorders (achalasia). Surgical procedures include simple endoscopy, esophageal dilatation, cervical esophagomyotomy, open or thoracoscopic distal esophagomyotomy, insertion or removal of esophageal stents, and esophagectomy. Squamous cell carcinomas account for the majority of esophageal tumors; adenocarcinomas are less common, whereas benign tumors (leiomyomas) are rare. Most tumors occur in the distal esophagus. Operative treatment may be palliative or curative. Although the prognosis is generally poor, surgical therapy offers the only hope of a cure. After esophageal resection, the stomach is pulled up into the thorax, or the esophagus is functionally replaced with part of the colon (interposition).

Gastroesophageal reflux is treated surgically when the esophagitis is refractory to medical management or results in complications such as stricture, recurrent pulmonary aspiration, or Barrett's esophagus (columnar epithelium). A variety of antireflux operations may be performed (Nissen, Belsey, Hill, or Collis-Nissen) via thoracic or abdominal approaches, often laparoscopically. They all involve wrapping part of the stomach around the esophagus.

Achalasia and systemic sclerosis (scleroderma) account for the majority of surgical procedures performed for motility disorders. The former usually occurs as an isolated finding, whereas the latter is part of a generalized collagen–vascular disorder. Cricopharyngeal muscle dysfunction can be associated with a variety of neurogenic or myogenic disorders and often results in a Zenker’s diverticulum.

ANESTHETIC CONSIDERATIONS

9 Regardless of the procedure, a common anesthetic concern in patients with esophageal disease is the risk of pulmonary aspiration. This may result from obstruction, altered motility, or abnormal sphincter function. In fact, most patients typically complain of dysphagia, heartburn, regurgitation, coughing, and/or wheezing when lying flat. Dyspnea on exertion may also be prominent when chronic aspiration results in pulmonary fibrosis. Patients with malignancies may present with anemia and weight loss. Esophageal cancer patients usually have a history of cigarette smoking and alcohol consumption, so patients should be evaluated for coexisting chronic obstructive pulmonary disease, coronary artery disease, and liver dysfunction. Patients with systemic sclerosis (scleroderma) should be evaluated for involvement of other organs, particularly the kidneys, heart, and lungs; Raynaud’s phenomena is also common.

In patients with reflux, consideration should be given to administering metoclopramide, an H₂-receptor blocker, or a proton-pump inhibitor preoperatively. In such patients, a rapid-sequence induction should be used. A double-lumen tube is used for procedures involving thoracoscopy or thoracotomy. The anesthesiologist may be asked to pass a large-diameter bougie into the esophagus as part of the surgical procedure; great caution must be exercised to help avoid pharyngeal or esophageal injury.

Transhiatal (blunt) and thoracic esophagectomies deserve special consideration. These procedures often involve considerable blood loss. The former requires an upper abdominal incision and a left cervical incision, whereas the latter requires posterolateral thoracotomy, an abdominal incision, and, finally, a left cervical incision. Parts of the procedure may be performed using laparoscopy or VATS.

Monitoring of arterial and central venous pressure is indicated. Multiple large-bore intravenous access, fluid warmers, and a forced-air body warmer are advisable. During the trans hiatal approach to esophagectomy, substernal and diaphragmatic retractors can interfere with cardiac function. Moreover, as the esophagus is freed up blindly from the posterior mediastinum by blunt dissection, the surgeon’s hand transiently interferes with cardiac filling and produces profound hypotension. The dissection can also induce marked vagal stimulation.

Colonic interposition involves forming a pedicle graft of the colon and passing it through the posterior mediastinum up to the neck to take the place of the esophagus. This procedure is lengthy, and maintenance of an adequate blood pressure, cardiac output, and hemoglobin concentration is necessary to ensure graft viability. Graft ischemia may be heralded by a progressive metabolic acidosis.

Postoperative ventilation will often be used in patients undergoing esophagectomy, because so many of them will have coexisting cardiac and pulmonary disease. Postoperative surgical complications include damage to the phrenic, vagus, and left recurrent laryngeal nerves.

CASE DISCUSSION

Mediastinal Adenopathy

A 9-year-old boy with mediastinal lymphadenopathy seen on a chest radiograph presents for biopsy of a cervical lymph node.

What is the most important preoperative consideration?

Is there any evidence of airway compromise? Tracheal compression may produce dyspnea (proximal obstruction) or a nonproductive cough (distal obstruction).

Asymptomatic compression is also common and may be evident only as tracheal deviation on physical or radiographic examinations. A CT scan of the chest provides invaluable information about the presence, location, and severity of airway compression. Flow–volume loops will also detect

subtle airway obstruction and provide important information regarding the location and functional importance of the obstruction (above).

Does the absence of any preoperative dyspnea make severe intraoperative respiratory compromise less likely?

No. Severe airway obstruction can occur following induction of anesthesia in these patients even in the absence of any preoperative symptoms. This mandates that the chest radiograph and CT scan be reviewed for evidence of asymptomatic airway obstruction. The point of obstruction is typically distal to the tip of the tracheal tube. Moreover, loss of spontaneous ventilation can precipitate complete airway obstruction.

What is the superior vena cava syndrome?

Superior vena cava syndrome is the result of progressive enlargement of a mediastinal mass and compression of mediastinal structures, particularly the vena cava. Lymphomas are most commonly responsible, but primary pulmonary or mediastinal neoplasms can also produce the syndrome. Superior vena cava syndrome is often associated with severe airway obstruction and cardiovascular collapse on induction of general anesthesia. The caval compression produces venous engorgement and edema of the head, neck, and arms. Direct mechanical compression, as well as mucosal edema, severely compromise airflow in the trachea. Most patients favor an upright posture, as recumbency worsens the airway obstruction. Cardiac output may be severely depressed due to impeded venous return from the upper body, direct mechanical compression of the heart, and (with malignancies) pericardial invasion. An echocardiogram is useful in evaluating cardiac function and detecting pericardial fluid.

What is the anesthetic of choice for a patient with superior vena cava syndrome?

The absence of signs or symptoms of airway compression or superior vena cava syndrome does not preclude potentially life-threatening

complications following induction of general anesthesia. Therefore, biopsy of a peripheral node (usually cervical or scalene) under local anesthesia is safest whenever possible. Although establishing a diagnosis is of prime importance, the presence of significant airway compromise or the superior vena cava syndrome may dictate empiric treatment with corticosteroids prior to tissue diagnosis at surgery (cancer is the most common cause); preoperative radiation therapy or chemotherapy may also be considered. The patient can usually safely undergo surgery with general anesthesia once airway compromise and other manifestations of the superior vena cava syndrome are alleviated.

General anesthesia may be indicated for establishing a diagnosis in young or uncooperative patients who have no evidence of airway compromise or the superior vena cava syndrome, and, rarely, for patients unresponsive to steroids, radiation, and chemotherapy.

How does the presence of airway obstruction and the superior vena cava syndrome influence management of general anesthesia?

1. *Premedication:* Only an anticholinergic should be given. The patient should be transported to the operating room in a semiupright position with supplemental oxygen.
2. *Monitoring:* In addition to standard monitors, an arterial line is helpful, but it should be placed after induction in young patients. At least one large-bore intravenous catheter should be placed in a lower extremity, as venous drainage from the upper body may be unreliable.
3. *Airway management:* Difficulties with ventilation and intubation should be anticipated. Following preoxygenation, awake intubation with an armored tracheal tube may be safest in a cooperative patient. Use of a flexible bronchoscope is advantageous in the presence of airway distortion and will define the site and degree of obstruction. Coughing or straining, however, may precipitate complete airway obstruction because the resultant positive pleural pressure increases intrathoracic

tracheal compression. Passing the armored tube beyond the area of compression may obviate this problem. Uncooperative patients require a sevoflurane inhalation induction.

4. *Induction:* The goal should be a smooth induction maintaining spontaneous ventilation and hemodynamic stability. The ability to ventilate the patient with a good airway should be established prior to use of an NMB. Using 100% oxygen, one of three induction techniques can be used: (1) intravenous ketamine (because it results in greater hemodynamic stability in patients with reduced cardiac output); (2) inhalational induction with a volatile agent (usually sevoflurane); or (3) incremental small doses of propofol or etomidate.

Positive-pressure ventilation can precipitate severe hypotension, and volume loading prior to induction may partly offset impaired ventricular filling secondary to caval obstruction.

5. *Maintenance of anesthesia:* The technique selected should be tailored to the patient's hemodynamic status. Following intubation, neuromuscular blockade prevents coughing or straining.
6. *Extubation:* At the end of the procedure, patients should be left intubated until the airway obstruction has resolved, as determined

by flexible bronchoscopy or the presence of an air leak around the tracheal tube when the tracheal cuff is deflated.

Neurophysiology & Anesthesia

KEY CONCEPTS

- 1 Cerebral perfusion pressure is the difference between mean arterial pressure and intracranial pressure (or central venous pressure, whichever is greater).
- 2 The cerebral autoregulation curve is shifted to the right in patients with chronic arterial hypertension.
- 3 The most important extrinsic influences on cerebral blood flow (CBF) are respiratory gas tensions—particularly P_{aCO_2} . CBF is directly proportionate to P_{aCO_2} between tensions of 20 and 80 mm Hg. Blood flow changes approximately 1–2 mL/100 g/min per mm Hg change in P_{aCO_2} .
- 4 CBF changes 5% to 7% per 1°C change in temperature. Hypothermia decreases both cerebral metabolic rate and CBF, whereas pyrexia has the reverse effect.
- 5 The movement of a given substance across the blood–brain barrier is governed simultaneously by its size, charge, lipid solubility, and degree of protein binding in blood.
- 6 The blood–brain barrier may be disrupted by severe hypertension, tumors, trauma, strokes, infection, marked hypercapnia, hypoxia, and sustained seizure activity.
- 7 The cranial vault is a rigid structure with a fixed total volume, consisting of brain (80%), blood (12%), and cerebrospinal fluid (8%). Any increase in one component must be offset by an equivalent decrease in another to prevent a rise in intracranial pressure.
- 8 With the exception of ketamine, all intravenous agents either have little effect on or reduce cerebral metabolic rate and CBF.
- 9 With normal autoregulation and an intact blood–brain barrier, vasopressors increase CBF only when mean arterial blood pressure is below 50–60 mm Hg or above 150–160 mm Hg.
- 10 The brain is very vulnerable to ischemic injury because of its relatively high oxygen consumption and near total dependence on aerobic glucose metabolism.
- 11 Hypothermia is the most effective method for protecting the brain during focal and global ischemia.

Anesthetic agents may have profound effects on cerebral metabolism, blood flow, cerebrospinal fluid (CSF) dynamics, and intracranial volume and pressure. In some instances, these alterations are deleterious, whereas in others they may be

beneficial. This chapter reviews important physiological concepts in anesthetic practice and discusses the effects of commonly used anesthetics on cerebral physiology.

Cerebral Physiology

CEREBRAL METABOLISM

The brain normally consumes 20% of total body oxygen. Most cerebral oxygen consumption (60%) is used to generate adenosine triphosphate (ATP) to support neuronal electrical activity (Figure 26-1). The cerebral metabolic rate (CMR) is usually expressed in terms of oxygen consumption (CMRO_2) and averages 3–3.8 mL/100 g/min (50 mL/min) in adults. CMRO_2 is greatest in the gray matter of the cerebral cortex and generally parallels cortical electrical activity. Because of the relatively high oxygen consumption and the absence of significant oxygen reserves, interruption of cerebral perfusion usually results in unconsciousness within 10 sec, as oxygen tension rapidly drops below 30 mm Hg. If blood flow is not reestablished within 3–8 min under most conditions, ATP stores are depleted, and irreversible cellular injury begins to occur. The hippocampus and cerebellum seem to be most sensitive to hypoxic injury.

Neuronal cells normally utilize glucose as their primary energy source. Brain glucose consumption is approximately 5 mg/100 g/min, of which more than 90% is metabolized aerobically. CMRO_2 therefore normally parallels glucose consumption. This relationship is not maintained during starvation, when ketone bodies (acetoacetate and β -hydroxybutyrate) also become major energy substrates. Although the brain can also take up and metabolize lactate, cerebral function is normally dependent on a continuous supply of glucose. Acute sustained hypoglycemia is injurious to

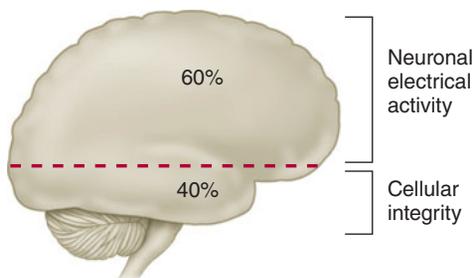

FIGURE 26-1 Normal brain oxygen requirements.

the brain. Paradoxically, hyperglycemia can exacerbate global and focal hypoxic brain injury by accelerating cerebral acidosis and cellular injury. Tight control of perioperative blood glucose concentration has been advocated in part because of adverse effects of hyperglycemia during ischemic episodes; however, overzealous blood glucose control can likewise produce injury through iatrogenic hypoglycemia.

CEREBRAL BLOOD FLOW

Cerebral blood flow (CBF) varies with metabolic activity. There are a variety of methods available to directly measure CBF. These methods include: positron emission tomography, xenon enhanced computed tomography, single photon emission computed tomography, and computed tomography perfusion scans. These methods do not lend themselves to bedside monitoring of CBF. Blood flow studies confirm that regional CBF parallels metabolic activity and can vary from 10–300 mL/100 g/min. For example, motor activity of a limb is associated with a rapid increase in regional CBF of the corresponding motor cortex. Similarly, visual activity is associated with an increase in regional CBF of the corresponding occipital visual cortex.

Although total CBF averages 50 mL/100 g/min, flow in gray matter is about 80 mL/100 g/min, whereas that in white matter is estimated to be 20 mL/100 g/min. Total CBF in adults averages 750 mL/min (15% to 20% of cardiac output). Flow rates below 20–25 mL/100 g/min are usually associated with cerebral impairment, as evidenced by slowing on the electroencephalogram (EEG). CBF rates between 15 and 20 mL/100 g/min typically produce a flat (isoelectric) EEG, whereas rates below 10 mL/100 g/min are usually associated with irreversible brain damage.

Indirect measures are often used to estimate the adequacy of CBF and brain tissue oxygen delivery in clinical settings. These methods include:

- The velocity of CBF can be measured using transcranial Doppler (TCD); see Chapters 5 and 6 for a discussion of the Doppler effect. An ultrasound probe (2 mHz, pulse wave Doppler) is placed in the temporal area above the

zygomatic arch, which allows insonation of the middle cerebral artery. Normal velocity in the middle cerebral artery is approximately 55 cm/sec. Velocities greater than 120 cm/sec can indicate cerebral artery vasospasm following subarachnoid hemorrhage or hyperemic blood flow. Comparison between the velocities in the extracranial internal carotid artery and the middle cerebral artery (the Lindegaard ratio) can distinguish between these conditions. Middle cerebral artery velocity three times that of the velocity measured in the extracranial internal carotid artery more likely reflects cerebral artery vasospasm.

- Near infrared spectroscopy was discussed in Chapter 6. Decreased saturation is associated with impaired cerebral oxygen delivery, although near infrared spectroscopy primarily reflects cerebral venous oxygen saturation.
- Brain tissue oximetry measures the oxygen tension in brain tissue through placement of a bolt with a Clark electrode oxygen sensor. Brain tissue CO_2 tension can also be measured using a similarly placed infrared sensor. Normal brain tissue oxygen tension varies from 20–50 mm Hg. Brain tissue oxygen tensions less than 20 mm Hg warrant interventions, and values less than 10 mm Hg are indicative of brain ischemia.
- Intracerebral microdialysis can be used to measure changes in brain tissue chemistry that are indicative of ischemia and/or brain injury. Microdialysis can be used to measure cerebral lactate, neurotransmitters, markers of inflammation, and glucose concentration. Increases in the ratio of lactate/pyruvate have been associated with cerebral ischemia.

REGULATION OF CEREBRAL BLOOD FLOW

1. Cerebral Perfusion Pressure

1 Cerebral perfusion pressure (CPP) is the difference between mean arterial pressure (MAP) and intracranial pressure (ICP) (or central venous

pressure [CVP], if it is greater than ICP). $\text{MAP} - \text{ICP}$ (or CVP) = CPP. CPP is normally 80–100 mm Hg. Moreover, because ICP is normally less than 10 mm Hg, CPP is primarily dependent on MAP.

Moderate to severe increases in ICP (>30 mm Hg) can compromise CPP and CBF, even in the presence of a normal MAP. Patients with CPP values less than 50 mm Hg often show slowing on the EEG, whereas those with a CPP between 25 and 40 mm Hg typically have a flat EEG. Sustained perfusion pressures less than 25 mm Hg may result in irreversible brain damage.

2. Autoregulation

Much like the heart and kidneys, the brain normally tolerates a wide range of blood pressure, with little change in blood flow. The cerebral vasculature rapidly (10–60 s) adapts to changes in CPP. Decreases in CPP result in cerebral vasodilation, whereas elevations induce vasoconstriction. In normal individuals, CBF remains nearly constant between MAPs of about 60 and 160 mm Hg (**Figure 26–2**). Beyond these limits, blood flow becomes pressure dependent. Pressures above 150–160 mm Hg can disrupt the blood–brain barrier (see below) and may result in cerebral edema and hemorrhage.

2 The cerebral autoregulation curve (**Figure 26–2**) is shifted to the right in patients with chronic

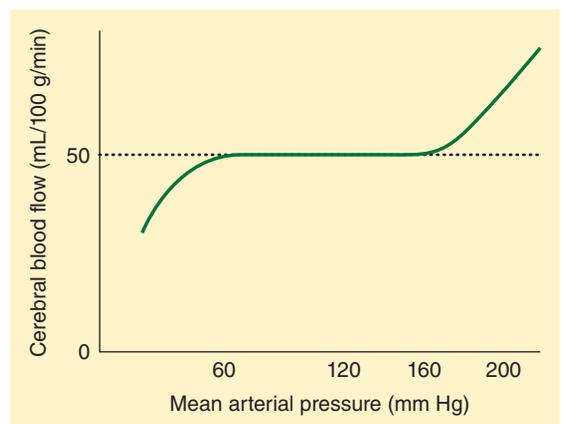

FIGURE 26–2 Normal cerebral autoregulation curve.

arterial hypertension. Both upper and lower limits are shifted. Flow becomes more pressure dependent at low “normal” arterial pressures in return for cerebral protection at higher arterial pressures. Studies suggest that long-term antihypertensive therapy can restore cerebral autoregulation limits toward normal.

Both myogenic and metabolic mechanisms may explain cerebral autoregulation. Myogenic mechanisms involve an intrinsic response of smooth muscle cells in cerebral arterioles to changes in MAP. Metabolic mechanisms indicate that cerebral metabolic demands determine arteriolar tone. Thus, when tissue demand exceeds blood flow, the release of tissue metabolites causes vasodilation and increases flow. Whereas hydrogen ions were once thought to mediate this response, other metabolites are likely involved.

3. Extrinsic Mechanisms

Respiratory Gas Tensions

3 The most important extrinsic influences on CBF are respiratory gas tensions—particularly PaCO_2 . CBF is directly proportionate to PaCO_2 between tensions of 20 and 80 mm Hg (Figure 26-3). Blood flow changes approximately 1–2 mL/100 g/min per mm Hg change in PaCO_2 . This effect is almost immediate and is thought to

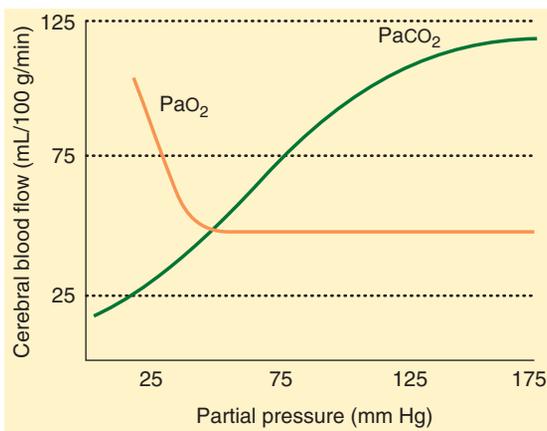

FIGURE 26-3 The relationship between cerebral blood flow and arterial respiratory gas tensions.

be secondary to changes in the pH of CSF and cerebral tissue. Because ions do not readily cross the blood–brain barrier (see below) but CO_2 does, acute changes in PaCO_2 but not HCO_3^- affect CBF. Thus, acute metabolic acidosis has little effect on CBF because hydrogen ions (H^+) cannot readily cross the blood–brain barrier. After 24–48 hr, CSF HCO_3^- concentration adjusts to compensate for the change in PaCO_2 , so that the effects of hypocapnia and hypercapnia are diminished. Marked hyperventilation ($\text{PaCO}_2 < 20$ mm Hg) shifts the oxygen–hemoglobin dissociation curve to the left, and, with changes in CBF, may result in EEG changes suggestive of cerebral impairment, even in normal individuals.

Only marked changes in PaO_2 alter CBF. Whereas hyperoxia may be associated with only minimal decreases (–10%) in CBF, severe hypoxemia ($\text{PaO}_2 < 50$ mm Hg) greatly increases CBF (Figure 26-3).

Temperature

4 CBF changes 5% to 7% per 1°C change in temperature. Hypothermia decreases both CMR and CBF, whereas hyperthermia has the reverse effect. Between 17°C and 37°C , the Q10 for humans is approximately 2—that is, for every 10° increase in temperature, the CMR doubles. Conversely, the CMR decreases by 50% if the temperature of the brain falls by 10°C (eg, from 37°C to 27°C) and another 50% if the temperature decreases from 27°C to 17°C . At 20°C , the EEG is isoelectric, but further decreases in temperature continue to reduce CMR throughout the brain. Hyperthermia (above 42°C) may result in neuronal cell injury.

Viscosity

The most important determinant of blood viscosity is hematocrit. A decrease in hematocrit decreases viscosity and can improve CBF; unfortunately, a reduction in hematocrit also decreases the oxygen-carrying capacity and thus can potentially impair oxygen delivery. Elevated hematocrit, as may be seen with marked polycythemia, increases blood viscosity and can reduce CBF. Some studies suggest

that optimal cerebral oxygen delivery may occur at hematocrits of approximately 30%.

Autonomic Influences

Intracranial vessels are innervated by the sympathetic (vasoconstrictive) and parasympathetic (vasodilatory) systems. Intense sympathetic stimulation induces vasoconstriction in these vessels, which can limit CBF. Autonomic innervation may also play an important role in cerebral vasospasm following brain injury and stroke.

BLOOD–BRAIN BARRIER

Cerebral blood vessels are unique in that the junctions between vascular endothelial cells are nearly fused. The paucity of pores is responsible for what is termed the blood–brain barrier. This lipid barrier allows the passage of lipid-soluble substances, but restricts the movement of those that are ionized or **5** have large molecular weights. Thus, the movement of a given substance across the blood–brain barrier is governed simultaneously by its size, charge, lipid solubility, and degree of protein binding in blood. Carbon dioxide, oxygen, and lipid-soluble molecules (such as most anesthetics) freely enter the brain, whereas most ions, proteins, and large substances (such as mannitol) penetrate poorly.

Water moves freely across the blood–brain barrier as a consequence of bulk flow, whereas movement of even small ions is impeded (the equilibration half-life of Na^+ is 2–4 h). As a result, rapid changes in plasma electrolyte concentrations (and, secondarily, osmolality) produce a transient osmotic gradient between plasma and the brain. Acute hypertonicity of plasma results in net movement of water out of the brain, whereas acute hypotonicity causes a net movement of water into the brain. These effects are short-lived, as equilibration eventually occurs, but, when marked, they can cause rapid fluid shifts in the brain. Mannitol, an osmotically active substance that does not normally cross the blood–brain barrier, causes a sustained decrease in brain water content and is often used to decrease brain volume.

6 The blood–brain barrier may be disrupted by severe hypertension, tumors, trauma, strokes,

infection, marked hypercapnia, hypoxia, and sustained seizure activity. Under these conditions, fluid movement across the blood–brain barrier becomes dependent on hydrostatic pressure rather than osmotic gradients.

CEREBROSPINAL FLUID

CSF is found in the cerebral ventricles and cisterns and in the subarachnoid space surrounding the brain and spinal cord. Its major function is to protect the central nervous system (CNS) against trauma.

Most of the CSF is formed by the choroid plexuses of the cerebral (mainly lateral) ventricles. Smaller amounts are formed directly by the ventricles' ependymal cell linings, and yet smaller quantities are formed from fluid leaking into the perivascular spaces surrounding cerebral vessels (blood–brain barrier leakage). In adults, normal total CSF production is about 21 mL/hr (500 mL/d), yet total CSF volume is only about 150 mL. CSF flows from the lateral ventricles through the intraventricular foramina (of Monro) into the third ventricle, through the cerebral aqueduct (of Sylvius) into the fourth ventricle, and through the median aperture of the fourth ventricle (foramen of Magendie) and the lateral apertures of the fourth ventricle (foramina of Luschka) into the cerebellomedullary cistern (cisterna magna) (**Figure 26–4**). From the cerebellomedullary cistern, CSF enters the subarachnoid space, circulating around the brain and spinal cord before being absorbed in arachnoid granulations over the cerebral hemispheres.

CSF formation involves active secretion of sodium in the choroid plexuses. The resulting fluid is isotonic with plasma despite lower potassium, bicarbonate, and glucose concentrations. Its protein content is limited to the very small amounts that leak into perivascular fluid. Carbonic anhydrase inhibitors (acetazolamide), corticosteroids, spironolactone, furosemide, isoflurane, and vasoconstrictors decrease CSF production.

Absorption of CSF involves the translocation of fluid from the arachnoid granulations into the cerebral venous sinuses. Smaller amounts are absorbed at nerve root sleeves and by meningeal lymphatics.

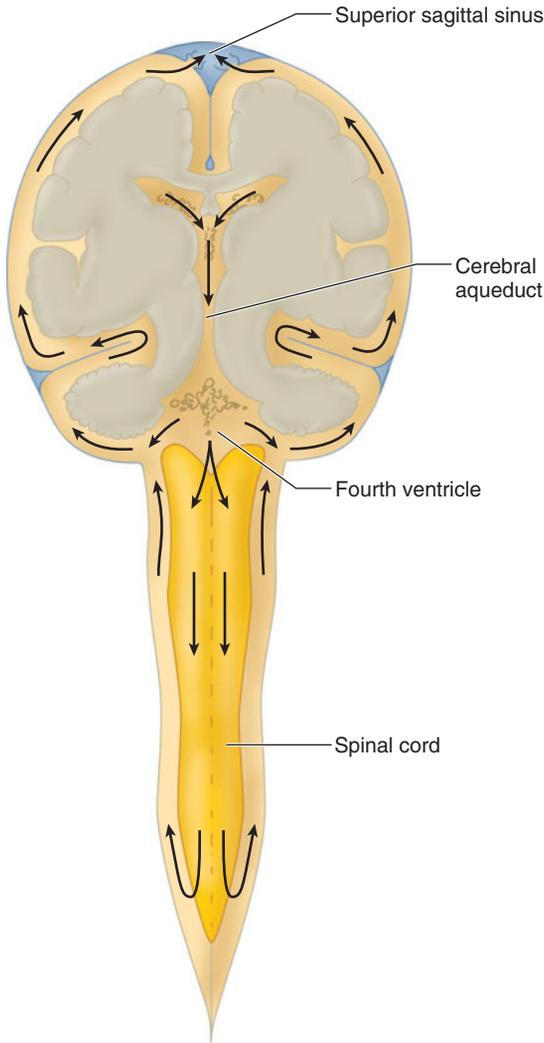

FIGURE 26-4 The flow of cerebrospinal fluid in the central nervous system. (Reproduced, with permission, from Waxman SG: *Correlative Neuroanatomy*, 24th ed. McGraw-Hill, 2000.)

Because the brain and spinal cord lack lymphatics, absorption of CSF is also the principal means by which perivascular and interstitial protein is returned to the blood.

INTRACRANIAL PRESSURE

7 The cranial vault is a rigid structure with a fixed total volume, consisting of brain (80%), blood (12%), and CSF (8%). Any increase in one

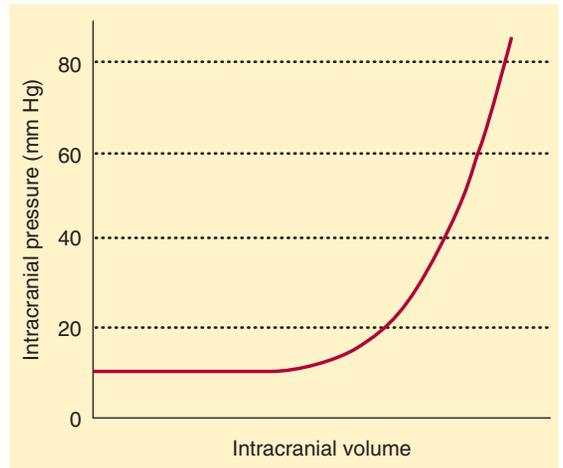

FIGURE 26-5 Normal intracranial elastance.

component must be offset by an equivalent decrease in another to prevent a rise in ICP. By convention, ICP means supratentorial CSF pressure measured in the lateral ventricles or over the cerebral cortex and is normally 10 mm Hg or less. Minor variations may occur, depending on the site measured, but, in the lateral recumbent position, lumbar CSF pressure normally approximates supratentorial pressure.

Intracranial elastance is determined by measuring the change in ICP in response to a change in intracranial volume. Normally, small increases in volume of one component are initially well compensated (**Figure 26-5**). A point is eventually reached, however, at which further increases produce precipitous rises in ICP. Major compensatory mechanisms include: (1) an initial displacement of CSF from the cranial to the spinal compartment, (2) an increase in CSF absorption, (3) a decrease in CSF production, and (4) a decrease in total cerebral blood volume (primarily venous).

The concept of total intracranial compliance is useful clinically, even though compliance probably varies in the different compartments of the brain and is affected by arterial blood pressure and PaCO_2 . Cerebral blood volume is estimated to increase 0.05 mL/100 g of brain per 1 mm Hg increase in PaCO_2 . Blood pressure effects upon cerebral blood volume are dependent on the autoregulation of CBF.

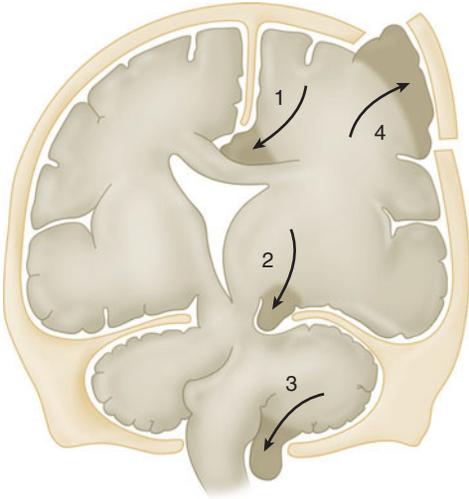

FIGURE 26-6 Potential sites of brain herniation. (Reproduced, with permission, from Fishman RA: Brain edema. *N Engl J Med* 1975;293:706.)

Sustained elevations in ICP can lead to catastrophic herniation of the brain. Herniation may occur at one of four sites (Figure 26-6): (1) the cingulate gyrus under the falx cerebri, (2) the uncinate

gyrus through the tentorium cerebelli, (3) the cerebellar tonsils through the foramen magnum, or (4) any area beneath a defect in the skull (transcalvarial).

Effect of Anesthetic Agents on Cerebral Physiology

Overall, most general anesthetics have a favorable effect on the CNS by reducing electrical activity. Determination of the effects of the specific agents is complicated by the concomitant administration of other drugs, surgical stimulation, intracranial compliance, blood pressure, and CO₂ tension. For example, hypocapnia blunts the increases in CBF and ICP that usually occur with ketamine and volatile agents.

This section describes the changes generally associated with each drug when given alone. Table 26-1 summarizes and compares the effects of the various anesthetics. The effects of vasoactive agents and neuromuscular blocking agents are also discussed.

TABLE 26-1 Comparative effects of anesthetic agents on cerebral physiology.¹

¹↑, increase; ↓, decrease; ±, little or no change; ?, unknown; CMR, cerebral metabolic rate; CBF, cerebral blood flow; CSF, cerebrospinal fluid; CBV, cerebral blood volume; ICP, intracranial pressure.

EFFECT OF INHALATION AGENTS

1. Volatile Anesthetics

Cerebral Metabolic Rate

Halothane, desflurane, sevoflurane, and isoflurane produce dose-dependent decreases in CMR. Isoflurane produces the greatest maximal depression (up to 50% reduction), whereas halothane has the least effect (<25% reduction). The effects of desflurane and sevoflurane seem to be similar to that of isoflurane. No further reduction in CMR is produced by doses of anesthetics or other drugs greater than the doses that render the EEG isoelectric.

Cerebral Blood Flow & Volume

At normocarbida, volatile anesthetics dilate cerebral vessels and impair autoregulation in a dose-dependent manner (Figure 26–7). Halothane has the greatest effect on CBF; at concentrations greater than 1%, it nearly abolishes cerebral autoregulation. Moreover, the increase in blood flow is generalized throughout all parts of the brain. At an equivalent minimum alveolar concentration (MAC) and blood pressure, halothane increases CBF up to 200%,

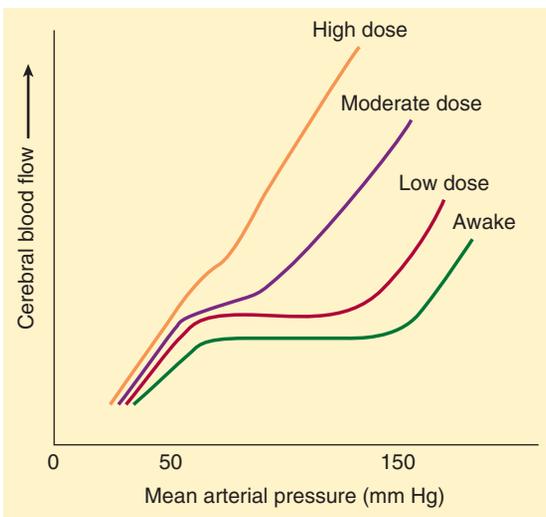

FIGURE 26–7 Dose-dependent depression of cerebral autoregulation by the volatile anesthetics.

compared with 20% for isoflurane. Qualitatively and quantitatively, desflurane may be closest to isoflurane. Sevoflurane produces the least cerebral vasodilation. The effect of volatile agents on CBF also seems to be time dependent, because, with continued administration (2–5 h), blood flow begins to return to normal.

The response of the cerebral vasculature to CO_2 is generally retained with all volatile agents. Hyperventilation (hypocapnia) can therefore abolish or blunt the initial effects of these agents on CBF. With halothane, the timing of the hyperventilation is important. Only if hyperventilation is initiated prior to the administration of halothane will halothane-induced increases in CBF be prevented. In contrast, simultaneous hyperventilation with administration of either isoflurane or sevoflurane can prevent increases in CBF and ICP.

Increases in cerebral blood volume (10% to 12%) generally parallel increases in CBF, but the relationship is not necessarily linear. Expansion of cerebral blood volume can markedly elevate ICP in patients with reduced intracranial compliance. Hypocapnia can blunt the increase in cerebral blood volume associated with volatile anesthetic administration.

Altered Coupling of Cerebral Metabolic Rate & Blood Flow

As is apparent from the discussion above, volatile agents alter, but do not uncouple, the normal relationship of CBF and CMR. The combination of a decrease in neuronal metabolic demand with an increase in CBF (metabolic supply) has been termed luxury perfusion. In contrast to this potentially beneficial effect during global ischemia, a detrimental **circulatory steal phenomenon** is possible with volatile anesthetics in the setting of focal ischemia. Volatile agents can increase blood flow in normal areas of the brain, but not in ischemic areas, where arterioles are already maximally vasodilated. The end result may be a redistribution (“steal”) of blood flow away from ischemic to normal areas.

Cerebrospinal Fluid Dynamics

Volatile anesthetics affect both formation and absorption of CSF. Halothane impedes absorption

of CSF, but only minimally retards formation. Isoflurane, on the other hand, facilitates absorption and is therefore an agent with favorable effects on CSF dynamics.

Intracranial Pressure

The net effect of volatile anesthetics on ICP is the result of immediate changes in cerebral blood volume, delayed alterations on CSF dynamics, and arterial CO₂ tension. Based on these factors, isoflurane and sevoflurane seem to be the volatile agents of choice in patients with decreased intracranial compliance.

2. Nitrous Oxide

The effects of nitrous oxide are influenced by other agents or changes in CO₂ tension. Thus, when combined with intravenous agents, nitrous oxide has minimal effects on CBF, CMR, and ICP. Adding this agent to a volatile anesthetic, however, can further increase CBF. When given alone, nitrous oxide causes mild cerebral vasodilation and can potentially increase ICP.

EFFECT OF INTRAVENOUS AGENTS

1. Induction Agents

8 With the exception of ketamine, all intravenous agents either have little effect on or reduce CMR and CBF. Moreover, with some exceptions, changes in blood flow generally parallel those in metabolic rate. Cerebral autoregulation and CO₂ responsiveness are preserved with all agents.

Barbiturates

Barbiturates have four major actions on the CNS: (1) hypnosis, (2) depression of CMR, (3) reduction of CBF due to increased cerebral vascular resistance, and (4) anticonvulsant activity. Barbiturates produce dose-dependent decreases in CMR and CBF until the EEG becomes isoelectric. At that point, maximum reductions of nearly 50% are observed; additional barbiturate dosing does not further reduce metabolic rate. Unlike isoflurane,

barbiturates reduce metabolic rate uniformly throughout the brain. CMR is depressed slightly more than CBF, such that metabolic supply exceeds metabolic demand (as long as CPP is maintained). Because barbiturate-induced cerebral vasoconstriction occurs only in normal areas, these agents tend to redistribute blood flow from normal to ischemic areas in the brain (Robin Hood, or reverse steal phenomenon). The cerebral vasculature in ischemic areas remains maximally dilated and is less affected by the barbiturate because of ischemic vasomotor paralysis.

Barbiturates also seem to facilitate absorption of CSF. The resultant reduction in CSF volume, combined with decreases in CBF and cerebral blood volume, makes barbiturates highly effective in lowering ICP. Their anticonvulsant properties are also advantageous in neurosurgical patients who are at increased risk of seizures.

Opioids

Opioids generally have minimal effects on CBF, CMR, and ICP, unless PaCO₂ rises secondary to respiratory depression. Increases in ICP have been reported in some patients with intracranial tumors following administration of sufentanil and to a lesser degree, alfentanil. The mechanism seems to be a precipitous drop in blood pressure; reflex cerebral vasodilation likely increases intracranial blood volume and potentially ICP. Significant decreases in blood pressure can adversely affect CPP, regardless of the opioid selected. In addition, small doses of alfentanil (<50 mg/kg) can activate seizure foci in patients with epilepsy. Morphine is generally not considered optimal as a component of anesthesia for intracranial surgery. Morphine's poor lipid solubility results in slow CNS penetration and prolonged sedative effects. Normeperidine, a metabolite of meperidine, can induce seizures, particularly in patients with renal failure. The accumulation of normeperidine and the associated cardiac depression limit the use of meperidine, except in small doses to treat shivering.

Etomidate

Etomidate decreases the CMR, CBF, and ICP in much the same way as thiopental. Its effect on CMR

is nonuniform, affecting the cortex more than the brainstem. Its limited effect on the brainstem may be responsible for greater hemodynamic stability during anesthesia induction, compared with that of barbiturates. Etomidate also decreases production and enhances absorption of CSF.

Induction with etomidate is associated with a relatively high incidence of myoclonic movements, but these movements are not associated with seizure activity on the EEG in normal individuals. The drug has been used to treat seizures, but reports of seizure activity following etomidate suggest that the drug is best avoided in patients with a history of epilepsy. In fact, small doses of etomidate can activate seizure foci in patients with epilepsy.

Propofol

Propofol reduces CBF and CMR, similar to barbiturates and etomidate; however, the decrease in CBF may exceed that in metabolic rate. Although it has been associated with dystonic and choreiform movements, propofol seems to have significant anticonvulsant activity. Moreover, its short elimination half-life makes it a useful agent for neuroanesthesia. Propofol infusion is commonly used for maintenance of anesthesia in patients with or at risk of intracranial hypertension. Propofol is by far the most common induction agent for neuroanesthesia.

Benzodiazepines

Benzodiazepines lower CBF and CMR, but to a lesser extent than barbiturates, etomidate, or propofol. Benzodiazepines also have useful anticonvulsant properties. Midazolam is the benzodiazepine of choice in neuroanesthesia because of its short half-life. Midazolam used as an induction agent frequently causes decreases in CPP in elderly and unstable patients and may result in prolonged emergence.

Ketamine

Ketamine is the only intravenous anesthetic that dilates the cerebral vasculature and increases CBF (50% to 60%). Selective activation of certain areas (limbic and reticular) is partially offset by depression of other areas (somatosensory and

auditory) such that total CMR does not change. Seizure activity in thalamic and limbic areas is also described. Ketamine may also impede absorption of CSF without affecting formation. Increases in CBF, cerebral blood volume, and CSF volume can potentially increase ICP markedly in patients with decreased intracranial compliance. However, ketamine administration does not increase ICP in neurologically impaired patients under controlled ventilation with concomitant administration of propofol or a benzodiazepine. Additionally, ketamine may offer neuroprotective effects, according to some investigations. Ketamine's blockade of the *N*-methyl-D-aspartate (NMDA) receptor during periods of increased glutamate concentrations, as occurs during brain injury, may be protective against neuronal cell death (Figure 26-8).

2. Anesthetic Adjuncts

Intravenous lidocaine decreases CMR, CBF, and ICP, but to a lesser degree than other agents. Its principal advantage is that it decreases CBF (by increasing cerebral vascular resistance) without causing other significant hemodynamic effects. Lidocaine may also have neuroprotective effects. Lidocaine infusions are used in some centers as a supplement to general anesthesia to reduce emergence delirium and the requirement for opioids.

Droperidol has little or no effect on CMR and minimally reduces CBF. When used in larger doses with an opioid as part of a neuroleptic technique, droperidol may sometimes cause undesirable prolonged sedation. Droperidol and narcotics were once mainstays of neuroanesthesia. Droperidol's prolongation of the QT interval and risk of fatal arrhythmia, as well as official warnings related to the drug, have retarded its use.

Reversal of opioids or benzodiazepines with naloxone or flumazenil, respectively, can reverse any beneficial reductions in CBF and CMR. Reversal of narcotics or benzodiazepines in chronic users can lead to symptoms of substance withdrawal.

3. Vasopressors

9 With normal autoregulation and an intact blood-brain barrier, vasopressors increase

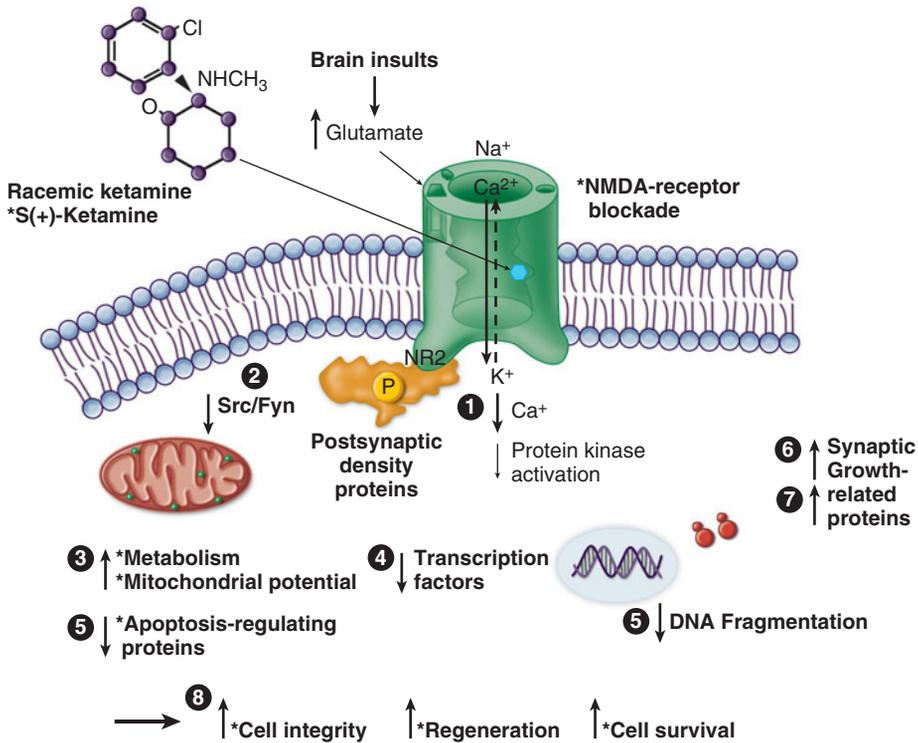

FIGURE 26-8 Pharmacological effects reported for racemic and S(+)-ketamine which are presumed to be relevant for neuroprotection. After onset of brain injury, blockade of excessive stimulation of N-methyl-D-aspartate (NMDA) receptors by ketamine reduces calcium influx through the receptor channel (1). This attenuates supraphysiological increases in the assembly and interaction of NMDA receptor subunits, postsynaptic density proteins, and other intracellular signaling systems such as protein kinases (2). Thus, several kinase transduction cascades become less activated. This improves preservation of metabolism and maintenance of the mitochondrial transmembrane potential (3). This,

in turn, reduces pathological activation of transcription factors (4). Proteins involved in apoptosis are less activated, which is associated with less DNA fragmentation (5). A better preservation of synaptic proteins occurs, and the expression of growth proteins indicating regeneration in adult neurons is enhanced. The prevention of pathological amplification of NMDA receptor signaling finally results in increased cellular survival, preserved cellular and synaptic integrity, and regenerative efforts. *Superiority of effects induced by S(+)-ketamine, only. (Reproduced, with permission, from Himmelseher S, Durieux ME: Revising a dogma: ketamine for patients with neurological injury? *Anesth Analg* 2005;101:524.)

CBF only when mean arterial blood pressure is below 50–60 mm Hg or above 150–160 mm Hg. In the absence of autoregulation, vasopressors increase CBF by their effect on CPP. Changes in CMR generally parallel those in blood flow. β -Adrenergic agents seem to have a greater effect on the brain when the blood–brain barrier is disrupted; central β_1 -receptor stimulation increases CMR and blood flow. β -Adrenergic blockers generally have no direct

effect on CMR or CBF, whereas α_2 -adrenergic agonists produce cerebral vasoconstriction. Excessive elevations in blood pressure with any agent can disrupt the blood–brain barrier.

4. Vasodilators

In the absence of hypotension, most vasodilators induce cerebral vasodilation and increase CBF in a

dose-related fashion. When these agents decrease blood pressure, CBF is usually maintained and may even increase. The resultant increase in cerebral blood volume can significantly elevate ICP in patients with decreased intracranial compliance. Of this group of drugs, only the ganglionic blocker trimethaphan has little or no effect on CBF and cerebral blood volume. Trimethaphan is no longer available in the United States.

5. Neuromuscular Blocking Agents

Neuromuscular blockers (NMBs) lack direct action on the brain but can have important secondary effects. Hypertension and histamine-mediated cerebral vasodilation increase ICP, whereas systemic hypotension (from histamine release or ganglionic blockade) lowers CPP. Succinylcholine can increase ICP, possibly as a result of cerebral activation associated with enhanced muscle spindle activity, but the increase is generally minimal and clinically unimportant, if an adequate dose of propofol is given and hyperventilation is initiated at induction. Moreover, a small (defasciculating) dose of a nondepolarizing NMB seems to blunt the increase, at least partially. In the majority of instances, increases in ICP following administration of an NMB are the result of a hypertensive response due to light anesthesia during laryngoscopy and tracheal intubation. Acute elevations in ICP will also be seen, if hypercapnia or hypoxemia results from prolonged apnea.

Physiology of Brain Protection

PATHOPHYSIOLOGY OF CEREBRAL ISCHEMIA

10 The brain is very vulnerable to ischemic injury because of its relatively high oxygen consumption and near total dependence on aerobic glucose metabolism (above). Interruption of cerebral perfusion, metabolic substrate (glucose), or severe hypoxemia rapidly results in functional impairment; reduced perfusion also impairs clearance of potentially toxic metabolites. If normal

oxygen tension, blood flow, and glucose supply are not reestablished within 3–8 min under most conditions, ATP stores are depleted, and irreversible neuronal injury begins. When CBF decreases below 10 mL/100 g/min, cell function is deranged, and ion pumps fail to maintain cellular vitality. The ratio of lactate to pyruvate is increased secondary to anaerobic metabolism. During ischemia, intracellular K^+ decreases, and intracellular Na^+ increases. More importantly, intracellular Ca^{2+} increases because of failure of ATP-dependent pumps to either extrude the ion extracellularly or into intracellular cisterns, increased intracellular Na^+ concentration, and release of the excitatory neurotransmitter glutamate. Glutamate acts at the NMDA receptor, further enhancing Ca^{2+} entry into the cell, hence the potential benefit of NMDA blockers for neuroprotection.

Sustained increases in intracellular Ca^{2+} activate lipases and proteases, which initiate and propagate structural damage to neurons. Increases in free fatty acid concentration and cyclooxygenase and lipoxigenase activities result in the formation of prostaglandins and leukotrienes, some of which are potent mediators of cellular injury. Accumulation of toxic metabolites, such as lactic acid, also impairs cellular function and interferes with repair mechanisms. Lastly, reperfusion of ischemic tissues can cause additional tissue damage due to the formation of oxygen-derived free radicals. Likewise, inflammation and edema can promote further neuronal damage, leading to cellular apoptosis.

STRATEGIES FOR BRAIN PROTECTION

Ischemic brain injury is usually classified as focal (incomplete) or global (complete). Global ischemia includes total circulatory arrest as well as global hypoxia. Cessation of perfusion may be caused by cardiac arrest or deliberate circulatory arrest, whereas global hypoxia may be caused by severe respiratory failure, drowning, and asphyxia (including anesthetic mishaps). Focal ischemia includes embolic, hemorrhagic, and atherosclerotic strokes, as well as blunt, penetrating, and surgical trauma.

In some instances, interventions aimed at restoring perfusion and oxygenation are possible; these include reestablishing effective circulation, normalizing arterial oxygenation and oxygen-carrying capacity, or reopening an occluded vessel. With focal ischemia, the brain tissue surrounding a severely damaged area may suffer marked functional impairment but still remain viable. Such areas are thought to have very marginal perfusion (<15 mL/100 g/min), but, if further injury can be limited and normal flow is rapidly restored, these areas (the “ischemic penumbra”) may recover completely. When the above interventions are not applicable or available, the emphasis must be on limiting the extent of brain injury.

From a practical point of view, efforts aimed at preventing or limiting neuronal tissue damage are often the same whether the ischemia is focal or global. Clinical goals are usually to optimize CPP, decrease metabolic requirements (basal and electrical), and possibly block mediators of cellular injury. Clearly, the most effective strategy is prevention, because once injury has occurred, measures aimed at cerebral protection become less effective.

Hypothermia

11 Hypothermia is an effective method for protecting the brain during focal and global ischemia. Indeed, profound hypothermia is often used for up to 1 hr of total circulatory arrest. Unlike anesthetic agents, hypothermia decreases both basal and electrical metabolic requirements throughout the brain; metabolic requirements continue to decrease even after complete electrical silence. Additionally, hypothermia reduces free radicals and other mediators of ischemic injury. Induced hypothermia has shown benefit following cardiac arrest and is a routine part of most postarrest protocols for comatose patients.

Anesthetic Agents

Barbiturates, etomidate, propofol, and isoflurane can produce complete electrical silence of the brain and eliminate the metabolic cost of electrical activity; unfortunately, these agents have no effect on basal energy requirements. Furthermore, with the exception of barbiturates, their effects are nonuniform,

affecting different parts of the brain to variable extents.

Ketamine may also have a protective effect because of its ability to block the actions of glutamate at the (NMDA) receptor.

No anesthetic agent has consistently been shown to be protective against global ischemia. The ever increasing number of studies highlighting the potential neurotoxicity of anesthetics (especially in infants) also questions the role of volatile anesthetics in neuroprotection.

Specific Adjuncts

Nimodipine plays a role in the in the treatment of vasospasm associated with subarachnoid hemorrhage. Studies are ongoing to discern the roles of various NMDA receptor antagonists, erythropoietin, Ca^{2+} antagonists, and free radical scavengers to mitigate ischemic neuronal injury.

General Measures

Maintenance of a satisfactory CPP is critical. Thus, arterial blood pressure should be normal or slightly elevated, and increases in venous and ICP should be avoided. Oxygen-carrying capacity should be maintained and normal arterial oxygen tension preserved. Hyperglycemia aggravates neurological injuries following either focal or global ischemia, and blood glucose should be maintained at less than 180 mg/dL. Normocarbica should be maintained, as both hypercarbia and hypocarbica have no beneficial effect in the setting of ischemia and could prove detrimental; hypocarbica-induced cerebral vasoconstriction may aggravate the ischemia, whereas hypercarbia may induce a steal phenomenon (with focal ischemia) or worsen intracellular acidosis.

EFFECT OF ANESTHESIA ON ELECTROPHYSIOLOGICAL MONITORING

Electrophysiological monitors are used to assess the functional integrity of the CNS. The most commonly used monitor for neurosurgical procedures is evoked potentials. EEG is much less commonly used. Proper application of these monitoring modalities

TABLE 26–2 Electroencephalographic changes during anesthesia.

Activation	Depression
Inhalational agents (subanesthetic)	Inhalation agents (1–2 MAC)
Barbiturates (small doses)	Barbiturates
Benzodiazepines (small doses)	Opioids
Etomidate (small doses)	Propofol
Nitrous oxide	Etomidate
Ketamine	Hypocapnia
Mild hypercapnia	Marked hypercapnia
Sensory stimulation	Hypothermia
Hypoxia (early)	Hypoxia (late) Ischemia

is critically dependent on monitoring the specific area at risk and recognizing anesthetic-induced changes. Both monitoring modalities are described in Chapter 6.

The effects of anesthetic agents on the EEG are summarized in [Table 26–2](#).

ELECTROENCEPHALOGRAPHY

EEG monitoring is useful for assessing the adequacy of cerebral perfusion during carotid endarterectomy (CEA), as well as anesthetic depth (most often with processed EEG). EEG changes can be simplistically described as either activation or depression. EEG activation (a shift to predominantly high-frequency and low-voltage activity) is seen with light anesthesia and surgical stimulation, whereas EEG depression (a shift to predominantly low-frequency and high-voltage activity) occurs with deep anesthesia or cerebral compromise. **Most anesthetics produce an EEG consisting of an initial activation (at subanesthetic doses) followed by dose-dependent depression.**

Inhalation Anesthetics

Isoflurane can produce an isoelectric EEG at high clinical doses (1–2 MAC). **Desflurane and**

sevoflurane produce a burst suppression pattern at high doses (>1.2 and >1.5 MAC, respectively) but not electrical silence. Nitrous oxide is also unusual in that it increases both frequency and amplitude (high-amplitude activation).

Intravenous Agents

Benzodiazepines can produce both activation and depression of the EEG. Barbiturates, etomidate, and propofol produce a similar pattern and are the only intravenous agents capable of producing burst suppression and electrical silence at high doses. In contrast, opioids characteristically produce only dose-dependent depression of the EEG. Lastly, ketamine produces an unusual activation consisting of rhythmic high-amplitude theta activity followed by very high-amplitude gamma and low-amplitude beta activities.

EVOKED POTENTIALS

Somatosensory evoked potentials test the integrity of the spinal dorsal columns and the sensory cortex and may be useful during resection of spinal tumors, instrumentation of the spine, CEA, and aortic surgery. The adequacy of perfusion of the spinal cord during aortic surgery is probably better assessed with motor evoked potentials (which assess the anterior part of the spinal cord). Brainstem auditory evoked potentials test the integrity of the eighth cranial nerve and the auditory pathways above the pons and are used for surgery in the posterior fossa. Visual evoked potentials may be used to monitor the optic nerve and occipital cortex during resections of large pituitary tumors.

Interpretation of evoked potentials is more complicated than that of the EEG. Evoked potentials have poststimulus latencies that are described as short, intermediate, and long. Short-latency evoked potentials arise from the nerve stimulated or the brain stem. Intermediate- and long-latency evoked potentials are primarily of cortical origin. In general, short-latency potentials are least affected by anesthetic agents, whereas long-latency potentials are affected by even subanesthetic levels of most agents. Visual evoked potentials are most affected by anesthetics, whereas brain stem auditory evoked potentials are least affected.

Intravenous agents in clinical doses generally have less marked effects on evoked potentials than do volatile agents, but, in high doses, can also decrease amplitude and increase latencies (see Chapter 6).

CASE DISCUSSION

Postoperative Hemiplegia

A 62-year-old man has undergone a right carotid endarterectomy (CEA). Immediately following surgery, in the recovery room, he is noted to be weak on the contralateral side.

How is a patient undergoing CEA evaluated preoperatively?

Patients with cerebrovascular disease, and, in particular, carotid stenosis are at very high risk of coronary artery and peripheral arterial disease. It would be unusual for a patient to have carotid stenosis who did not have evidence of atherosclerosis elsewhere. Patients undergoing CEA, therefore, require a preoperative cardiac evaluation, according to American College of Cardiology/American Heart Association guidelines.

With respect to patient risk factors, the guidelines provide algorithms for how patients should be evaluated and managed intraoperatively. As part of this patient's preoperative evaluation, a thorough neurological examination should have been performed with special attention paid to motor function. This patient may well have been weak on the left side prior to surgery, in which case the hemiparesis might be due to a preexisting condition. If this is a new finding, it requires aggressive management.

Is general or regional anesthesia the optimal anesthetic technique for managing patients undergoing CEA?

For the past several decades, the majority of patients undergoing CEAs in the United States have had general anesthesia. General anesthesia was chosen because many surgeons operating in the neck area felt more comfortable if the airway was controlled, and the patient was completely

anesthetized should evidence of cerebral ischemia develop.

More recently, regional anesthesia has been advocated as providing an adequate surgical field, a comfortable and relaxed patient (if done with monitored anesthesia care), stable hemodynamics, and ideal monitoring of cerebral function during crossclamping because an awake patient provides the best evidence of adequate cerebral perfusion. The patient can indicate or be observed for evidence of aphasia, facial droop, or hemiparesis. Regional anesthesia is usually performed with superficial cervical plexus blocks.

How should cerebral function be monitored intraoperatively in this patient?

When the carotid is crossclamped, the ability to identify inadequate cerebral circulation in the ipsilateral hemisphere is critical, as there is a window of opportunity for immediate intervention and correction of any deficit.

Global and focal neurological status can continuously be assessed in awake patients, if the patient is mildly sedated when undergoing regional anesthesia. In such a situation, practical assessment consists of frequent (every 2–5 min) examination of strength using the contralateral handgrip and maintenance of constant verbal contact with the patient to assess level of consciousness.

In patients undergoing general anesthesia, indirect cerebral monitoring techniques have been used to assess the adequacy of the cerebral circulation. These techniques include stump bleeding, stump pressure, jugular venous oxygen saturation, EEG, a processed EEG (such as the bispectral index or evoked potentials), TCD, arteriography, and measurement of blood flow using xenon. Back bleeding of the distal carotid artery following crossclamp and incision of the artery suggests reasonable collateral circulation above the clamp. It is very subjective and nonquantitative.

To better qualify and quantify the adequacy of collateral perfusion (Figure 26–9), stump pressure measurements can be used. Some surgeons

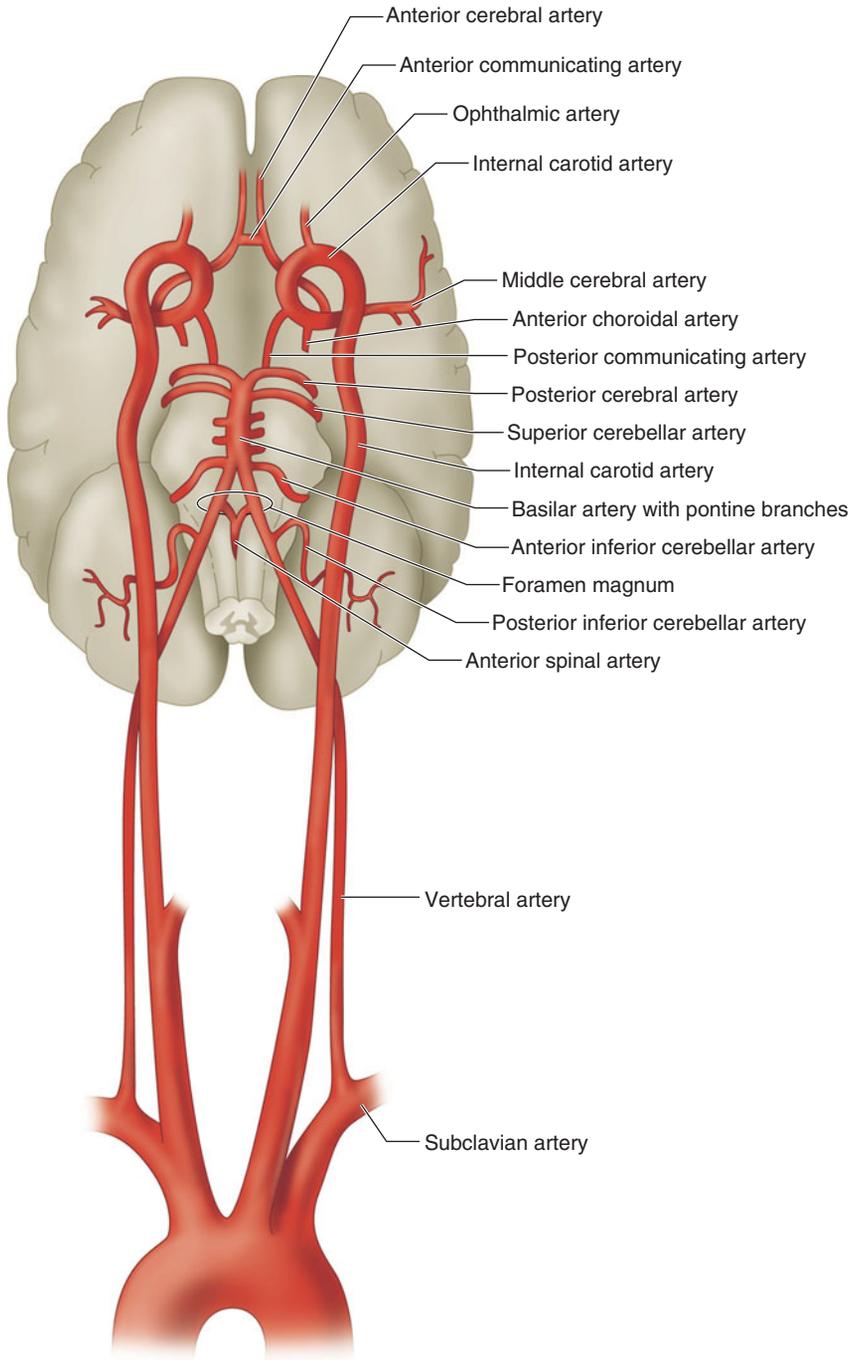

FIGURE 26-9 The cerebral circulation.

believe that a shunt should be used in all patients with a previous cerebrovascular accident, independent of stump pressure, and for any patient whose stump pressure is less than 25 mm Hg. However, this is controversial, as many neurosurgeons and vascular surgeons use 50 mm Hg as a cutoff.

The EEG is sometimes used for monitoring patients undergoing CEA under general anesthesia. In such a circumstance, inhalation or intravenous anesthesia can influence the EEG, but gross changes associated with carotid clamping can be detected. However, analyzing the EEG is labor and technology intensive and requires interpretation of the data.

For this reason, techniques that employ a processed EEG (eg, the bispectral index monitor) are being explored as a monitor for cerebral ischemia. Evoked potentials, such as auditory and visual evoked potentials, have also been examined, but do not seem to have significant clinical application.

Jugular venous oxygen saturation has been studied in an attempt to identify the acute onset of cerebral ischemia. Because it is a global measure, it does not reflect regional, or, in particular, focal cerebral ischemia and therefore is not used for routine clinical practice. TCD ultrasonography provides noninvasive assessment of blood flow in the middle cerebral artery.

How should hemodynamics be controlled intraoperatively?

During carotid clamping and immediately afterward in the recovery room, patients are often hemodynamically labile. **Bradycardia can develop during surgical manipulation of the carotid sinus because of the direct stimulation of the vagus nerve.** Tachycardia may develop as a result of stress or pain or as a direct result of manipulation of the carotid sinus with release of catecholamines into the circulation.

Hypotension is also observed because of the direct vasodilating and negative inotropic effects of anesthetic agents. Hypotension following carotid unclamping is common, particularly

in patients with more severe carotid stenosis. This could be due to a cerebral protective process. Cerebral autoregulation protects the brain from reperfusion by reducing cerebral production of renin, vasopressin, and norepinephrine, which results in hypotension. Hypertension is also a frequent finding in patients undergoing CEA. Many patients have hypertension as a comorbid condition, which is often further exacerbated by the surgical stress and manipulation of the carotid body, which causes release of catecholamines and sympathetic stimulation.

Invasive arterial pressure monitoring and suitable venous access to infuse vasoactive medications are necessary during carotid surgery.

What is the most likely etiology of this patient's findings?

This patient most likely has had a cerebrovascular accident due to an arterio-to-arterial embolus; more than 95% of patients will fit into this category. Weakness can also develop as a result of a hyperperfusion syndrome, which occurs in patients with severe carotid stenosis who have now reestablished flow to the affected cerebral hemisphere. Such patients usually have a greater than 95% carotid stenosis with a less than 1-mm channel in the affected carotid artery. Typically, the syndrome does not develop in the postoperative anesthesia care unit (PACU), but several hours afterward when the patient begins complaining of a headache, and, in severe cases, develops hemiparesis.

Because a cerebrovascular accident is most likely, when the anesthesiologist is called to see such a patient in the PACU, a thorough neurological examination quantifying any cranial nerve involvement and the degree of weakness on the contralateral side should be performed. Any hemodynamic changes need to be treated immediately, with assurance of adequate hemoglobin and oxygenation levels. Ultrasonic evaluation of the carotid artery is frequently required. The surgeon needs to be notified at once, as it may be necessary to return to the operating room to explore the carotid artery.

Anesthesia for Neurosurgery

KEY CONCEPTS

- 1 Regardless of the cause, intracranial masses present according to growth rate, location, and intracranial pressure. Slowly growing masses are frequently asymptomatic for long periods (despite relatively large size), whereas rapidly growing ones may present when the mass remains relatively small.
- 2 Computed tomographic and magnetic resonance imaging scans should be reviewed for evidence of brain edema, a midline shift greater than 0.5 cm, and ventricular displacement or compression.
- 3 Operations in the posterior fossa can injure vital circulatory and respiratory brainstem centers, as well as cranial nerves or their nuclei.
- 4 Venous air embolism can occur when the pressure within an open vein is subatmospheric. These conditions may exist in any position (and during any procedure) whenever the wound is above the level of the heart.
- 5 Optimal recovery of air following venous air embolism is provided by a multiorificed catheter positioned at the junction between the right atrium and the superior vena cava. Confirmation of correct catheter positioning can be accomplished by intravascular electrocardiography, radiography, or transesophageal echocardiography.
- 6 In a patient with head trauma, correction of hypotension and control of any bleeding take precedence over radiographic studies and definitive neurosurgical treatment because systolic arterial blood pressures of less than 80 mm Hg predict a poor outcome.
- 7 Massive blood loss from injuries to the great vessels can occur intraoperatively with thoracic or lumbar spine procedures.

Anesthetic techniques must be modified in the presence of intracranial hypertension and marginal cerebral perfusion. In addition, many neurosurgical procedures require patient positions (eg, sitting, prone) that further complicate management. This chapter applies the principles developed in Chapter 26 to the anesthetic care of neurosurgical patients.

Intracranial Hypertension

Intracranial hypertension is defined as a sustained increase in intracranial pressure (ICP) above 15 mm Hg. Intracranial hypertension may result from an expanding tissue or fluid mass, a depressed skull fracture, interference with normal absorption

of cerebrospinal fluid (CSF), excessive cerebral blood volume (CBV), or systemic disturbances promoting brain edema (see below). Multiple factors are often simultaneously present. For example, tumors in the posterior fossa usually are not only associated with some degree of brain edema and mass effect, but they also readily obstruct CSF outflow by compressing the fourth ventricle (obstructive hydrocephalus).

Although many patients with increased ICP are initially asymptomatic, they typically develop characteristic symptoms and signs, including headache, nausea, vomiting, papilledema, focal neurological deficits, and altered consciousness. When ICP exceeds 30 mm Hg, cerebral blood flow (CBF) progressively decreases, and a vicious circle is established: ischemia causes brain edema, which in turn, increases ICP, resulting in more ischemia. If left unchecked, this cycle continues until the patient dies of progressive neurological damage or catastrophic herniation. **Periodic increases in arterial blood pressure with reflex slowing of the heart rate (Cushing response) can be correlated with abrupt increases in ICP (plateau or A waves) lasting 1–15 min.** This phenomenon is the result of autoregulatory mechanisms periodically decreasing cerebral vascular resistance and increasing arterial blood pressure in response to cerebral ischemia; unfortunately, the latter further increases ICP as CBV increases. Eventually, severe ischemia and acidosis completely abolish autoregulation (vasomotor paralysis).

CEREBRAL EDEMA

An increase in brain water content can be produced by several mechanisms. Disruption of the blood–brain barrier (vasogenic edema) is most common and allows the entry of plasma-like fluid into the brain. Increases in blood pressure enhance the formation of this type of edema. Common causes of vasogenic edema include mechanical trauma, high altitudes, inflammatory lesions, brain tumors, hypertension, and infarction. Cerebral edema following metabolic insults (cytotoxic edema), such as hypoxemia or ischemia, results from failure of brain cells to actively extrude sodium causing progressive cellular swelling. Interstitial cerebral edema is the result

of obstructive hydrocephalus and entry of CSF into brain interstitium. Cerebral edema can also be the result of intracellular movement of water secondary to acute decreases in serum osmolality (water intoxication).

TREATMENT

Treatment of intracranial hypertension and cerebral edema is ideally directed at the underlying cause. Metabolic disturbances are corrected, and operative intervention is undertaken whenever appropriate. Vasogenic edema—particularly that associated with tumors—often responds to corticosteroids (dexamethasone). Vasogenic edema from trauma typically does not respond to corticosteroids. Blood glucose should be monitored frequently and controlled with insulin infusions (if indicated) when steroids are used. Regardless of the cause, fluid restriction, osmotic agents, and loop diuretics are usually effective in temporarily decreasing brain edema and ICP until more definitive measures can be undertaken. Diuresis lowers ICP chiefly by removing intracellular water from normal brain tissue. Moderate hyperventilation (P_{aCO_2} of 30–33 mm Hg) is often very helpful in reducing CBF, CBV, and ICP acutely, but may aggravate ischemia in patients with focal ischemia.

Mannitol, in doses of 0.25–0.5 g/kg, is particularly effective in rapidly decreasing intracranial fluid volume and ICP. Its efficacy is primarily related to its effect on serum osmolality. A serum osmolality of 300–315 mOsm/L is generally considered desirable. Mannitol can transiently decrease blood pressure by virtue of its weak vasodilating properties, but its principal disadvantage is a transient increase in intravascular volume, which can precipitate pulmonary edema in patients with borderline cardiac or renal function. Mannitol should generally not be used in patients with intracranial aneurysms, arteriovenous malformations (AVMs), or intracranial hemorrhage until the cranium is opened. Osmotic diuresis in such instances can expand a hematoma as the volume of the normal brain tissue around it decreases. Rapid osmotic diuresis in elderly patients can also occasionally cause a subdural hematoma due to rupture of fragile bridging veins entering the sagittal sinus. Rebound edema may follow the use of mannitol; thus, it is ideally used in procedures (such

as a craniotomy for tumor resection) in which intracranial volume will be reduced.

Use of a loop diuretic (furosemide), although having a lesser maximal effect than mannitol and requiring up to 30 min, may have the additional advantage of directly decreasing formation of CSF. The combined use of mannitol and furosemide may be synergistic, but requires close monitoring of the serum potassium concentration.

Anesthesia & Craniotomy for Patients with Mass Lesions

Intracranial masses may be congenital, neoplastic (benign or malignant), infectious (abscess or cyst), or vascular (hematoma or arteriovenous malformation). Craniotomy is commonly undertaken for neoplasms of the brain. Primary tumors usually arise from glial cells (astrocytoma, oligodendroglioma, or glioblastoma), ependymal cells (ependymoma), or supporting tissues (meningioma, schwannoma, or choroidal papilloma). Childhood tumors include medulloblastoma, neuroblastoma, and astrocytoma.

1 Regardless of the cause, intracranial masses present according to growth rate, location, and ICP. Slowly growing masses are frequently asymptomatic for long periods (despite relatively large size), whereas rapidly growing ones may present when the mass remains relatively small. Common presentations include headache, seizures, a general decline in cognitive or specific neurological functions, and focal neurological deficits. Symptoms typical to supratentorial masses include seizures, hemiplegia, or aphasia, whereas symptoms typical of infratentorial may include cerebellar dysfunction (ataxia, nystagmus, and dysarthria) or brainstem compression (cranial nerve palsies, altered consciousness, or abnormal respiration). As ICP increases, signs of intracranial hypertension also develop (see above).

PREOPERATIVE MANAGEMENT

The preoperative evaluation for patients undergoing craniotomy should attempt to establish the presence **2** or absence of intracranial hypertension. Computed tomography (CT) and magnetic resonance imaging (MRI) scans should be reviewed for

evidence of brain edema, a midline shift greater than 0.5 cm, and ventricular displacement or compression. The neurological examination should document mental status and any sensory or motor deficits. Medications should be reviewed with special reference to corticosteroid, diuretic, and anti-convulsant therapy. Laboratory evaluation should rule out corticosteroid-induced hyperglycemia, electrolyte disturbances due to diuretics, or abnormal secretion of antidiuretic hormone. Anticonvulsant blood concentrations may be measured, particularly when seizures are not well controlled.

Premedication

Sedative or opioid premedication is best avoided if intracranial hypertension is suspected. Hypercapnia secondary to respiratory depression increases ICP. Corticosteroids and anticonvulsant therapy should be continued until the time of surgery.

INTRAOPERATIVE MANAGEMENT

Monitoring

In addition to standard monitors, direct intraarterial pressure monitoring and bladder catheterization are used for most patients undergoing craniotomy. Rapid changes in blood pressure during anesthetic procedures, positioning, and surgical manipulation are best managed with guidance from continuous invasive monitoring of blood pressure. Moreover, arterial blood gas analyses are necessary to closely regulate PaCO_2 . Many neuroanesthesiologists zero the arterial pressure transducer at the level of the head (external auditory meatus)—instead of the right atrium—to facilitate calculation of cerebral perfusion pressure (CPP). End-tidal CO_2 measurements alone cannot be relied upon for precise regulation of ventilation; the arterial to end-tidal CO_2 gradient must be determined. Central venous access and pressure monitoring should be considered for patients requiring vasoactive drugs. Use of the internal jugular vein for access is theoretically problematic because of concern that the catheter might interfere with venous drainage from the brain. Some clinicians avoid this issue by passing a long catheter into the central circulation from the median basilic

vein. The external jugular, subclavian, and femoral veins may be suitable alternatives for intraoperative use. A bladder catheter is necessary because of the use of diuretics, the long duration of most neurosurgical procedures, and its utility in guiding fluid therapy. Neuromuscular function should be monitored on the unaffected side in patients with hemiparesis because the twitch response is often abnormally resistant on the affected side. Monitoring visual evoked potentials may be useful in preventing optic nerve damage during resections of large pituitary tumors. Additional monitors for surgery in the posterior fossa are described below.

Management of patients with intracranial hypertension may be guided by monitoring ICP perioperatively. Various ventricular, intraparenchymal, and subdural devices can be placed by neurosurgeons to provide measurements of ICP. The transducer should be zeroed to the same reference level as the arterial pressure transducer (usually the external auditory meatus; see above). A ventriculostomy catheter provides the added advantage of allowing removal of CSF to decrease ICP.

Induction

Induction of anesthesia and tracheal intubation are critical periods for patients with compromised intracranial pressure to volume relationships, particularly if there is an elevated ICP. Intracranial elastance can be improved by osmotic diuresis, dexamethasone, or removal of small volumes of CSF via a ventriculostomy drain. The goal of any technique should be to induce anesthesia and intubate the trachea without increasing ICP or compromising CBF. Arterial hypertension during induction increases CBV and promotes cerebral edema. Sustained hypertension can lead to marked increases in ICP, decreasing CPP and risking herniation. Excessive decreases in arterial blood pressure can be equally detrimental by compromising CPP.

The most common induction technique employs propofol together with modest hyperventilation to reduce ICP and blunt the noxious effects of laryngoscopy and intubation. Cooperative patients can be asked to hyperventilate during preoxygenation. All patients receive controlled ventilation once the propofol has been injected. A neuromuscular

blocker (NMB) is given to facilitate ventilation and prevent straining or coughing, both of which can abruptly increase ICP. An intravenous opioid given with propofol blunts the sympathetic response, particularly in young patients. Esmolol, 0.5–1.0 mcg/kg, is effective in preventing tachycardia associated with intubation in lightly anesthetized patients.

The actual induction technique can be varied according to individual patient responses and coexisting diseases). Succinylcholine may theoretically increase ICP, particularly if intubation is attempted prior to the establishment of deep anesthesia. Succinylcholine, however, remains the agent of choice for rapid sequence induction or when there are concerns about a potentially difficult airway, as hypoxemia and hypercarbia are much more detrimental than any effect of succinylcholine to the patient with intracranial hypertension.

Hypertension during induction can be treated with β_1 -blockers or by deepening the anesthetic with additional propofol. Modest concentrations of volatile agents (eg, sevoflurane) may also be used, provided that hyperventilation is also used. Sevoflurane best preserves autoregulation of CBF and produces limited vasodilatation; it may be the preferred volatile agent in patients with elevated ICP. Because of their potentially deleterious effect on CBV and ICP, vasodilators (eg, nicardipine, nitroprusside, nitroglycerin, and hydralazine) are avoided until the dura is opened. Hypotension is generally treated with incremental doses of vasopressors (eg, phenylephrine).

Positioning

Frontal, temporal, and parietooccipital craniotomies are performed in the supine position. The head is elevated 15–30° to facilitate venous and CSF drainage of CSF. The head may also be turned to the side to facilitate exposure. Excessive flexion or rotation of the neck impedes jugular venous drainage and can increase ICP. Before and after positioning, the tracheal tube should be secured, and all breathing circuit connections checked. The risk of unrecognized disconnections may be increased because the patient's airway will not be easily assessed after surgical draping; moreover, the operating table is usually turned 90° or 180° away from the anesthesiologist.

Maintenance of Anesthesia

Anesthesia can be maintained with inhalation anesthesia, total intravenous anesthesia techniques (TIVA), or a combination of an opioid and intravenous hypnotic (most often propofol) and a low-dose inhalation agent. Even though periods of stimulation are few, neuromuscular blockade is recommended—unless neurophysiological monitoring contradicts its use—to prevent straining, bucking, or movement. Increased anesthetic requirements can be expected during the most stimulating periods: laryngoscopy–intubation, skin incision, dural opening, periosteal manipulations, including Mayfield pin placement and closure. TIVA with remifentanyl and propofol facilitates rapid emergence and immediate neurological assessment. Likewise, the α_2 -agonist dexmedetomidine can be employed during both asleep and awake craniotomies to similar effect.

Hyperventilation should be continued intraoperatively to maintain PaCO_2 at roughly 30–35 mm Hg. Lower PaCO_2 tensions provide little additional benefit and may be associated with cerebral ischemia and impaired oxygen dissociation from hemoglobin. Positive end-expiratory pressure (PEEP) and ventilatory patterns resulting in high mean airway pressures (a low rate with large tidal volumes) should be avoided because of a potentially adverse effect on ICP by increasing central venous pressure and the potential for lung injury. Hypoxic patients may require PEEP and increased mean airway pressures; in such patients, the effect of PEEP on ICP is variable.

Intravenous fluid replacement should be limited to glucose-free isotonic crystalloid or colloid solutions. Hyperglycemia is common in neurosurgical patients (corticosteroid effect) and has been implicated in increasing ischemic brain injury. Colloid solutions can be used to restore intravascular volume deficits, whereas isotonic crystalloid solutions are used for maintenance fluid requirements. Neurosurgical procedures are often associated with “occult” blood loss (underneath surgical drapes or on the floor).

Emergence

Most patients undergoing elective craniotomy can be extubated at the end of the procedure, provided

that neurological function is intact. Patients who will remain intubated should be sedated to prevent agitation. Extubation in the operating room requires special handling during emergence. Straining or bucking on the tracheal tube may precipitate intracranial hemorrhage or worsen cerebral edema. As the skin is being closed, the patient should resume breathing spontaneously. Should the patient’s head be secured in a Mayfield pin apparatus, care must be taken to avoid any patient motions (eg, “bucking on the tube”), which could promote neck or cranial injuries. After the head dressing is applied and full access to the patient is regained (the table is turned back to its original position as at induction), any anesthetic gases are completely discontinued, and the neuromuscular blockade is reversed. Rapid awakening facilitates immediate neurological assessment and can generally be expected following an appropriate anesthetic. Delayed awakening may be seen following opioid or sedative overdose, when the end-tidal concentration of the volatile agent remains $>.2$ minimum alveolar concentration (MAC), because of various metabolic derangements, or when there is a perioperative neurological injury. Patients may need to be transported to the CT scanner directly from the operating room for evaluation when they do not respond as predicted. Immediate reexploration may be required. Most patients are taken to the intensive care unit postoperatively for close monitoring of neurological function.

Anesthesia for Surgery in the Posterior Fossa

Craniotomy for a mass in the posterior fossa presents a unique set of potential problems: obstructive hydrocephalus, possible injury to vital brainstem centers, pneumocephalus, and, with unusual positioning, postural hypotension and **venous air embolism**.

Obstructive Hydrocephalus

Infratentorial masses can obstruct CSF flow through the fourth ventricle or the cerebral aqueduct of Sylvius. Small but critically located lesions can markedly increase ICP. In such cases, a ventriculostomy is

often performed under local anesthesia to decrease ICP prior to induction of general anesthesia.

Brain Stem Injury

3 Operations in the posterior fossa can injure vital circulatory and respiratory brainstem centers and cranial nerves or their nuclei. Such injuries may occur as a result of direct surgical trauma or ischemia from retraction or other interruptions of the blood supply. Damage to respiratory centers is said to nearly always produce circulatory changes; therefore, abrupt changes in blood pressure, heart rate, or cardiac rhythm should alert the anesthesiologist to the possibility of such an injury. Such changes should be communicated to the surgeon. Isolated damage to respiratory centers may rarely occur without premonitory circulatory signs during operations in the floor of the fourth ventricle. Historically, some clinicians have employed spontaneous ventilation during these procedures as an additional monitor of brain function. At completion of the surgery, brainstem injuries may present as an abnormal respiratory pattern or an inability to maintain a patent airway following extubation. Monitoring brainstem auditory evoked potentials may be useful in preventing eighth nerve damage during resections of acoustic neuromas. Electromyography is also used to avoid injury to the facial nerve, but requires incomplete neuromuscular blockade intraoperatively.

Positioning

Although most explorations of the posterior fossa can be performed with the patient in either a modified lateral or prone position, the sitting position may be preferred by some surgeons.

The patient is actually semirecumbent in the standard sitting position (**Figure 27-1**); the back is elevated to 60°, and the legs are elevated with the knees flexed. The head is fixed in a three-point holder with the neck flexed; the arms remain at the sides with the hands resting on the lap.

Careful positioning and padding helps avoid injuries. Pressure points, such as the elbows, ischial spines, heels, and forehead, must be protected. Excessive neck flexion has been associated with swelling of the upper airway (due to venous

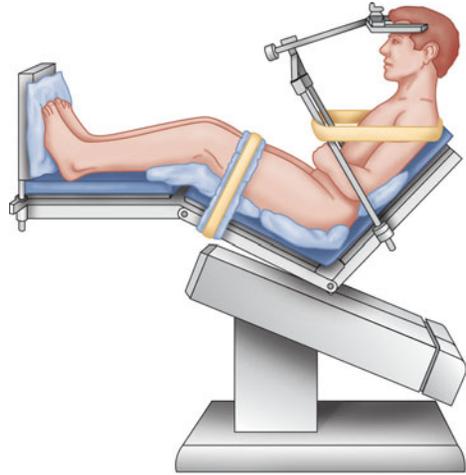

FIGURE 27-1 The sitting position for craniotomy.

obstruction), and, rarely, quadriplegia (due to compression of the cervical spinal cord). Preexisting cervical spinal stenosis probably predisposes patients to the latter injury.

Pneumocephalus

The sitting position increases the likelihood of pneumocephalus. In this position, air readily enters the subarachnoid space, as CSF is lost during surgery. In patients with cerebral atrophy, drainage of CSF is marked; air can replace CSF on the surface of the brain and in the lateral ventricles. Expansion of a pneumocephalus following dural closure can compress the brain. Postoperative pneumocephalus can cause delayed awakening and continued impairment of neurological function. Because of these concerns, nitrous oxide is rarely used for sitting craniotomies. (see also below).

Venous Air Embolism

4 Venous air embolism can occur when the pressure within an open vein is subatmospheric. These conditions may exist in any position (and during any procedure) whenever the wound is above the level of the heart. The incidence of venous air embolism is greater during sitting craniotomies (20% to 40%) than in craniotomies in any other

position. Entry into large cerebral venous sinuses increases the risk.

The physiological consequences of venous air embolism depend on the volume and the rate of air entry and whether the patient has a right-to-left intracardiac shunt (eg, patent foramen ovale [10% to 25% incidence]). The latter are important because they can facilitate passage of air into the arterial circulation (**paradoxical air embolism**). Modest quantities of air bubbles entering the venous system ordinarily lodge in the pulmonary circulation, where they are eventually absorbed. Small quantities of embolized air are well tolerated by most patients. When the amount entrained exceeds the rate of pulmonary clearance, pulmonary artery pressure rises progressively. Eventually, cardiac output decreases in response to increases in right ventricular afterload. Preexisting cardiac or pulmonary disease enhances the effects of venous air embolism; relatively small amounts of air may produce marked hemodynamic changes. Nitrous oxide, by diffusing into the bubbles and increasing their volume, can markedly accentuate the effects of even small amounts of entrained air. The dose for lethal venous air embolism in animals receiving nitrous oxide anesthesia is one-third to one-half that of control animals not receiving nitrous oxide.

Definitive signs of venous air embolism are often not apparent until large volumes of air have been entrained. A decrease in end-tidal CO_2 or arterial oxygen saturation might be noticed prior to hemodynamic changes. Arterial blood gas values may show only slight increases in PaCO_2 as a result of increased pulmonary dead space (areas with normal ventilation but decreased perfusion). Conversely, major hemodynamic manifestations, such as sudden hypotension, can occur well before hypoxemia is noted. Moreover, large amounts of intracardiac air impair tricuspid and pulmonic valve function and can produce sudden circulatory arrest by obstructing right ventricular outflow.

Paradoxical air embolism can result in a stroke or coronary occlusion, which may be apparent only postoperatively. Paradoxical air emboli are more likely to occur in patients with right-to-left intracardiac shunts, particularly when the normal transatrial (left > right) pressure gradient is reversed. Some studies suggest that a right > left

pressure gradient can develop at some time during the cardiac cycle, even when the overall mean gradient remains left > right.

A. Central Venous Catheterization

A properly positioned central venous catheter can be used to aspirate entrained air, but there is only limited evidence that this influences outcomes after venous air embolism. Some clinicians have considered right atrial catheterization mandatory for sitting craniotomies, but this is a minority viewpoint.

5 Optimal recovery of air following venous air embolism is provided by a multiorificed catheter positioned at the junction between the right atrium and the superior vena cava. Confirmation of correct catheter positioning can be accomplished by intravascular electrocardiography, radiography, or transesophageal echocardiography (TEE). Intravascular electrocardiography is accomplished by using the saline-filled catheter as a “V” lead. Correct high atrial position is indicated by the appearance of a biphasic P wave. If the catheter is advanced farther into the heart, the P wave changes from a biphasic to a unidirectional deflection. A right ventricular or pulmonary artery waveform may also be observed when the catheter is connected to a pressure transducer and advanced too far.

B. Monitoring for Venous Air Embolism

The most sensitive monitors available should be used. Detecting even small amounts of venous air embolism is important because it allows surgical control of the entry site before additional air is entrained. Currently, the most sensitive intraoperative monitors are TEE and precordial Doppler sonography. These monitors can detect air bubbles as small as 0.25 mL. TEE has the added benefit of detecting the volume of the bubbles and any transatrial passage through a patent foramen ovale, as well as evaluating any effect venous air embolism may have on cardiac function. Doppler methods employ a probe over the right atrium (usually to the right of the sternum and between the third and sixth ribs). Interruption of the regular swishing of the Doppler signal by sporadic roaring sounds indicates venous air embolism. Changes in end-tidal respiratory gas concentrations are less sensitive but are important monitors that can

also detect venous air embolism before overt clinical signs are present. Venous air embolism causes a sudden decrease in end-tidal CO_2 tension in proportion to the increase in pulmonary dead space; however, decreases can also be seen with hemodynamic changes unrelated to venous air embolism, such as decreased cardiac output. A reappearance (or increase) of nitrogen in expired gases may also be seen with venous air embolism. Changes in blood pressure and heart sounds (“mill wheel” murmur) are late manifestations of venous air embolism.

C. Treatment of Venous Air Embolism

1. The surgeon should be notified so that he or she can flood the surgical field with saline or pack it with wet gauzes and apply bone wax to the skull edges until the entry site is identified and occluded.
2. Nitrous oxide (if used) should be discontinued, and the inhalation anesthetic should be delivered in 100% oxygen.
3. If a central venous catheter is present, it should be aspirated in an attempt to retrieve the entrained air.
4. Intravascular volume infusion should be given to increase central venous pressure.
5. Vasopressors should be given to treat hypotension.
6. Bilateral jugular vein compression, by increasing cranial venous pressure, may slow air entrainment and cause back bleeding, which might help the surgeon identify the entry point of the embolus.
7. Some clinicians advocate PEEP to increase cerebral venous pressure; however, reversal of the normal transatrial pressure gradient may promote paradoxical embolism in a patient with incomplete closure of the foramen ovale.
8. If the above measures fail, the patient should be placed in a head-down position, and the wound should be closed quickly.
9. Persistent circulatory arrest necessitates the supine position and institution of resuscitation efforts using advanced cardiac life support algorithms.

Anesthesia for Stereotactic Surgery

Stereotaxis can be employed in treating involuntary movement disorders, intractable pain, and epilepsy and can also be used when diagnosing and treating tumors that are located deep within the brain.

These procedures are often performed under local anesthesia to allow evaluation of the patient. Propofol or dexmedetomidine infusions are routinely used for sedation and amnesia. Sedation should be omitted, however, if the patient already has increased ICP. The ability to rapidly provide controlled ventilation and general anesthesia for emergency craniotomy is mandatory, but is complicated by the platform and localizing frame that is attached to the patient's head for the procedure. Although mask ventilation or ventilation through a laryngeal mask airway (LMA) or orotracheal intubation might be readily accomplished in an emergency, awake intubation with a fiberoptic bronchoscope prior to positioning and surgery may be the safest approach when intubation is necessary for a patient whose head is already in a stereotactic head frame.

Functional neurosurgery is increasingly performed for removal of lesions adjacent to speech and other vital brain centers. Sometimes patients are managed with an asleep-awake-asleep technique, with or without instrumentation of the airway. Such operations require the patient to be awake to participate in cortical mapping to identify key speech centers, such as Broca's area. Patients sleep during the painful periods of surgery (ie, during opening and closure). LMAs are often employed to assist airway management during the asleep portions of these surgeries.

Patients undergo deep brain stimulator insertion for control of movement and other disorders. A stimulator electrode is placed via a burr hole using radiologic guidance to establish coordinates for electrode placement. A microelectrode recording (MER) is obtained to determine the correct placement of the stimulator in brain structures. The effect of stimulation upon the patient is noted. Sedative medications can adversely affect MER potentials, complicating the location of the correct depth of

TABLE 27-1 Advantages and disadvantages of drugs used for conscious sedation.

Agents	Advantages	Disadvantages
GABA receptor agonists Benzodiazepines	Anxiolysis	Large dose abolishes MER Alters the threshold for stimulation Induces dyskinesia
Propofol	Widely used Short acting Predictable emergence profile	Abolish tremors Attenuation of MER Unpredictable dosing in patients with Parkinson disease Induces dyskinesia Tendency to cause sneezing
Opioids Fentanyl Remifentanyl	? Minimal effect on MER Short acting	Rigidity Suppression of tremors
Alpha-2 agonist Dexmedetomidine	Non-GABA-mediated action Less effect on MER Anxiolysis and analgesic effects Sedation—easily arousable Does not ameliorate clinical signs of Parkinsonism Maintains hemodynamic stability Preserves respiration	High doses can abolish MER Hypotension, bradycardia

stimulator placement. Dexmedetomidine has been used to provide sedation to these patients; however, during MER and stimulation testing, sedative infusions should be discontinued to facilitate patient participation in determining correct electrode placement ([Table 27-1](#)).

Anesthesia for Head Trauma

Head injuries are a contributory factor in up to 50% of deaths due to trauma. Most patients with head trauma are young, and many (10% to 40%) have associated intraabdominal or intrathoracic injuries, long bone fractures, and/or spinal injuries. The outcome from a head injury is dependent not only on the extent of the neuronal damage at the time of injury, but also on the occurrence of any secondary insults. These additional insults include: (1) systemic factors such as hypoxemia,

hypercapnia, or hypotension; (2) formation and expansion of an epidural, subdural, or intracerebral hematoma; and (3) sustained intracranial hypertension. Surgical and anesthetic management of these patients is directed at preventing these secondary insults. The **Glasgow Coma Scale (GCS) score** ([Table 27-2](#)) generally correlates well with the severity of injury and outcome. A GCS score of 8 or less on admission is associated with approximately 35% mortality. Evidence of greater than a 5-mm midline shift (on imaging) and ventricular compression on imaging are associated with substantially increased morbidity.

Specific lesions include skull fractures, subdural and epidural hematomas, brain contusions (including intracerebral hemorrhages), penetrating head injuries, and traumatic vascular occlusions and dissections. The presence of a skull fracture greatly increases the likelihood of an intracranial lesion. Linear skull fractures are commonly associated

with subdural or epidural hematomas. Basilar skull fractures may be associated with CSF rhinorrhea, pneumocephalus, cranial nerve palsies, or even a cavernous sinus–carotid artery fistula. Depressed skull fractures often present with an underlying brain contusion. Contusions may be limited to the surface of the brain or may involve hemorrhage in deeper hemispheric structures or the brainstem. Deceleration injuries often produce both coup (frontal) and contrecoup (occipital) lesions. Epidural and subdural hematomas can occur as isolated lesions, as well as in association with cerebral contusions (more commonly with subdural than epidural lesions).

Operative treatment is usually elected for depressed skull fractures; evacuation of epidural, subdural, and some intracerebral hematomas; and debridement of penetrating injuries. Decompressive craniectomy is used to provide room for cerebral swelling. The cranium is subsequently reconstructed following resolution of cerebral edema.

ICP monitoring is usually indicated in patients with lesions associated with intracranial hypertension: large contusions, mass lesions, intracerebral

hemorrhage, or evidence of edema on imaging studies. ICP monitoring should also be considered in patients with signs of intracranial hypertension who are undergoing nonneurological procedures. Intracranial hypertension should be treated with moderate hyperventilation, mannitol, pentobarbital, or propofol. Studies suggest that sustained increases in ICP of greater than 60 mm Hg result in severe disability or death. Unlike treatment following spinal cord trauma, multiple randomized trials have failed to detect the efficacy of early use of large doses of glucocorticoids in patients with head trauma.

PREOPERATIVE MANAGEMENT

Anesthetic care of patients with severe head trauma begins in the emergency department. Measures to ensure patency of the airway, adequacy of ventilation and oxygenation, and correction of systemic hypotension should go forward simultaneously with neurological and trauma surgical evaluation. Airway obstruction and hypoventilation are common. Up to 70% of such patients have hypoxemia, which may be complicated by pulmonary contusion, fat emboli, or neurogenic pulmonary edema. The latter is attributed to marked systemic and pulmonary hypertension secondary to intense sympathetic nervous system activity. Supplemental oxygen should be given to all patients while the airway and ventilation are evaluated. All patients must be assumed to have a cervical spine injury (up to 10% incidence) until the contrary is proven radiographically. Patients with obvious hypoventilation, an absent gag reflex, or a persistent score below 8 on the GCS (Table 27-2) require tracheal intubation and hyperventilation. All other patients should be carefully observed for deterioration.

Intubation

All patients should be regarded as having a full stomach and should have cricoid pressure applied during ventilation and tracheal intubation. In-line stabilization should be used during airway manipulation to maintain the head in a neutral position, unless radiographs confirm that there is no cervical

spine injury. Following preoxygenation and hyperventilation by mask, the adverse effects of intubation on ICP are blunted by prior administration of propofol, 1.5–3.0 mg/kg, and a rapid-onset NMB. Succinylcholine may produce mild and transient increases in ICP in patients with closed head injury; however, the necessity for expeditious airway management trumps these concerns. Rocuronium is often used to facilitate intubation. Video laryngoscopy performed with in-line stabilization generally permits neutral position intubation of the trauma patient. An intubating bougie should be available to facilitate tube placement. If a difficult intubation is encountered with video laryngoscopy, fiberoptic or other techniques (eg, intubating LMA) can be attempted. If airway attempts are unsuccessful, a surgical airway should be obtained. Blind nasal intubation is contraindicated in the presence of a basilar skull fracture, which is suggested by CSF rhinorrhea or otorrhea, hemotympanum, or ecchymosis into periorbital tissues (raccoon sign) or behind the ear (Battle's sign).

Hypotension

Hypotension in the setting of head trauma is nearly always related to other associated injuries (often intraabdominal). Bleeding from scalp lacerations may be responsible in children. Hypotension may be seen with spinal cord injuries because of the **6** sympathectomy associated with spinal shock. In a patient with head trauma, correction of hypotension and control of any bleeding take precedence over radiographic studies and definitive neurosurgical treatment because systolic arterial blood pressures of less than 80 mm Hg predict a poor outcome. Glucose-containing or hypotonic solutions should not be used (see above). Otherwise, a mix of colloid, crystalloid, and blood products can be administered as necessary. Massive blood loss in the patient with multiple injuries should result in activation of a massive transfusion protocol to provide a steady supply of platelets, fresh frozen plasma, and packed red blood cells. Invasive monitoring of arterial pressure, central venous pressure, and ICP are valuable, but should not delay diagnosis and treatment. Arrhythmias

and electrocardiographic abnormalities in the T wave, U wave, ST segment, and QT interval are common following head injuries, but are not necessarily associated with cardiac injury; they likely represent altered autonomic function.

Diagnostic Studies

The choice between operative and medical management of head trauma is based on radiographic and clinical findings. Patients should be stabilized prior to any CT or other imaging studies. Critically ill patients should be closely monitored during such studies. Restless or uncooperative patients may additionally require general anesthesia. Sedation without control of the airway should generally be avoided because of the risk of further increases in ICP from hypercapnia or hypoxemia.

INTRAOPERATIVE MANAGEMENT

Anesthetic management is generally similar to that for other mass lesions associated with intracranial hypertension. Management of the airway is discussed above. Invasive monitoring should be established, if not already present, but should not delay surgical decompression in a rapidly deteriorating patient.

Anesthetic technique and agents are designed to preserve cerebral perfusion and mitigate increases in intracranial pressure. Hypotension may occur after induction of anesthesia as a result of the combined effects of vasodilation and hypovolemia and should be treated with an α -adrenergic agonist and volume infusion if necessary. Subsequent hypertension is common with surgical stimulation, but may also occur with acute elevations in ICP. The latter may be associated with bradycardia (Cushing reflex).

Hypertension can be treated with additional doses of the induction agent, with increased concentrations of an inhalation anesthetic or vasodilators. β -Adrenergic blockade is usually effective in controlling hypertension associated with tachycardia. CPP should be maintained between 70 and 110 mm Hg. Vasodilators should be avoided until the dura

is opened. Hyperventilation to a $\text{PaCO}_2 < 30$ should be avoided in trauma patients to avoid excessive decreases in oxygen delivery.

Disseminated intravascular coagulation occasionally may be seen with severe head injuries. Such injuries cause the release of large amounts of brain thromboplastin and may also be associated with the acute respiratory distress syndrome. Pulmonary aspiration and neurogenic pulmonary edema may also be responsible for deteriorating lung function. PEEP can be applied on the ventilator. When PEEP is used, ICP monitoring can be useful to confirm an adequate CPP. Diabetes insipidus, characterized by excessive dilute urine, is frequently seen following injuries to the pituitary stalk. Other likely causes of polyuria should be excluded and the diagnosis confirmed by measurement of urine and serum osmolality prior to treatment with fluid restriction and vasopressin. Gastrointestinal bleeding is common in patients not receiving prophylaxis; it is usually due to stress ulceration.

The decision whether to extubate the trachea at the conclusion of the surgical procedure depends on the severity of the injury, the presence of concomitant abdominal or thoracic injuries, preexisting illnesses, and the preoperative level of consciousness. Young patients who were conscious preoperatively may be extubated following the removal of a localized lesion, whereas patients with diffuse brain injury should remain intubated. Moreover, persistent intracranial hypertension requires continued paralysis, sedation, and hyperventilation.

Anesthesia & Craniotomy for Intracranial Aneurysms & Arteriovenous Malformations

Saccular aneurysms and AVMs are common causes of nontraumatic intracranial hemorrhages. Surgical or interventional neuroradiologic treatment may be undertaken either electively to prevent hemorrhage or emergently to prevent further complications once hemorrhage has taken place. Other nontraumatic hemorrhages (eg, from hypertension, sickle cell disease, or vasculitis) are usually treated medically.

CEREBRAL ANEURYSMS

Preoperative Considerations

Cerebral aneurysms typically occur at the bifurcation of the large arteries at the base of the brain; most are located in the anterior circle of Willis. Approximately 10% to 30% of patients have more than one aneurysm. The general incidence of saccular aneurysms in some estimates is reported to be 5%, but only a minority of those with aneurysms will have complications. Rupture of a saccular aneurysm is the most common cause of subarachnoid hemorrhage. The acute mortality following rupture is approximately 10%. Of those that survive the initial hemorrhage, about 25% die within 3 months from delayed complications. Moreover, up to 50% of survivors are left with neurological deficits. As a result, the emphasis in management is on prevention of rupture. Unfortunately, most patients present only after rupture has already occurred.

Unruptured Aneurysms

Patients may present with prodromal symptoms and signs suggesting progressive enlargement. The most common symptom is headache, and the most common physical sign is a third-nerve palsy. Other manifestations could include brainstem dysfunction, visual field defects, trigeminal nerve dysfunction, cavernous sinus syndrome, seizures, and hypothalamic–pituitary dysfunction. The most commonly used techniques to diagnose an aneurysm are MRI angiography, angiography, and helical CT angiography. Following diagnosis, patients are brought to the operating room, or more likely the radiology suite, for elective clipping or obliteration of the aneurysm. Most patients are in the 40- to 60-year-old age group and in otherwise good health.

Ruptured Aneurysms

Ruptured aneurysms usually present acutely as subarachnoid hemorrhage. Patients typically complain of a sudden severe headache without focal neurological deficits, but often associated with nausea and vomiting. Transient loss of consciousness may

TABLE 27-3 Hunt and Hess grading scale for SAH.

Grade	Clinical Description
I	Asymptomatic or minimal headache and slight nuchal rigidity
II	Moderate to severe headache, nuchal rigidity, no neurological deficit other than cranial nerve palsy
III	Drowsiness, confusion, or mild focal deficit
IV	Stupor, moderate to severe hemiparesis, and possibly early decerebrate rigidity and vegetative disturbances
V	Deep coma, decerebrate rigidity, and moribund appearance

occur and may result from a sudden rise in ICP and precipitous drop in CPP. If ICP does not decrease rapidly after the initial sudden increase, death usually follows. Large blood clots can cause focal neurological signs in some patients. Minor bleeding may cause only a mild headache, vomiting, and nuchal rigidity. Unfortunately, even minor bleeding in the subarachnoid space seems to predispose to delayed complications. The severity of subarachnoid hemorrhage (SAH) is graded according to the Hunt and Hess scale (Table 27-3), as well as the World Federation of Neurological Surgeons Grading Scale of SAH (Table 27-4). The Fisher grading scale, which uses CT to assess the amount of blood detected, gives the best indication of the likelihood of the development of cerebral vasospasm and patient outcome (Table 27-5).

Delayed complications include cerebral vasospasm, rerupture, and hydrocephalus. Cerebral vasospasm occurs in 30% of patients (usually after 4–14 days) and is a major cause of morbidity and mortality. Manifestations of vasospasm are due to cerebral ischemia and infarction and depend on the severity and distribution of the involved vessels. The Ca^{2+} channel antagonist nimodipine may antagonize vasospasm. Both transcranial Doppler and brain tissue oxygen monitoring can be used to

guide vasospasm therapy (Figure 27-2). Increased velocity of flow $>200\text{cm/sec}$ is indicative of severe spasm. The Lindegaard ratio compares the blood velocity of the cervical carotid artery with that of the middle cerebral artery. A ratio >3 is likewise indicative of severe spasm. Brain tissue oxygen tension less than 20 mm Hg is also worrisome. **In patients with symptomatic vasospasm with an inadequate response to nimodipine, intravascular volume expansion and induced hypertension (“triple H” therapy: hypervolemia, hemodilution, and hypertension) are added as part of the therapeutic regimen.** Refractory vasospasm may be treated with infusion of papaverine, infusion of nicardipine, or angioplasty. However, radiologic improvement in the vessel diameter does not necessarily correlate with an improvement in clinical status.

TABLE 27-5 Fisher grading scale of cranial computerized tomography (CCT).

Grade	Findings on CCT
1	No subarachnoid blood detected
2	Diffuse or vertical layers $\leq 1\text{mm}$
3	Localized clot and/or vertical layer $> 1\text{mm}$
4	Intracerebral or intraventricular clot with diffuse or no subarachnoid haemorrhage

The endovascular operating room as an extension of the intensive care unit: changing strategies in the management of neurovascular disease. *Neurosurgery* 2006;59:53–56.)

PREOPERATIVE MANAGEMENT

In addition to assessing neurological findings, the preoperative evaluation should include a search for coexisting diseases, such as hypertension and renal, cardiac, or ischemic cerebrovascular disease. Electrocardiographic abnormalities are commonly seen in patients with subarachnoid hemorrhage, but do not necessarily reflect underlying heart disease. However, increases of cardiac troponin during SAH are associated with myocardial injury and may herald a poor outcome. Most conscious patients with normal ICP are sedated following rupture to prevent rebleeding; such sedation should be continued until induction of anesthesia. Patients with

persistent elevation in ICP should receive little or no premedication to avoid hypercapnia.

INTRAOPERATIVE MANAGEMENT

Aneurysm surgery can result in exsanguinating hemorrhage as a consequence of rupture or rebleeding. Blood should be available prior to the start of these operations.

Regardless of the anesthetic technique employed, anesthetic management should focus on preventing rupture (or rebleeding) and avoiding factors that promote cerebral ischemia or vasospasm.

Intraarterial and central venous pressure monitoring are useful. Sudden increases in blood pressure with tracheal intubation or surgical stimulation should be avoided. Judicious intravascular volume loading permits surgical levels of anesthesia without excessive decreases in blood pressure. Because calcium channel blockers, angiotensin receptor blockers, and ACE inhibitors cause systemic vasodilation and reduce systemic vascular resistance, patients receiving these agents preoperatively may be particularly prone to hypotension. Hyperventilation is unlikely to overcome ischemia-induced vasodilation. Once the dura is opened, mannitol is often given to facilitate surgical exposure and reduce the need for surgical retraction. Rapid decreases in ICP prior to dural opening may promote rebleeding by removing a tamponading effect on the aneurysm.

Elective (controlled) hypotension has been used in aneurysm surgery. Decreasing mean arterial blood pressure reduces the transmural tension across the aneurysm, making rupture (or rebleeding) less likely and facilitating surgical clipping. Controlled hypotension can also decrease blood loss and improve surgical visualization in the event of bleeding. The combination of a slightly head-up position with a volatile anesthetic enhances the effects of any of the commonly used hypotensive agents. Should accidental rupture of the aneurysm occur, the surgeon may request transient hypotension to facilitate control of the bleeding aneurysm.

Technical improvements in temporary vascular clips have enabled surgeons to use them more often to interrupt blood flow during aneurysm surgery; induced hypertension is often requested when temporary clips are applied. Neurophysiologic monitoring may be employed during aneurysm surgery to identify potential ischemia during temporary clip application.

Mild hypothermia has been used to protect the brain during periods of prolonged or excessive hypotension or vascular occlusion; however, its efficacy has been questioned. Rarely, hypothermic circulatory arrest is used for large basilar artery aneurysms.

Depending on neurological condition, most patients should be extubated at the end of surgery. Extubation should be handled similarly to other craniotomies (see above). A rapid awakening allows

neurological evaluation in the operating room, prior to transfer to the intensive care unit.

The anesthetic concerns of patients taken for aneurysmal coiling in the neurointerventional suite are similar to those of surgical interventions. General anesthesia is employed. Patients require heparin anticoagulation and radiologic contrast. Communication with the surgeon or neuroradiologist as to the desired activated clotting time and need for protamine reversal is essential. Moreover, anesthesia staff in the neuroradiology suite must be prepared to manipulate and monitor the blood pressure, as with an open surgical procedure.

ARTERIOVENOUS MALFORMATIONS

AVMs cause intracerebral hemorrhage more often than subarachnoid hemorrhage. These lesions are developmental abnormalities that result in arteriovenous fistulas; they typically grow in size with time. AVMs may present at any age, but bleeding is most common between 10 and 30 years of age. Other common presentations include headache and seizures. The combination of high blood flow with low vascular resistance can rarely result in high-output cardiac failure. Acutely, neuroradiologists try to embolize AVMs. When neuro-radiological interventions are not successful or available, surgical excision may be undertaken. Neuroradiological embolization employs various coils, glues, and balloons to obliterate the AVM. Risks include embolization into cerebral arteries feeding the normal brain, as well as systemic or pulmonary embolism.

Anesthetic management of patients undergoing surgical treatment of AVMs may be complicated by extensive blood loss. Venous access with multiple large-bore cannulas is necessary. Embolization may be carried out prior to surgery to reduce operative blood loss. Hyperventilation and mannitol may be used to facilitate surgical access. Hyperemia and swelling can develop following resection, possibly because of altered autoregulation in the remaining normal brain. Emergence hypertension is typically controlled using β_1 -blockers to avoid any vasodilator induced increase in CBF.

Anesthesia for Surgery on the Spine

Spinal surgery is most often performed for symptomatic nerve root or cord compression secondary to trauma or degenerative disorders. Compression may occur from protrusion of an intervertebral disk or osteophytic bone (spondylosis) into the spinal canal or an intervertebral foramen. Prolapse of an intervertebral disk usually occurs at either the fourth or fifth lumbar or the fifth or sixth cervical levels in patients 30–50 years old. Spondylosis tends to affect the lower cervical spine more than the lumbar spine and typically afflicts older patients. Operations on the spinal column can help correct deformities (eg, scoliosis), decompress the cord, and fuse the spine if disrupted by trauma. Spinal surgery may also be performed to resect a tumor or vascular malformation or to drain an abscess or hematoma.

PREOPERATIVE MANAGEMENT

Preoperative evaluation should focus on any existing anatomic abnormalities and limited neck movements due to disease, traction, or braces that might complicate airway management and necessitate special techniques. Neurological deficits should be documented. Neck mobility should be assessed in all patients presenting for spine surgery at any level. Patients with unstable cervical spines can be managed with either awake fiberoptic intubation or asleep intubation with in-line stabilization.

INTRAOPERATIVE MANAGEMENT

For many of these procedures, anesthetic management is complicated by the use of the prone position. Spinal operations involving multiple levels, fusion, and instrumentation are also complicated by the potential for large intraoperative blood losses; a red cell salvage device is often used. Excessive distraction during spinal instrumentation (Harrington rod

or pedicle screw fixation) can additionally injure the spinal cord. Transthoracic approaches to the spine require one-lung ventilation. Anterior/posterior approaches require the patient to be repositioned in the middle of surgery.

Positioning

Most spine surgical procedures are carried out in the prone position. The supine position may be used for an anterior approach to the cervical spine, making anesthetic management easier, but increasing the risk of injury to the trachea, esophagus, recurrent laryngeal nerve, sympathetic chain, carotid artery, or jugular vein. A sitting (for cervical spine procedures) or lateral decubitus (most commonly for lumbar spine procedures) position may occasionally be used.

Following induction of anesthesia and tracheal intubation in the supine position, the patient is turned to the prone position. Care must be taken to maintain the neck in a neutral position. Once in the prone position, the head may be turned to the side (not exceeding the patient's normal range of motion) or (more commonly) can remain face down on a cushioned holder. Caution is necessary to avoid corneal abrasions or retinal ischemia from pressure on either globe, or pressure injuries of the nose, ears, forehead, chin, breasts (females), or genitalia (males). The chest should rest on parallel rolls (of foam, gel, or other padding) or special supports—if a frame is used—to facilitate ventilation. The arms may be tucked by the sides in a comfortable position or extended with the elbows flexed (avoiding excessive abduction at the shoulder).

Turning the patient prone is a critical maneuver, sometimes complicated by hypotension. Abdominal compression, particularly in obese patients, may impede venous return and contribute to excessive intraoperative blood loss from engorgement of epidural veins. Prone positioning that permits the abdomen to hang freely can mitigate this increase in venous pressure. Deliberate hypotension has been advocated in the past to reduce bleeding associated with spine surgery. However, this should only be undertaken with a full understanding that controlled hypotension may increase the risk of perioperative vision loss (POVL).

POVL occurs secondary to:

- Ischemic optic neuropathy
- Perioperative glaucoma
- Cortical hypotension/embolism

Prolonged surgery in a head-down position, major blood loss, relative hypotension, diabetes, obesity, and smoking all put patients at greater risk of POVL following spine surgery.

Airway and facial edema can likewise develop after prolonged “head-down” positioning. Reintubation, if required, will likely present more difficulty than the intubation at the start of surgery.

When patients are placed in the prone position, the face must be checked periodically to determine that the eyes, nose, and ears are free of pressure. Even foam cushions can exert pressure over time on the chin, orbit, and maxilla. Turning the head is not easily accomplished when the head is positioned on a cushion; therefore, if prolonged procedures are planned, the head can be secured with pins keeping the face free from any pressure.

Monitoring

7 When major blood loss is anticipated or the patient has preexisting cardiac disease, intra-arterial and possibly central venous pressure monitors should be considered prior to “positioning” or “turning.” Massive blood loss from injuries to the great vessels can occur intraoperatively with thoracic or lumbar spine procedures.

Instrumentation of the spine requires the ability to intraoperatively detect spinal cord injury. Intraoperative wake-up techniques employing nitrous oxide-narcotic or total intravenous anesthesia allow the testing of motor function following distraction. Once preservation of motor function is established, the patient’s anesthetic can be deepened. Continuous monitoring of somatosensory evoked potentials and motor evoked potentials provides alternatives that avoid the need for intraoperative awakening. These monitoring techniques require substitution of propofol, opioid, and/or ketamine infusions for volatile anesthetics and avoidance of neuromuscular paralysis.

CASE DISCUSSION

Resection of a Pituitary Tumor

A 41-year-old woman presents to the operating room for resection of a 10-mm pituitary tumor. She had complained of amenorrhea and had started noticing some decrease in visual acuity.

What hormones does the pituitary gland normally secrete?

Functionally and anatomically, the pituitary is divided into two parts: anterior and posterior. The latter is part of the neurohypophysis, which also includes the pituitary stalk and the median eminence.

The anterior pituitary is composed of several cell types, each secreting a specific hormone. Anterior pituitary hormones include adrenocorticotropic hormone (ACTH), thyroid-stimulating hormone (TSH), growth hormone (GH), the gonadotropins (follicle-stimulating hormone [FSH] and luteinizing hormone [LH]), and prolactin (PRL). Secretion of each of these hormones is regulated by hypothalamic peptides (releasing hormones) that are transported to the adenohypophysis by a capillary portal system. The secretion of FSH, LH, ACTH, TSH, and their respective releasing hormones is also under negative feedback control by the products of their target organs. For example, an increase in circulating thyroid hormone inhibits the secretion of TSH-releasing factor and TSH.

The posterior pituitary secretes antidiuretic hormone (ADH, also called vasopressin) and oxytocin. These hormones are actually formed in supra-optic and paraventricular neurons, respectively, and are transported down axons that terminate in the posterior pituitary. Hypothalamic osmoreceptors, and, to a lesser extent, peripheral vascular stretch receptors, regulate secretion of ADH.

What is the function of these hormones?

ACTH stimulates the adrenal cortex to secrete glucocorticoids. Unlike production of mineralocorticoids, production of glucocorticoids is dependent on ACTH secretion. TSH accelerates the synthesis and release of thyroid hormone (thyroxine).

Normal thyroid function is dependent on production of TSH. The gonadotropins FSH and LH are necessary for normal production of testosterone and spermatogenesis in males and cyclic ovarian function in females. GH promotes tissue growth and increases protein synthesis as well as fatty acid mobilization. Its effects on carbohydrate metabolism are to decrease cellular glucose uptake and utilization and increase insulin secretion. PRL functions to support breast development during pregnancy. Dopamine receptor antagonists are known to increase secretion of PRL.

Through its effect on water permeability in renal collecting ducts, ADH regulates extracellular osmolarity and blood volume. Oxytocin acts on areolar myoepithelial cells as part of the milk letdown reflex during suckling and enhances uterine activity during labor.

What factors determine the surgical approach in this patient?

The pituitary gland is attached to the brain by a stalk and extends downward to lie in the sella turcica of the sphenoid bone. Anteriorly, posteriorly, and inferiorly, it is bordered by bone. Laterally, it is bordered by the cavernous sinus, which contains cranial nerves III, IV, V₁, and VI, as well as the cavernous portion of the carotid artery. Superiorly, the diaphragma sella, a thick dural reflection, usually tightly encircles the stalk and forms the roof of the sella turcica. In close proximity to the stalk lie the optic nerves and chiasm. The hypothalamus lies contiguous and superior to the stalk.

Tumors less than 10 mm in diameter are usually approached via the transsphenoidal route, whereas tumors greater than 20 mm in diameter and with significant suprasellar extension are approached via a bifrontal craniotomy. With the use of prophylactic antibiotics, morbidity and mortality rates are significantly less with the transsphenoidal approach; the operation is carried out with the aid of a microscope through an incision in the gingival mucosa beneath the upper lip. The surgeon enters the nasal cavity, dissects through the nasal septum, and finally penetrates the roof of the sphenoid sinus to enter the floor of the sella turcica.

What are the major problems associated with the transsphenoidal approach?

Problems include (1) the need for mucosal injections of epinephrine-containing solution to reduce bleeding, (2) the accumulation of blood and tissue debris in the pharynx and stomach, (3) the risk of hemorrhage from inadvertent entry into the cavernous sinus or the internal carotid artery, (4) cranial nerve damage, and (5) pituitary hypofunction. Prophylactic administration of glucocorticoids is routinely used in most centers. Diabetes insipidus develops postoperatively in up to 40% of patients but is usually transient. Less commonly, the diabetes insipidus presents intraoperatively. The supine and slightly head-up position used for this procedure may also predispose to venous air embolism.

What type of tumor does this patient have?

Tumors in or around the sella turcica account for 10% to 15% of intracranial neoplasms. Pituitary adenomas are most common, followed by craniopharyngiomas and then parasellar meningiomas. Primary malignant pituitary and metastatic tumors are rare. Pituitary tumors that secrete hormones (functional tumors) usually present early, when they are still relatively small (<10 mm). Other tumors present late, with signs of increased ICP (headache, nausea, and vomiting) or compression of contiguous structures (visual disturbances or pituitary hypofunction). Compression of the optic chiasm classically results in bitemporal hemianopia. Compression of normal pituitary tissue produces progressive endocrine dysfunction. Failure of hormonal secretion usually progresses in the order of gonadotropins, GH, ACTH, and TSH. Diabetes insipidus can also be seen preoperatively. Rarely, hemorrhage into the pituitary results in acute panhypopituitarism (pituitary apoplexy) with signs of a rapidly expanding mass, hemodynamic instability, and hypoglycemia.

This patient has the most common type of secretory adenoma—that producing hyperprolactinemia. Women with this tumor typically have amenorrhea, galactorrhea, or both. Men with

prolactin-secreting adenomas may have galactorrhea or infertility, but more commonly present with symptoms of an expanding mass.

What other types of secretory hormones are seen?

Adenomas secreting ACTH (Cushing's disease) produce classic manifestations of Cushing's syndrome: truncal obesity, moon facies, abdominal striae, proximal muscle weakness, hypertension, and osteoporosis. Glucose tolerance is typically impaired, but frank diabetes is less common (<20%). Hirsutism, acne, and amenorrhea are also commonly seen in women.

Adenomas that secrete GH are often large and result in either gigantism (prepubertal patients) or acromegaly (adults). Excessive growth prior to epiphyseal fusion results in massive growth of the entire skeleton. After epiphyseal closure, the abnormal growth is limited to soft tissues and acral parts: hands, feet, nose, and mandible. Patients develop osteoarthritis, which often affects the temporomandibular joint and spine. Diabetes, myopathies, and neuropathies are common. Cardiovascular complications include hypertension, premature coronary disease, and cardiomyopathy in some patients. The most serious anesthetic problem encountered in these patients is difficulty in intubating the trachea.

Are any special monitors required for transsphenoidal surgery?

Monitoring should be carried out in somewhat the same way as for craniotomies. Visual evoked potentials may be employed with large tumors that involve the optic nerves. Precordial Doppler sonography may be used for detecting venous air embolism. Venous access with large bore catheters is desirable in the event of massive hemorrhage

What modifications, if any, are necessary in the anesthetic technique?

The same principles discussed for craniotomies apply, particularly if the patient has evidence of increased ICP. Intravenous antibiotic prophylaxis

and glucocorticoid coverage (hydrocortisone, 100 mg) are usually given prior to induction. Many clinicians avoid nitrous oxide to prevent problems with a postoperative pneumocephalus (see above). Intense neuromuscular blockade is important to prevent movement while the surgeon is using the microscope. In some circumstances, the surgeon may request placement of a lumbar intrathecal catheter to drain CSF, thereby facilitating surgical exposure.

Anesthesia for Patients with Neurologic & Psychiatric Diseases

KEY CONCEPTS

- 1 Induction of anesthesia in patients receiving long-term levodopa therapy may result in either marked hypotension or hypertension.
- 2 In patients with multiple sclerosis, increases in body temperature cause exacerbation of symptoms.
- 3 The major risk of anesthesia in patients with autonomic dysfunction is severe hypotension, compromising cerebral and coronary blood flow.
- 4 Autonomic hyperreflexia should be expected in patients with lesions above T6 and can be precipitated by surgical manipulations.
- 5 The most important interaction between anesthetic agents and tricyclic antidepressants is an exaggerated response to both indirect-acting vasopressors and sympathetic stimulation.

Patients with vascular and nonvascular neurologic diseases and/or psychiatric disorders are frequently encountered by anesthesia staff. Anesthesiologists must have a basic understanding of the major neurologic and psychiatric disorders and their drug therapy. Failure to recognize potential adverse anesthetic interactions may result in avoidable perioperative morbidity.

Cerebrovascular Disease

Preoperative Considerations

Patients with diagnosed cerebrovascular disease typically have a history of transient ischemic attacks (TIAs) or stroke. Patients with TIAs undergoing surgery for other indications have an increased risk of perioperative stroke. Asymptomatic carotid bruits occur in up to 4% of patients older than age 40 years, but do not necessarily indicate significant carotid artery obstruction. Fewer than 10%

of patients with completely asymptomatic bruits have hemodynamically significant carotid artery lesions. An asymptomatic carotid bruit may not increase the risk of stroke following surgery, but increases the likelihood of coexisting coronary artery disease. Moreover, the absence of a bruit does not exclude significant carotid obstruction.

The risk of perioperative stroke increases with patient age and varies with the type of surgery. The overall risk of stroke associated with surgery is low, but is greater in patients undergoing cardiovascular surgery. Rates of stroke after general anesthesia and surgery range from 0.08% to 0.4%. Even in patients with known cerebrovascular disease, the risk is only 0.4% to 3.3%. Patients at greatest risk of postoperative stroke are those undergoing open heart procedures for valvular disease, coronary artery disease with ascending aortic atherosclerosis, and diseases of the thoracic aorta. Stroke following open heart surgery is usually due to embolism of air, clots, or atheromatous debris. In

one study, 6.1% of patients experienced an adverse neurological outcome following cardiac surgery. Stroke following thoracic aortic surgery may be due to emboli or ischemia secondary to prolonged circulatory arrest or a clamp placed close to the origin of the carotid artery.

The pathophysiology of postoperative strokes following noncardiovascular surgery is less clear, but may involve severe sustained hypotension or hypertension. Hypotension with severe hypoperfusion can result in so-called “watershed” zone infarctions or thrombosis of cerebral arteries, whereas hypertension can result in intracerebral hemorrhage (hemorrhagic stroke). Sustained hypertension can disrupt the blood–brain barrier and promote cerebral edema. Widened pulse pressure (>80 mm Hg) can produce endothelial vessel injury, potentially resulting in cerebral hypoperfusion or embolism. Perioperative atrial fibrillation can likewise lead to atrial clot formation and cerebral embolism. The period of time during which anesthesia and surgery should best be avoided following a stroke has not been determined. Abnormalities in regional blood flow and metabolic rate usually resolve after 2 weeks, whereas alterations in CO₂ responsiveness and the blood–brain barrier may require more than 4 weeks. However, urgent surgery is performed for acute intracranial hemorrhage, symptomatic carotid disease, and cardiac sources of emboli.

Patients with TIAs have a history of transient (<24 h) impairment, and, by definition, no residual neurologic impairment. These attacks are thought to result from emboli of fibrin-platelet aggregates or atheromatous debris from plaques in extracranial vessels. Unilateral visual impairment, numbness or weakness of an extremity, or aphasia is suggestive of carotid disease, whereas bilateral visual impairment, dizziness, ataxia, dysarthria, bilateral weakness, or amnesia is suggestive of vertebral–basilar disease. Patients with TIAs have a 30% to 40% chance of developing a frank stroke within 5 years; 50% of these strokes occur within the first year. Patients with TIAs should not undergo any elective surgical procedure without an adequate medical evaluation that generally includes at least noninvasive (Doppler) flow and

imaging studies. The presence of an ulcerative plaque of greater than 60% occlusion is generally an indication for carotid endarterectomy or endovascular intervention.

PREOPERATIVE MANAGEMENT

Preoperative assessment requires neurologic and cardiovascular evaluations. The type of stroke, the presence of neurologic deficits, and the extent of residual impairment should be determined. Thromboembolic strokes usually occur in patients with generalized atherosclerosis. Most patients are elderly and have comorbid conditions, such as hypertension, hyperlipidemia, and diabetes. Coexisting coronary artery disease and renal impairment are common. Following nonhemorrhagic strokes or TIAs, many patients are placed on long-term warfarin and/or antiplatelet therapy. Management of antiplatelet therapy and antithrombotic therapy should be reviewed by the anesthesia, primary care, and surgical teams to determine the risk/benefit of the discontinuation or maintenance of such therapy perioperatively. Other systemic diseases, such as diabetes, hypertension, coronary artery disease, heart failure, and chronic obstructive lung disease frequently manifest in the patient with cerebrovascular disease.

INTRAOPERATIVE MANAGEMENT

Patients may present for surgery following embolic, thrombotic, and hemorrhagic strokes.

Management of the patient following acute embolic stroke is directed toward the embolic source. Cardiac surgery is performed to remove atrial myxomas. Systemic emboli can also be produced from endocarditic vegetations, as well as from degenerated heart valves and intracardiac thrombus.

Patients with acute strokes secondary to carotid occlusive disease present for carotid endarterectomy and endovascular procedures. When an awake carotid endarterectomy is undertaken, the patient serves as a monitor of the adequacy of cerebral blood flow during application of vessel

clamps to facilitate the surgical repair. When general anesthesia is used electroencephalography, evoked potentials, carotid stump pressure, cerebral infrared spectroscopy, transcranial Doppler, and surgeon subjective sense of collateral back flow are all used to estimate the adequacy of cerebral oxygen delivery during cross clamp. When monitors or lack of appropriate patient response indicate hypoperfusion, the surgeon places a shunt to deliver blood to the brain around the cross-clamped vessel. Even with adequate cerebral blood flow, perioperative stroke can occur during carotid surgery secondary to emboli.

Management of patients following thrombotic or hemorrhagic stroke for nonneurological surgery must be individualized. Cerebral autoregulation of blood flow may fail, leaving flow directly dependent upon cerebral perfusion pressure (Figure 28-1). The penumbra of potentially salvageable neurologic tissue may therefore be very sensitive to injury from the effects of both hypotension and hypertension (Figure 28-2).

Patients taken to surgery following administration of thrombolytic therapy are at risk of cerebral hemorrhage, and tighter blood pressure control may be indicated to mitigate the possibility of cerebral bleeding.

Patients with intracerebral hemorrhage or traumatic brain injury undergo evacuation of

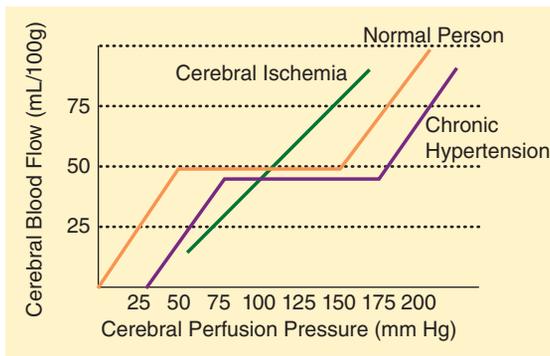

FIGURE 28-1 Cerebral autoregulation in a normal person, cerebral ischemia, and chronic hypertension. (Reproduced, with permission, from Shaikh S: Anesthesia consideration for the patient with acute ischemic stroke. *Semin Cardiothorac Vasc Anesth* 2010;14:62.)

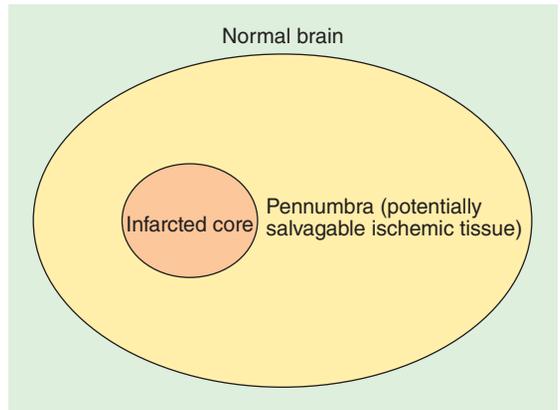

FIGURE 28-2 Penumbra. (Reproduced, with permission, from Shaikh S: Anesthesia consideration for the patient with acute ischemic stroke. *Semin Cardiothorac Vasc Anesth* 2010;14:62.)

hematoma and decompressive craniectomy. These patients usually require invasive arterial pressure monitoring to facilitate blood pressure management in settings where cerebral autoregulation is likely deranged (Figure 28-1). Hypertension is frequently treated with intravenous vasodilators and β -blockers. Subarachnoid hemorrhage is discussed in Chapter 27.

INTRACRANIAL MASS LESIONS

Patients with intracranial mass lesions present to surgery with both malignant and nonmalignant lesions. Such patients frequently present to their primary care physicians with complaints of headache, vision disturbance, or seizures. Radiologic studies confirm the presence of a lesion, and initial treatment is aimed at decreasing cerebral edema with dexamethasone. Electrolytes should be reviewed perioperatively in all patients undergoing cranial surgery, as both hyponatremia and hypernatremia can develop secondary to cerebral salt wasting, inappropriate antidiuretic hormone secretion, or central diabetes insipidus (Table 28-1). Patients with altered mentation preoperatively may likewise be dehydrated. Hyperglycemia secondary to steroid use is frequently seen.

TABLE 28-1 Fluid and electrolyte disorders associated with intracranial pathology.

Condition	Serum Sodium Concentration	Plasma Volume	Serum Osmolality	Urine Sodium Concentration	Urine Osmolality	Treatment
SIADH	Low	Normal or increased	Low	High	High	Fluid restriction
CSWS	Low	Decreased	Normal or high	High	Normal or high	Isotonic or hypertonic saline
DI	High	Decreased	High	Normal	Low	Hypotonic saline + vasopressin

CSWS, cerebral salt wasting; DI, diabetes insipidus; SIADH, syndrome of inappropriate antidiuretic hormone secretion.

Seizure Disorders

Preoperative Considerations

Seizures represent abnormal synchronized electrical activity in the brain. They may be a manifestation of an underlying central nervous system disease, a systemic disorder, or idiopathic. Potential underlying mechanisms are thought to include (1) loss of inhibitory activity, (2) enhanced release of excitatory amino acids, and (3) enhanced neuronal firing due to abnormal voltage-mediated Ca^{2+} currents. Up to 2% of the population may experience a seizure in their lifetime. Epilepsy is a disorder characterized by recurrent paroxysmal seizure activity. Healthy individuals who experience an isolated nonrecurrent seizure are not considered to have epilepsy.

Seizure activity may be localized to a specific area in the brain or may be generalized. Moreover, initially localized (focal) seizures can subsequently spread, becoming generalized. A simple classification scheme is presented in [Table 28-2](#). Partial

seizures (also called focal) are clinically manifested by motor, sensory, autonomic, or psychiatric symptoms, depending on the cortical area affected. Focal seizures associated with impairment in consciousness are termed “complex partial” (psychomotor or temporal lobe) seizures. Generalized seizures characteristically produce bilaterally symmetric electrical activity without local onset. They result with or without abnormal motor activity, loss of consciousness, or both. Generalized activity resulting in isolated, transient lapses in consciousness are called absence (petit mal) seizures. Other generalized seizures are usually classified according to the type of motor activity. Tonic-clonic (grand mal) seizures are most common and are characterized by a loss of consciousness followed by clonic and then tonic motor activity.

PREOPERATIVE MANAGEMENT

Anesthetic evaluation should focus primarily on the underlying disorder and secondarily on the seizures. One should determine the cause and type of seizure activity and the drugs with which the patient is being treated. Seizures in adults are most commonly due to structural brain lesions (head trauma, tumor, degeneration, or stroke) or metabolic abnormalities (uremia, hepatic failure, hypoglycemia, hypocalcemia, drug toxicity, or drug/alcohol withdrawal). Idiopathic seizures occur most often in children, but may persist into adulthood. Characterization of the type of seizure is important in detecting such activity

TABLE 28-2 Classification of seizures.

TABLE 28-3 Commonly used antiepileptic drugs, mechanisms of action and common side effects.

Drug	Mechanism of Action	Major Side Effects	Comments
Phenytoin	Blocks voltage sensitive Na ⁺ channels	Dizziness, drowsiness, blurred vision, ataxia Fatigue Nausea and vomiting Constipation, abdominal pain, anorexia	Low therapeutic index Zero order kinetics Enzyme inducer Gingival hyperplasia Megaloblastic anaemia
Phenobarbital	Potentiates GABAergic inhibition AMPA receptor blockade	Sedation, dizziness, confusion, excitement	
Carbamazepine	Blocks voltage sensitive Na ⁺ channels	Allergic reactions	Introduced slowly
Oxycarbamazepine		Visual disturbance Enzyme induction Tetratogenic	Titrated to side effects
Valproic acid	Increases synthesis and release of GABA Reduces GHB Inhibits NMDA receptors	Sedation, tremor Weight gain Spina bifida Thrombocytopenia	Drug of choice in elderly Caution when combined with lamotrigine
Lamotrigine	Blocks voltage sensitive Na ⁺ channels	Allergic reactions	Non-sedative
Ethosuximide	Reduces low-threshold T-type Ca ²⁺ currents in animals	Apathy, depression and drowsiness Nausea and vomiting	
Vigabatrine	Structural GABA analogue Irreversibly inhibits GABA-transaminase	Visual field defects	
Topiramate	Potentiates GABAergic inhibition	Allergic reactions Depression	Pulmonary embolism
Gabapentin	Unknown Reduces GABA	Somnolence, fatigue Ataxia	Used in intractable complex partial seizures

AMPA, α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid; GABA, γ -amino butyric acid; GHB, γ -hydroxybutyric acid; NMDA, *N*-methyl-D-aspartate. Adapted, with permission, from Veenith T, Burnstein RM. Management of patients with neurological and psychiatric disorders. *Surgery* 2010;28:441.

perioperatively. Seizures—particularly grand mal seizures—are serious complicating factors in surgical patients and should be treated promptly to prevent musculoskeletal injury, hypoventilation, hypoxemia, and aspiration of gastrointestinal content. Even partial seizures can progress to grand mal seizures. If a seizure occurs, maintaining an open airway and adequate oxygenation are the first priorities. Intravenous propofol (50–100 mg), phenytoin (500–1000 mg slowly), or a benzodiazepine such as diazepam (5–10 mg) or midazolam (1–5 mg) can be used to terminate the seizure.

Most patients with seizure disorders receive antiepileptic drugs preoperatively (Table 28-3). Antiseizure medications should be continued throughout the perioperative period to maintain therapeutic levels.

INTRAOPERATIVE MANAGEMENT

In selecting anesthetic agents, drugs with epileptogenic potential should be avoided, most notably the general anesthetic enflurane (now of only historic

interest). Theoretically, ketamine and methohexital (in small doses) can precipitate seizure activity. Hypothetically, large doses of atracurium, cisatracurium, or meperidine may be relatively contraindicated because of the reported epileptogenic potential of their respective metabolites, laudanosine, and normeperidine. Hepatic microsomal enzyme induction should be expected from chronic antiseizure therapy. Enzyme induction may increase the dose requirement and frequency of intravenous anesthetics and nondepolarizing neuromuscular blockers (NMBs) and may increase the risk for hepatotoxicity from halothane.

Degenerative & Demyelinating Diseases

PARKINSON DISEASE

Preoperative Considerations

Parkinson disease (PD) is a common movement disorder that typically afflicts individuals aged 50–70 years; it has a prevalence of 3% in the United States and Canada. This neurodegenerative disease is characterized by bradykinesia, rigidity, postural instability, and resting (pill-rolling) tremor. Additional frequently occurring findings include facial masking, hypophonia, dysphagia, and gait disturbances. Increasing problems with freezing, rigidity, and tremor eventually result in physical incapacitation. Early in the course of the disease, intellectual function is usually preserved, but declines in intellectual function may be severe as the disease progresses. PD is caused by a progressive loss of dopamine in the nigrostriatum. The severity of loss of dopamine correlates with the severity of bradykinesia. Concurrent with the loss of dopamine, the activity of the gamma-aminobutyric acid (GABA) nuclei in the basal ganglia increases, leading to an inhibition of thalamic and brainstem nuclei. Thalamic inhibition, in turn, suppresses the motor system in the cortex, resulting in the characteristic signs and symptoms.

Medical treatment is directed at controlling the symptoms. A variety of drugs may be used for mild disease, including the anticholinergic agents

trihexyphenidyl, benztropine, and ethopropazine; the irreversible monoamine oxidase (MAO) inhibitors selegiline and rasagiline; and the antiviral drug, amantadine. Moderate to severe disease is typically treated pharmacologically with dopaminergic agents, either levodopa (a precursor of dopamine) or a dopamine-receptor agonist. Levodopa, which is given with a decarboxylase inhibitor to retard the peripheral breakdown of the drug (thereby increasing its central delivery and decreasing the dose of levodopa that is required to control symptoms), is the most effective therapy and is used to treat moderate to severe symptoms. Catechol methyltransferase inhibitors are also used to prevent the decarboxylation of levodopa. Levodopa is available in either an immediate or sustained-release formulation, with durations of action of 2–4 hr and 3–6 hr, respectively. Side effects include nausea, vomiting, dyskinesias, sudden sleepiness, cardiac irritability, and orthostatic hypotension. Dopamine receptor agonists include both ergot derivatives (bromocriptine, cabergoline, lisuride, and apomorphine) and nonergot derivatives (pramipexole and ropinirole). The nonergot derivatives have been shown to be beneficial when used as monotherapy in early PD; all dopamine receptor agonists are effective when given as combination therapy with levodopa in the treatment of moderate to severe PD. Side effects are similar to those found with the use of levodopa alone, and, in addition, include headache, confusion, and hallucinations. Pulmonary and retroperitoneal fibrosis, pleural effusion and thickening, Raynaud syndrome, and erythromyalgia are more common side effects with the use of ergot derivatives than with nonergot derivatives.

The surgical treatment of PD includes both ablative procedures (thalamotomy and pallidotomy), as well as electrical stimulation of the ventral intermediate nucleus of the thalamus, the globus pallidus internus, or the subthalamic nucleus. Pallidotomy is effective for treating the dyskinesia (70% to 90%), as well as the tremor, rigidity, bradykinesia, and gait symptoms (30% to 50%) of the disorder. Thalamotomy is most effective in treating the contralateral tremor, but not for the other symptoms of the disease, and has been largely replaced

by the use of thalamic stimulation. The efficacy of deep brain stimulation of the thalamus is related to the effect on tremor; it has little to no effect on the other symptoms of PD. Subthalamic stimulation improves all of the primary symptoms of PD and decreases the amount of medication necessary for symptom relief. Bilateral stimulation has greater efficacy than unilateral stimulation. Some decrease in cognitive function may occur with this treatment, and, therefore, it should be used with caution in patients with cognitive impairment. The effects of globus pallidus internus stimulation are similar to those of pallidotomy with improvements in dyskinesia.

Anesthetic Considerations

Medications for PD should be continued perioperatively, including the morning of surgery. The half-life of levodopa is short. Abrupt withdrawal of levodopa can cause worsening of muscle rigidity and may interfere with ventilation. Phenothiazines, butyrophenones (droperidol), and metoclopramide can exacerbate symptoms as a consequence of their antidopaminergic activity and should be avoided. Anticholinergics (atropine) or antihistamines (diphenhydramine) may be used for acute exacerbation of symptoms. Diphenhydramine may be used for premedication and intraoperative sedation in **1** patients with tremor. Induction of anesthesia in patients receiving long-term levodopa therapy may result in either marked hypotension or hypertension. Relative hypovolemia, catecholamine depletion, autonomic instability, and sensitization to catecholamines are probably contributory. Arterial blood pressure should be monitored carefully. Hypotension should be treated with small doses of a direct-acting vasopressor, such as phenylephrine, rather than ephedrine. The response to NMBs is generally normal, however, hyperkalemia may rarely follow succinylcholine. As mentioned previously, patients who fail medical treatment are candidates for surgical intervention—for example, an ablative therapy, such as a thalamotomy or pallidotomy or implantation of a deep brain stimulator of the subthalamic nucleus, the ventral intermediate nucleus, or the globus pallidus internus. Because general anesthesia alters the threshold for stimulation,

correct placement of the electrodes can be affected. Awake craniotomy has been the norm for epilepsy surgery, and is being used increasingly for deep brain stimulation procedures. Two techniques are advocated—a true awake craniotomy with heavy sedation (dexmedetomidine is often used) and an approach in which the patient receives a general anesthetic, usually a total intravenous anesthetic with propofol and remifentanyl and a laryngeal mask airway for control of the airway. Following appropriate surgical exposure, the intravenous infusions are discontinued, and the laryngeal mask airway is removed. The patient can be reanesthetized once the implantation of leads is complete.

ALZHEIMER DISEASE

Preoperative Considerations

Neurodegenerative diseases often lead to dementia. Along with a loss of gray matter, elderly patients have altered pharmacokinetic and pharmacodynamic responses to many drugs that are used to induce and maintain anesthesia or sedation. Alzheimer disease (AD) is the most common neurodegenerative disease, causing approximately 40% to 80% of all cases of dementia, with a prevalence of approximately 20% in patients older than age 80 years. The disease is characterized by a slow decline in intellectual function. Progressive impairment of memory, judgment, and decision-making and emotional lability are hallmarks of the disease. Late in the course of the disease, severe extrapyramidal signs, apraxias, and aphasia are often present. Although some degree of brain atrophy is normal with advancing age, patients with AD usually show marked cortical atrophy with ventricular enlargement; the pathological hallmarks of AD seen at necropsy include neurofibrillary tangles that contain the phosphorylated microtubular protein tau and neuritic plaques composed of the peptide β -amyloid.

Anesthetic Considerations

Anesthetic management of patients with moderate to severe AD is often complicated by disorientation and uncooperativeness. New onset of

temporary cognitive impairment is frequent in elderly patients and often persists for 1–3 days following surgery. Such patients require repeated reassurance and explanation. Legally incompetent patients cannot provide informed consent for anesthesia or surgery. Premedication is usually not given, and only small doses are used. Centrally acting anticholinergics, such as atropine and scopolamine, may contribute to postoperative confusion. Glycopyrrolate, which does not cross the blood–brain barrier, may be the preferred agent when an anticholinergic is required.

Laboratory studies have shown that anesthetic agents are increasingly associated with neuronal injury and cell death. The outcome implications of general anesthesia in both the elderly and small children are currently the subject of much investigation and debate. Apoptotic neurodegeneration has been linked to the use of GABA receptor modulators and *N*-methyl-*D*-aspartic acid receptor antagonists, of which both mechanisms are used by common general anesthetics. Moreover, increased β -amyloid production is associated with both anesthetic exposure and AD. Consequently, there are concerns that anesthetic exposure may worsen dementia in the patient with AD; however, definitive conclusions regarding the risk of anesthetic toxicity in the patient with AD are not yet available.

MULTIPLE SCLEROSIS

Preoperative Considerations

Multiple sclerosis (MS) is characterized by reversible demyelination at random and multiple sites in the brain and spinal cord; chronic inflammation, however, eventually produces scarring (gliosis). The disease may be an autoimmune disorder that is initiated by a viral infection. It primarily affects patients between 20 and 40 years of age, with a 2:1 female predominance, and typically follows an unpredictable course of frequent attacks and remissions. With time, remissions become less complete, and the disease progresses to incapacitation; almost 50% of patients will require help with walking within 15 years of diagnosis. Clinical manifestations

depend on the sites affected, but frequently include sensory disturbances (paresthesias), visual problems (optic neuritis and diplopia), and motor weakness. Symptoms develop over the course of days and remit over weeks to months. Early diagnosis of exacerbations can often be confirmed by analysis of cerebrospinal fluid and magnetic resonance imaging. Remyelination is limited and often fails to occur. Moreover, axonal loss can develop. Changes in neurological function seem to be related to changes in axonal conduction. Conduction can occur across demyelinated axons, but seems to be affected by multiple factors, particularly temperature. Increases in body temperature cause exacerbation of symptoms.

The treatment of MS may be primarily symptomatic or used in an attempt to arrest the disease process. Diazepam, dantrolene, or baclofen, and, in refractory cases, an intrathecal delivery system for baclofen are used to control spasticity; bethanechol and other anticholinergics are useful for urinary retention. Painful dysesthesia may respond to carbamazepine, phenytoin, or antidepressants. Glucocorticoids may decrease the severity and duration of acute attacks. Corticosteroid-resistant relapses may respond to five to seven courses of plasma exchange offered on alternate days. Interferon has also been used to treat MS. Immunosuppression with azathioprine or cyclophosphamide may also be attempted to halt disease progression. Mitoxantrone is used for relapsing and progressive MS. The systemic effects of these therapies on coagulation and immunologic and cardiac function should be reviewed preoperatively.

Anesthetic Considerations

The effect of stress, anesthesia, and surgery on the course of MS is controversial. Overall, the effect of anesthesia is unpredictable. Elective surgery should be avoided during relapse, regardless of the anesthetic technique employed. The preoperative consent record should document counseling of the patient to the effect that the stress of surgery and anesthesia might worsen the symptoms. Spinal anesthesia has been associated with exacerbation of the disease; however, the entire surgery/delivery/

anesthetic process may likewise lead to exacerbations. Peripheral nerve blocks are less of a concern because MS is a disease of the central nervous system; however, patients may also have peripheral neuropathies. Epidural and other regional techniques seem to have no adverse effect on the course of the disease. No specific interactions with general anesthetics are recognized. Patients with advanced disease may have a labile cardiovascular system due to autonomic dysfunction. In the setting of paresis or paralysis, succinylcholine should be avoided because of hyperkalemia. Regardless of the anesthetic technique employed, increases in body temperature should be avoided. Irrespective of anesthetic technique, patients may experience a worsening of symptoms perioperatively and should be counseled accordingly.

AMYOTROPHIC LATERAL SCLEROSIS

Motor neuron disease is another common neurodegenerative disease, with amyotrophic lateral sclerosis (ALS) being the most prevalent. The cause of ALS is unknown, although small numbers of patients with the familial form of the disease have a defect in the superoxide dismutase-1 gene. ALS is a rapidly progressive disorder of both upper and lower motor neurons. Clinically, patients present in the fifth or sixth decade of life with muscular weakness, atrophy, fasciculation, and spasticity. The disease may initially be asymmetric, but over the course of 2–3 years becomes generalized, involving all skeletal and bulbar muscles. Progressive respiratory muscle weakness makes the patient susceptible to aspiration and eventually leads to death from ventilatory failure. Although the heart is unaffected, autonomic dysfunction can be seen. There is no specific treatment for ALS.

The primary emphasis in management is judicious respiratory care. As with other patients with lower motor neuron disease, succinylcholine is contraindicated because of the risk of hyperkalemia. Adequacy of ventilation should be carefully assessed both intraoperatively and postoperatively; an awake extubation is desirable. Difficulty in weaning patients

from mechanical ventilation postoperatively is not uncommon in patients with moderate to advanced disease.

GUILLAIN–BARRÉ SYNDROME

Guillain–Barré syndrome (GBS), a relatively common disorder affecting one to four individuals per 100,000 population, is characterized by a sudden onset of ascending motor paralysis, areflexia, and variable paresthesias. Subtypes of GBS include acute inflammatory demyelinating polyneuropathy (about 75% of cases), acute motor axonal neuropathy (with antibodies against gangliosides), and acute motor sensory axonal neuropathy. Bulbar involvement, including respiratory muscle paralysis, is a frequent complication. Pathologically, the disease seems to be an immunologic reaction against the myelin sheath of peripheral nerves, particularly lower motor neurons. In most instances, the syndrome seems to follow viral respiratory or gastrointestinal infections; the disorder can also present as a paraneoplastic syndrome associated with Hodgkin's disease or as a complication of human immunodeficiency virus infection. Some patients respond to plasmapheresis. The prognosis is relatively good, with most patients recovering completely; unfortunately, however, approximately 10% of patients die of complications, and another 10% are left with long-term neurologic sequelae.

Anesthetic management is complicated by lability of the autonomic nervous system in addition to concerns about respiratory insufficiency. Exaggerated hypotensive and hypertensive responses during anesthesia may be seen. As with other lower motor neuron disorders, succinylcholine should not be used because of the risk of hyperkalemia. The use of regional anesthesia in these patients remains controversial, as it might worsen symptoms. As with all decisions, the risks and benefits of regional versus general anesthesia must be weighed on an individual basis. As damaged nerves are more susceptible to a second injury (the “double crush” effect), performance of neuraxial techniques in patients with pre-existent neurologic dysfunction should be carefully considered.

AUTONOMIC DYSFUNCTION

Preoperative Considerations

Autonomic dysfunction, or dysautonomia, may be due to generalized or segmental disorders of the central or peripheral nervous system. Symptoms can be generalized, segmental, or focal. These disorders may be congenital, familial, or acquired. Common manifestations include impotence; bladder and gastrointestinal dysfunction; abnormal regulation of body fluids; decreased sweating, lacrimation, and salivation; and orthostatic hypotension. The latter can be the most serious manifestation of the disorder.

Acquired autonomic dysfunction can be isolated (pure autonomic failure), part of a more generalized degenerative process (Shy–Drager syndrome, PD, olivopontocerebellar atrophy), part of a segmental neurological process (MS, syringomyelia, reflex sympathetic dystrophy, or spinal cord injury), or a manifestation of disorders affecting peripheral nerves (GBS, diabetes, chronic alcoholism, amyloidosis, or porphyria).

Congenital or familial dysautonomia occurs most frequently in Ashkenazi Jewish children and is usually referred to as Riley–Day syndrome. Autonomic dysfunction is prominent and is associated with generalized diminished sensation and emotional lability. Moreover, patients are predisposed to dysautonomic crises triggered by stress and characterized by marked hypertension, tachycardia, abdominal pain, diaphoresis, and vomiting. Intravenous diazepam is effective in resolving such episodes. Hereditary dysautonomia associated with a deficiency of dopamine β -hydroxylase is described. Administration of α -dihydroxyphenylserine improves symptoms in these patients.

Anesthetic Considerations

3 The major risk of anesthesia in patients with autonomic dysfunction is severe hypotension, compromising cerebral and coronary blood flow. Marked hypertension can be equally deleterious. Most patients are chronically hypovolemic. The vasodilatory effects of spinal and epidural anesthesia are poorly tolerated. Similarly, the vasodilatory

and cardiac depressant effects of most general anesthetic agents combined with positive airway pressure can be equally problematic. Continuous intraarterial blood pressure monitoring is useful. Hypotension should be treated with fluids and direct-acting vasopressors (in preference to indirect-acting agents). Enhanced sensitivity to vasopressors due to denervation sensitivity may be observed. Blood loss also is usually poorly tolerated. Body temperature should be monitored closely. Patients with anhidrosis are particularly susceptible to hyperpyrexia.

SYRINGOMYELIA

Syringomyelia results in progressive cavitation of the spinal cord. In many cases, obstruction of cerebrospinal fluid outflow from the fourth ventricle seems to be contributory. Many patients have craniovertebral abnormalities, particularly the Arnold–Chiari malformation. Increased pressure in the central canal of the spinal cord produces enlargement or diverticulation to the point of cavitation. Syringomyelia typically affects the cervical spine, producing sensory and motor deficits in the upper extremities, and, frequently, thoracic scoliosis. Extension upward into the medulla (syringobulbia) leads to cranial nerve deficits. Syringo-peritoneal shunting and other decompressive procedures have variable success in arresting the disease.

Anesthetic evaluation should focus on defining existing neurologic deficits and any pulmonary impairment due to scoliosis. Autonomic instability should be expected in patients with extensive lesions. Succinylcholine should be avoided when muscle wasting is present because of the risk of hyperkalemia. Adequacy of ventilation and reversal of nondepolarizing NMBs should be achieved prior to extubation. Neuraxial techniques in the setting of elevated intracranial pressure are contraindicated. Case reports of epidural anesthetics having been performed for labor analgesia in patients with Arnold Chiari malformations, with and without syringomyelia, can be found in the literature. Risks of cerebral herniation, worsening

nerve injury, and infection must be weighed against potential benefits.

Spinal Cord Injury

Preoperative Considerations

Most spinal cord injuries are traumatic and may arise from partial or complete transection. The majority of injuries are due to fracture and dislocation of the vertebral column. The mechanism is usually either compression and flexion at the thoracic spine or extension at the cervical spine. Clinical manifestations depend on the level of the injury. Injuries above C3–5 (diaphragmatic innervation) require patients to receive ventilatory support to stay alive. Transections above T1 result in quadriplegia, whereas those above L4 result in paraplegia. The most common sites of injury are C5–6 and T12–L1. Acute spinal cord transection produces loss of sensation, flaccid paralysis, and loss of spinal reflexes below the level of injury. These findings characterize a period of spinal shock that typically lasts 1–3 weeks.

Over the course of the next few weeks, spinal reflexes gradually return, together with muscle spasms and signs of sympathetic overactivity. Injury in the low thoracic or lumbar spine may result in cauda equina (conus medullaris) syndrome. The latter usually consists of incomplete injury to nerve roots rather than the spinal cord.

Overactivity of the sympathetic nervous system is common with transections at T5 or above, but is unusual with injuries below T10. Interruption of normal descending inhibitory impulses in the cord results in autonomic hyperreflexia. Cutaneous or visceral stimulation below the level of injury can induce intense autonomic reflexes: sympathetic discharge produces hypertension and vasoconstriction below the transection and a baroreceptor-mediated reflex bradycardia and vasodilation above the transection. Cardiac arrhythmias are common.

Emergent surgical management is undertaken whenever there is reversible compression of the spinal cord due to dislocation of a vertebral body or bony fragment. Operative treatment is also indicated for spinal instability to prevent further injury.

Anesthetic Considerations

A. Acute Transection

Anesthetic management depends on the age of the injury. In the early care of acute injuries, the emphasis should be on preventing further spinal cord damage during patient movement, airway manipulation, and positioning. High-dose corticosteroid therapy (methylprednisolone) can be used for the first 24 hr following injury to improve neurologic outcome. Airway management of the patient with unstable cervical spine is discussed in Chapter 19. Patients with high transections often have impaired airway reflexes and are further predisposed to hypoxemia because of a decrease in functional residual capacity and atelectasis. Spinal shock can lead to hypotension and bradycardia prior to any anesthetic administration. Direct arterial pressure monitoring is helpful. An intravenous fluid bolus and the use of ketamine for anesthesia may help to prevent further decreases in blood pressure; vaso-pressors may also be required. Succinylcholine can be used safely in the first 24 hr, but should not be used thereafter because of the risk of hyperkalemia. The latter can occur within the first week following injury and is due to excessive release of potassium secondary to the proliferation of acetylcholine receptors outside of the neuromuscular synaptic cleft.

B. Chronic Transection

Anesthetic management of patients with nonacute transections is complicated by the possibility of autonomic hyperreflexia and the risk of hyperkalemia. Autonomic hyperreflexia should be expected in patients with lesions above T6 and can be precipitated by surgical manipulations. **Regional anesthesia and deep general anesthesia are effective in preventing hyperreflexia.** Many clinicians, however, are reluctant to administer spinal and epidural anesthesia in these patients because of the difficulties encountered in determining anesthetic level, exaggerated hypotension, and technical problems resulting from deformities. Severe hypertension can result in pulmonary edema, myocardial ischemia, or cerebral hemorrhage and should be treated promptly. Direct arterial vasodilators should

be readily available. Nondepolarizing muscle relaxants may be used. Body temperature should be monitored carefully, particularly in patients with transections above T1, because chronic vasodilation and loss of normal reflex cutaneous vasoconstriction predispose to hypothermia.

Encephalitis

Various forms of encephalitis can present secondary to infectious or autoimmune mechanisms. Patients with encephalitis are managed with the normal care given any patient with potentially increased intracranial pressure at risk of cerebral hypoperfusion.

Psychiatric Disorders

DEPRESSION

Depression is a very common mood disorder characterized by sadness and pessimism. Its cause is multifactorial, but pharmacological treatment is based on the presumption that its manifestations are due to a brain deficiency of dopamine, norepinephrine, and serotonin or altered receptor activities. Up to 50% of patients with major depression hypersecrete cortisol and have abnormal circadian secretion. Current pharmacological therapy utilizes drugs that increase brain levels of these neurotransmitters: tricyclic antidepressants, selective serotonin reuptake inhibitors (SSRIs), MAO inhibitors, and atypical antidepressants. The mechanisms of action of these drugs result in some potentially serious anesthetic interactions. Electroconvulsive therapy (ECT) is increasingly used for refractory severe cases and may be continued prophylactically after the patient's mood recovers. The use of general anesthesia for ECT is largely responsible for its safety and widespread acceptance.

Tricyclic Antidepressants

Tricyclic antidepressants may be used for the treatment of depression and chronic pain syndromes. All tricyclic antidepressants work at nerve synapses by blocking neuronal reuptake of catecholamines, serotonin, or both. Desipramine and nortriptyline

are used because they are less sedating and tend to have fewer side effects. Other agents are generally more sedating and include amitriptyline, imipramine, protriptyline, amoxapine, doxepin, and trimipramine. Clomipramine is used in the treatment of obsessive-compulsive disorders. Most tricyclic antidepressants also have significant anticholinergic (antimuscarinic) actions: dry mouth, blurred vision, prolonged gastric emptying, and urinary retention. Quinidine-like cardiac effects include tachycardia, T-wave flattening or inversion, and prolongation of the PR, QRS, and QT intervals. Amitriptyline has the most marked anticholinergic effects, whereas doxepin has the fewest cardiac effects.

St. John's wort is being used with increased frequency as an over-the-counter therapy for depression. Because it induces hepatic enzymes, blood levels of other drugs may decrease, sometimes with serious complications. During the preoperative evaluation, the use of all over-the-counter medications should be reviewed.

Antidepressant drugs are generally continued perioperatively. Increased anesthetic requirements, presumably from enhanced brain catecholamine activity, have been reported with these agents. Potentiation of centrally acting anticholinergic agents (atropine and scopolamine) may increase the likelihood of postoperative confusion and delirium.

5 The most important interaction between anesthetic agents and tricyclic antidepressants is an exaggerated response to both indirect-acting vasopressors and sympathetic stimulation. Pancuronium, ketamine, meperidine, and epinephrine-containing local anesthetic solutions should be avoided. Chronic therapy with tricyclic antidepressants is reported to deplete cardiac catecholamines, theoretically potentiating the cardiac depressant effects of anesthetics. If hypotension occurs, small doses of a direct-acting vasopressor should be used instead of an indirect-acting agent. Amitriptyline's anticholinergic action may occasionally contribute to postoperative delirium.

Monoamine Oxidase Inhibitors

MAO inhibitors block the oxidative deamination of naturally occurring amines. At least two MAO isoenzymes (types A and B) with differential substrate

selectivities have been identified. MAO-A is selective for serotonin, dopamine, and norepinephrine, whereas MAO-B is selective for dopamine and phenylethylamine. Nonselective MAO inhibitors include phenelzine, isocarboxazid, and tranylcypromine. Selective MAO-B inhibitors are useful in the treatment of PD. Additionally, unlike older nonreversible MAO inhibitors, reversible, MAO-A inhibitors have been developed. Side effects include orthostatic hypotension, agitation, tremor, seizures, muscle spasms, urinary retention, paresthesias, and jaundice. The most serious sequela is a hypertensive crisis that occurs following ingestion of tyramine-containing foods (cheeses and red wines), because tyramine is used to generate norepinephrine.

The practice of discontinuing MAO inhibitors at least 2 weeks prior to elective surgery is not recommended. Phenelzine can decrease plasma cholinesterase activity and prolong the duration of succinylcholine. Opioids should generally be used with caution in patients receiving MAO inhibitors, as rare but serious reactions to opioids have been reported. Most serious reactions are associated with meperidine, resulting in hyperthermia, seizures, and coma. Meperidine should not be administered to patients receiving MAO inhibitors. As with tricyclic antidepressants, exaggerated responses to vasopressors and sympathetic stimulation should be expected. If a vasopressor is necessary, a direct-acting agent in small doses should be employed. Drugs that enhance sympathetic activity, such as ketamine, pancuronium, and epinephrine (in local anesthetic solutions), should be avoided.

Atypical Antidepressants and Selective Serotonin Reuptake Inhibitors

SSRIs include fluoxetine, sertraline, and paroxetine, which some clinicians consider first-line agents of choice for depression. A surprisingly large fraction of patients undergoing elective surgery will be receiving one of these agents. These agents have little or no anticholinergic activity and do not generally affect cardiac conduction. Their principal side effects are headache, agitation, and insomnia. Other agents include the norepinephrine/dopamine reuptake inhibitors, the serotonin/norepinephrine reuptake inhibitors, selective serotonin reuptake enhancers, and

norepinephrine-dopamine disinhibitors. Patients taking St. John's wort are at increased risk of serotonin syndrome, as are those taking drugs with similar effects (eg, MAO inhibitors, meperidine). Serotonin syndrome manifestations include agitation, hypertension, hyperthermia, tremor, acidosis, and autonomic instability. Treatment is supportive, along with the administration of a 5-HT antagonist (eg, cyprohepatadine).

BIPOLAR DISEASE

Mania is a mood disorder characterized by elation, hyperactivity, and flight of ideas. Manic episodes may alternate with depression in patients with a bipolar (formerly manic-depressive) disorder. Mania is thought to be related to excessive norepinephrine activity in the brain. Lithium which interferes with Na⁺ ion transport with effects on many signaling pathways in the brain affecting neurotransmitter release, and lamotrigine, which inhibits sodium channels and modulates release of excitatory amino acids, are the drugs of choice for treating acute manic episodes and preventing their recurrence, as well as suppressing episodes of depression. Concomitant administration of an antipsychotic (haloperidol) or a benzodiazepine (lorazepam) is usually necessary during acute mania. Alternative treatments include valproic acid, carbamazepine, and aripiprazole as well as ECT.

The mechanism of action of lithium is poorly understood. It has a narrow therapeutic range, with a desirable blood concentration between 0.8 and 1.0 mEq/L. Side effects include reversible T-wave changes, mild leukocytosis, and, on rare occasions, hypothyroidism or a vasopressin-resistant diabetes insipidus-like syndrome. Toxic blood concentrations produce confusion, sedation, muscle weakness, tremor, and slurred speech. Still higher concentrations result in widening of the QRS complex, atrioventricular block, hypotension, and seizures.

Although lithium is reported to decrease minimum alveolar concentration and prolong the duration of some NMBs, clinically these effects seem to be minor. Nonetheless, this is yet another reason why neuromuscular function should be monitored when NMBs are used. Blood levels should be checked perioperatively. Sodium depletion (secondary to

loop or thiazide diuretics) decreases renal excretion of lithium and can lead to lithium toxicity. Fluid restriction and overdiuresis should be avoided. Lithium dilution cardiac output measurements are contraindicated in patients on lithium therapy.

SCHIZOPHRENIA

Patients with schizophrenia display disordered thinking, withdrawal, paranoid delusions, and auditory hallucinations. This disorder is thought to be related to an excess of dopaminergic activity in the brain.

The most commonly used antipsychotics include phenothiazines, thioxanthenes, phenylbutylpiperadines, dihydroindolones, dibenzapines, benzisoxazoles, and butyrophenones. There are numerous trade names for these drugs. Older antipsychotic medications had strong dopamine antagonistic effects, leading to extrapyramidal side effects (eg, muscle rigidity and progression to tardive dyskinesia). Other agents have less dopamine antagonism and occupy the D2 dopamine receptor to a lesser degree, thereby reducing extrapyramidal effects. The antipsychotic effect of these agents seems to be due to dopamine antagonist activity. Most are sedating and mildly anxiolytic. Mild α -adrenergic blockade and anticholinergic activity are also observed. Side effects include orthostatic hypotension, acute dystonic reactions, and parkinsonism-like manifestations. Risperidone and clozapine have little extrapyramidal activity, but the latter is associated with a significant incidence of granulocytopenia. T-wave flattening, ST segment depression, and prolongation of the PR and QT intervals may be seen, increasing the risk of *les torsades des pointes*.

Continuing antipsychotic medication perioperatively is desirable. Reduced anesthetic requirements may be observed in some patients, and some patients may experience perioperative hypotension.

NEUROLEPTIC MALIGNANT SYNDROME

Neuroleptic malignant syndrome is a rare complication of antipsychotic therapy that may occur hours or weeks after drug administration. Meperidine and

metoclopramide can also precipitate the disorder. The mechanism is related to dopamine blockade in the basal ganglia and hypothalamus and impairment of thermoregulation. In its most severe form, the presentation is similar to that of malignant hyperthermia. Muscle rigidity, hyperthermia, rhabdomyolysis, autonomic instability, and altered consciousness are seen. Creatine kinase levels are often high. The mortality rate approaches 20% to 30%, with deaths occurring primarily as a result of renal failure or arrhythmias. Treatment with dantrolene seems to be effective; bromocriptine, a dopamine agonist, may also be effective. Differential diagnoses include malignant hyperthermia and serotonin syndrome.

SUBSTANCE ABUSE

Behavioral disorders from abuse of psychotropic (mind-altering) substances may involve a socially acceptable drug (alcohol), a medically prescribed drug (eg, diazepam), or an illegal substance (eg, cocaine). Characteristically, with chronic abuse, patients develop tolerance to the drug and varying degrees of psychological and physical dependence. Physical dependence is most often seen with opioids, barbiturates, alcohol, and benzodiazepines. Life-threatening complications primarily due to sympathetic overactivity can develop during abstinence.

Knowledge of a patient's substance abuse preoperatively may prevent adverse drug interactions, predict tolerance to anesthetic agents, and facilitate the recognition of drug withdrawal. The history of substance abuse may be volunteered by the patient (usually only on direct questioning) or deliberately hidden.

Anesthetic requirements for substance abusers vary, depending on whether the drug exposure is acute or chronic (see [Table 28-4](#)). Elective procedures should be postponed for acutely intoxicated patients and those with signs of withdrawal. When surgery is deemed necessary in patients with physical dependence, perioperative doses of the abused substance should be provided, or specific agents should be given to prevent withdrawal. In the case of opioid dependence, any opioid can be used, whereas for alcohol, a benzodiazepine is usually substituted due to the reluctance of hospital pharmacies to dispense

alcohol-containing beverages to patients. Alcoholic patients should receive B vitamin/folate supplementation to prevent Korsakoff's syndrome. Tolerance to most anesthetic agents is often seen, but is not always predictable. For general anesthesia, a technique primarily relying on a volatile inhalation agent may be preferable so that anesthetic depth can be readily adjusted according to individual need. Awareness monitoring should be likewise considered. Opioids with mixed agonist–antagonist activity should be avoided in opioid-dependent patients because such agents can precipitate acute withdrawal. Clonidine is a useful adjuvant in the treatment of postoperative withdrawal syndromes.

Patients routinely present acutely intoxicated for emergency surgery following trauma related to substance abuse. Patients have often consumed more than one class of intoxicating agent. Acute cocaine intoxication may produce hypertension secondary to the increase in central neurotransmitters, such as norepinephrine and dopamine. Hypertension and arrhythmias can occur perioperatively. Chronic abusers deplete their sympathomimetic neurotransmitters, potentially developing hypotension. Amphetamine abusers have similar anesthetic concerns, as amphetamines also affect the sympathetic nervous system.

Patients on chronic prescribed opioid therapy, or those taking medications illicitly, have substantially

increased opioid postoperative requirements. Multimodal approaches to pain control are useful perioperatively, and patients should be started on maintenance methadone as soon as possible.

Consultation with pain management and addiction specialists is often indicated.

CASE DISCUSSION

Anesthesia for Electroconvulsive Therapy

A 64-year-old man with depression refractory to drug therapy is scheduled for electroconvulsive therapy (ECT).

How is ECT administered?

The electroconvulsive shock is applied to one or both cerebral hemispheres to induce a seizure. Variables include stimulus pattern, amplitude, and duration. The goal is to produce a therapeutic generalized seizure 30–60 sec in duration. Electrical stimuli are usually administered until a therapeutic seizure is induced. A good therapeutic effect is generally not achieved until a total of 400–700 seizure seconds have been induced. Because only one treatment is given per day, patients are usually scheduled for a series of treatments, generally two or three a week. Progressive memory loss often occurs with an increasing number of treatments, particularly when electrodes are applied bilaterally.

Why is anesthesia necessary?

When the efficacy of ECT was discovered, enthusiasm was tempered in the medical community because drugs were not used to control the violent seizures caused by the procedure, thus engendering a relatively high incidence of musculoskeletal injuries. Moreover, when an NMB was used alone, patients sometimes recalled being paralyzed and awake just prior to the shock. The routine use of general anesthesia to ensure amnesia and neuromuscular blockade to prevent injuries has renewed interest in ECT. The current mortality rate for ECT is estimated to be one death per 10,000 treatments.

What are the physiological effects of ECT-induced seizures?

Seizure activity is characteristically associated with an initial parasympathetic discharge followed by a more sustained sympathetic discharge. The initial phase is characterized by bradycardia and increased secretions. Marked bradycardia (<30 beats/min) and even transient asystole (up to 6 s) are occasionally seen. The hypertension and tachycardia that follow are typically sustained for several minutes. Transient autonomic imbalance can produce arrhythmias and T-wave abnormalities on the electrocardiogram. Cerebral blood flow and ICP, intragastric pressure, and intraocular pressure all transiently increase.

Are there any contraindications to ECT?

Contraindications are a recent myocardial infarction (usually <3 months), a recent stroke (usually <1 month), an intracranial mass, or increased ICP from any cause. More relative contraindications include angina, poorly controlled heart failure, significant pulmonary disease, bone fractures, severe osteoporosis, pregnancy, glaucoma, and retinal detachment.

What are the important considerations in selecting anesthetic agents?

Amnesia is required only for the brief period (1–5 min) from when the NMB is given to when a therapeutic seizure has been successfully induced. The seizure itself usually results in a brief period of anterograde amnesia, somnolence, and often confusion. Consequently, only a short-acting induction agent is necessary. Moreover, because most induction agents (barbiturates, etomidate, benzodiazepines, and propofol) have anticonvulsant properties, small doses must be used. Seizure threshold is increased and **seizure duration** is decreased by all of these agents.

Following adequate preoxygenation, methohexital, 0.5–1 mg/kg, is most commonly employed. Propofol, 1–1.5 mg/kg, may be used, but higher doses reduce seizure duration. Benzodiazepines raise the seizure threshold and decrease duration. Ketamine increases seizure duration, but is generally not used

because it also increases the incidence of delayed awakening, nausea, and ataxia and is also associated with hallucinations during emergence. Use of etomidate also prolongs recovery. Short-acting opioids, such as alfentanil, are not given alone because they do not consistently produce amnesia. However, alfentanil (10–25 mg/kg) can be a useful adjunct when very small doses of methohexital (10–20 mg) are required in patients with a high seizure threshold. In very small doses, methohexital may actually enhance seizure activity. Increases in seizure threshold are often observed with each subsequent ECT.

Neuromuscular blockade is required from the time of electrical stimulation until the end of the seizure. A short-acting agent, such as succinylcholine (0.25–0.5 mg/kg), is most often selected. Controlled mask ventilation, using a self-inflating bag device or an anesthesia circle system, is required until spontaneous respirations resume.

Can seizure duration be increased without increasing the electrical stimulus?

Hyperventilation can increase seizure duration and is routinely employed in some centers. Intravenous caffeine, 125–250 mg (given slowly), has also been reported to increase seizure duration.

What monitors should be used during ECT?

Monitoring should be similar to what is appropriate with the use of any other general anesthetic. Seizure activity is sometimes monitored by an unprocessed electroencephalogram. It can also be monitored in an isolated limb: a tourniquet is inflated around one arm prior to injection of succinylcholine, preventing entry of the NMB and allowing observation of convulsive motor activity in that arm.

How can the adverse hemodynamic effects of the seizure be controlled in patients with limited cardiovascular reserve?

Exaggerated parasympathetic effects should be treated with atropine. In fact, premedication with glycopyrrrolate is desirable both to prevent the profuse secretions associated with seizures and to attenuate bradycardia. Nitroglycerin, nifedipine, and α - and β -adrenergic blockers have all been employed successfully to control sympathetic

manifestations. High doses of β -adrenergic blockers (esmolol, 200 mg), however, are reported to decrease seizure duration.

What if the patient has a pacemaker?

Patients with pacemakers may safely undergo electroconvulsive treatments, but a magnet should be readily available to convert the pacemaker to a fixed mode, if necessary.

Renal Physiology & Anesthesia

KEY CONCEPTS

- 1 The combined blood flow through both kidneys normally accounts for 20–25% of total cardiac output.
- 2 Autoregulation of renal blood flow normally occurs between mean arterial blood pressures of 80 and 180 mm Hg and is principally due to intrinsic myogenic responses of the afferent glomerular arterioles to blood pressure changes.
- 3 Renal synthesis of vasodilating prostaglandins (PGD₂, PGE₂, and PGI₂) is an important protective mechanism during periods of systemic hypotension and renal ischemia.
- 4 Dopamine and fenoldopam dilate afferent and efferent arterioles via D₁-receptor activation. Fenoldopam and low-dose dopamine infusion can at least partially reverse norepinephrine-induced renal vasoconstriction.
- 5 Reversible decreases in renal blood flow, glomerular filtration rate, urinary flow, and sodium excretion occur during both regional and general anesthesia. Acute kidney injury is less likely if an adequate intravascular volume and a normal blood pressure are maintained.
- 6 The endocrine response to surgery and anesthesia is at least partly responsible for transient fluid retention seen postoperatively in many patients.
- 7 Compound A, a breakdown product of sevoflurane, has been shown to cause renal damage in laboratory animals. Its accumulation in the breathing circuit is favored by low flow rates. No clinical study has detected significant renal injury in humans during sevoflurane anesthesia; nonetheless, some regulatory authorities recommend fresh gas flow of at least 2 L/min with sevoflurane to prevent this theoretical problem.
- 8 The pneumoperitoneum produced during laparoscopy causes an abdominal compartment syndrome–like state. The increase in intraabdominal pressure typically produces oliguria (or anuria) that is generally proportional to the insufflation pressures. Mechanisms include central venous compression (renal vein and vena cava); renal parenchymal compression; decreased cardiac output; and increases in plasma levels of renin, aldosterone, and antidiuretic hormone.

The kidneys play a vital role in regulating the volume and composition of body fluids, eliminating toxins, and elaborating hormones, including renin, erythropoietin, and the active form of vitamin D. Factors directly and indirectly related to operative procedures and to anesthetic management frequently have a physiologically significant impact on renal physiology and renal function, and may lead to perioperative fluid overload, hypovolemia, renal insufficiency, and kidney failure, which are major causes of perioperative morbidity and mortality.

Diuretics are frequently used in the perioperative period. Diuretics are commonly administered on a chronic basis to patients with cardiovascular disease, including hypertension and chronic heart failure, and to patients with liver and kidney disease. Diuretics may be used intraoperatively, particularly during neurosurgical, cardiac, major vascular, ophthalmic, and urological procedures. Familiarity with the various types of diuretics, their mechanisms of action, side effects, and potential anesthetic interactions, is therefore essential.

The Nephron

Each kidney is made up of approximately 1 million functional units called nephrons. Anatomically, a nephron consists of a tortuous tubule with at least six specialized segments. At its proximal end (the *renal corpuscle*, composed of a glomerulus and a Bowman's capsule), an ultrafiltrate of blood is formed, and as this fluid passes through the nephron, its volume and composition are modified by both the reabsorption and the secretion of solutes. The final product is eliminated as urine.

Nephrons are classified as *cortical* or *juxtamedullary* (see below), and the renal corpuscles of all nephrons are located in the renal cortex. The six major anatomical and functional divisions of the nephron are the renal corpuscle, the proximal convoluted tubule, the loop of Henle, the distal renal tubule, the collecting tubule, and the juxtaglomerular apparatus (Figure 29-1 and Table 29-1).

The Renal Corpuscle

Each renal corpuscle contains a glomerulus, which is composed of tufts of capillaries that jut into

Bowman's capsule, providing a large surface area for the filtration of blood. Blood flow is provided by a single afferent arteriole and is drained by a single efferent arteriole (see below). Endothelial cells of the glomeruli are separated from the epithelial cells of Bowman's capsule only by their fused basement membranes. The endothelial cells are perforated with relatively large fenestrae (70–100 nm), but the epithelial cells interdigitate tightly with one another, leaving relatively small filtration slits (about 25 nm). The two cell types with their basement membranes provide an effective filtration barrier to cells and large-molecular-weight substances. This barrier has multiple anionic sites that give it a net negative charge, favoring filtration of cations relative to anions. A third cell type, called *intraglomerular mesangial cells*, is located between the basement membrane and epithelial cells near adjacent capillaries. These contractile cells regulate glomerular blood flow and also exhibit phagocytic activity. They secrete various substances, absorb immune complexes, and contain contractile proteins that respond to vasoactive substance. Mesangial cells contract, reducing glomerular filtration, in response to angiotensin II, vasopressin, norepinephrine, histamine, endothelins, thromboxane A₂, leukotrienes (C₄ and D₄), prostaglandin F₂, and platelet-activating factor. They relax, thereby increasing glomerular filtration, in response to atrial natriuretic peptide (ANP), prostaglandin E₂, and dopaminergic agonists.

Glomerular filtration pressure (about 60 mm Hg) is normally approximately 60% of mean arterial pressure and is opposed by both plasma oncotic pressure (about 25 mm Hg) and renal interstitial pressure (about 10 mm Hg). Afferent and efferent arteriolar tone are both important in determining glomerular filtration pressure: filtration pressure is directly proportional to efferent arteriolar tone but inversely proportional to afferent tone. Approximately 20% of plasma is normally filtered as blood passes through the glomerulus.

The Proximal Tubule

Of the ultrafiltrate formed in Bowman's capsule 65–75% is normally reabsorbed isotonicity (proportional amounts of water and sodium) in the

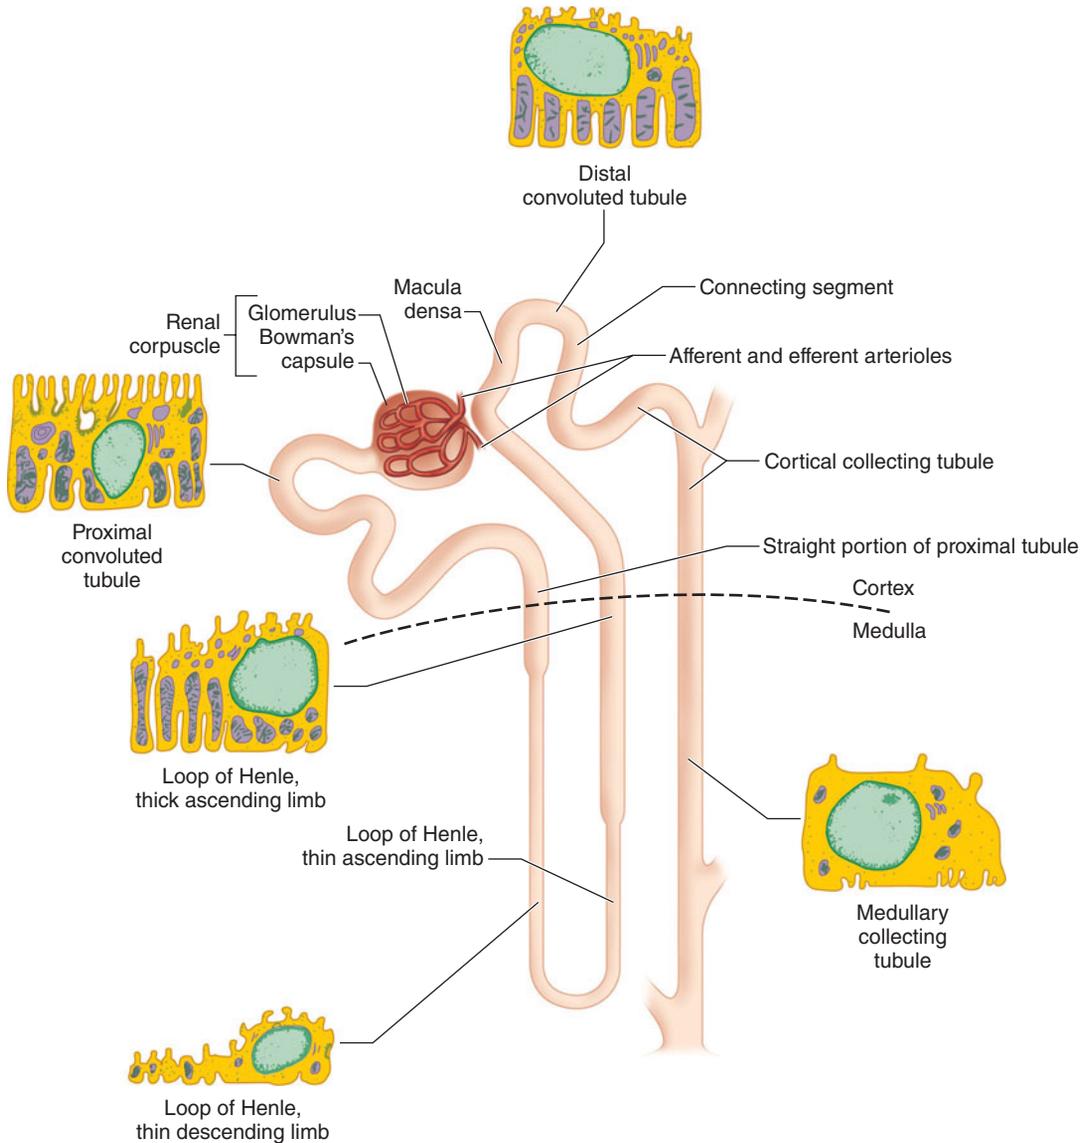

FIGURE 29-1 Major anatomic divisions of the nephron. (Reproduced, with permission, from Ganong WF: *Review of Medical Physiology*, 24th ed. McGraw-Hill, 2012.)

proximal renal tubules (**Figure 29-2**). To be reabsorbed, most substances must first traverse the tubular (apical) side of the cell membrane, and then cross the basolateral cell membrane into the renal interstitium before entering peritubular capillaries. The major function of the proximal tubule is Na^+ reabsorption. Sodium is actively transported out

of proximal tubular cells at their capillary side by membrane-bound $\text{Na}^+\text{-K}^+$ -adenosine triphosphatase ($\text{Na}^+\text{-K}^+\text{-ATPase}$) (**Figure 29-3**). The resulting low intracellular concentration of Na^+ allows passive movement of Na^+ down its gradient from tubular fluid into epithelial cells. Angiotensin II and norepinephrine enhance Na^+ reabsorption in the

early proximal tubule. In contrast, dopamine and fenoldopam decrease the proximal reabsorption of sodium via D₁-receptor activation.

Sodium reabsorption is coupled with the reabsorption of other solutes and the secretion of H⁺ (Figure 29–3). Specific carrier proteins use the low concentration of Na⁺ inside cells to transport phosphate, glucose, and amino acids. The net loss of intracellular positive charges, the result of Na⁺–K⁺-ATPase activity (exchanging 3Na⁺ for 2K⁺), favors the absorption of other cations (K⁺, Ca²⁺, and Mg²⁺). Thus, the Na⁺–K⁺-ATPase at the basolateral side of the renal cells provides the energy for the reabsorption of most solutes. Sodium reabsorption at the luminal membrane is also coupled with countertransport (secretion) of H⁺. The latter mechanism is responsible for reabsorption of 90% of the filtered bicarbonate ions (see Figure 50–3). Unlike other solutes, chloride can traverse the tight junctions between adjacent tubular epithelial cells, and accordingly, is passively resorbed via its concentration gradient. Active chloride reabsorption may also take place as a result of a K⁺–Cl[–] cotransporter that extrudes both ions at the capillary side of the cell membrane (Figure 29–3). Water moves passively out the proximal tubule along osmotic gradients. Apical membranes of epithelial cells contain specialized water channels, composed of a membrane protein called aquaporin-1, that facilitate water movement.

The proximal tubules are capable of secreting organic cations and anions. Organic cations such as creatinine, cimetidine, and quinidine may share the same pump mechanism and thus can compete for excretion with one another. Organic anions such as urate, ketoacids, penicillins, cephalosporins, diuretics, salicylates, and most radiocontrast dyes also share common secretory mechanisms. Both pumps probably play a major role in the elimination of many circulating toxins. Low-molecular-weight proteins, which are filtered by glomeruli, are normally reabsorbed by proximal tubular cells, to be metabolized intracellularly.

The Loop of Henle

The loop of Henle consists of *descending* and *ascending* portions. They are responsible for

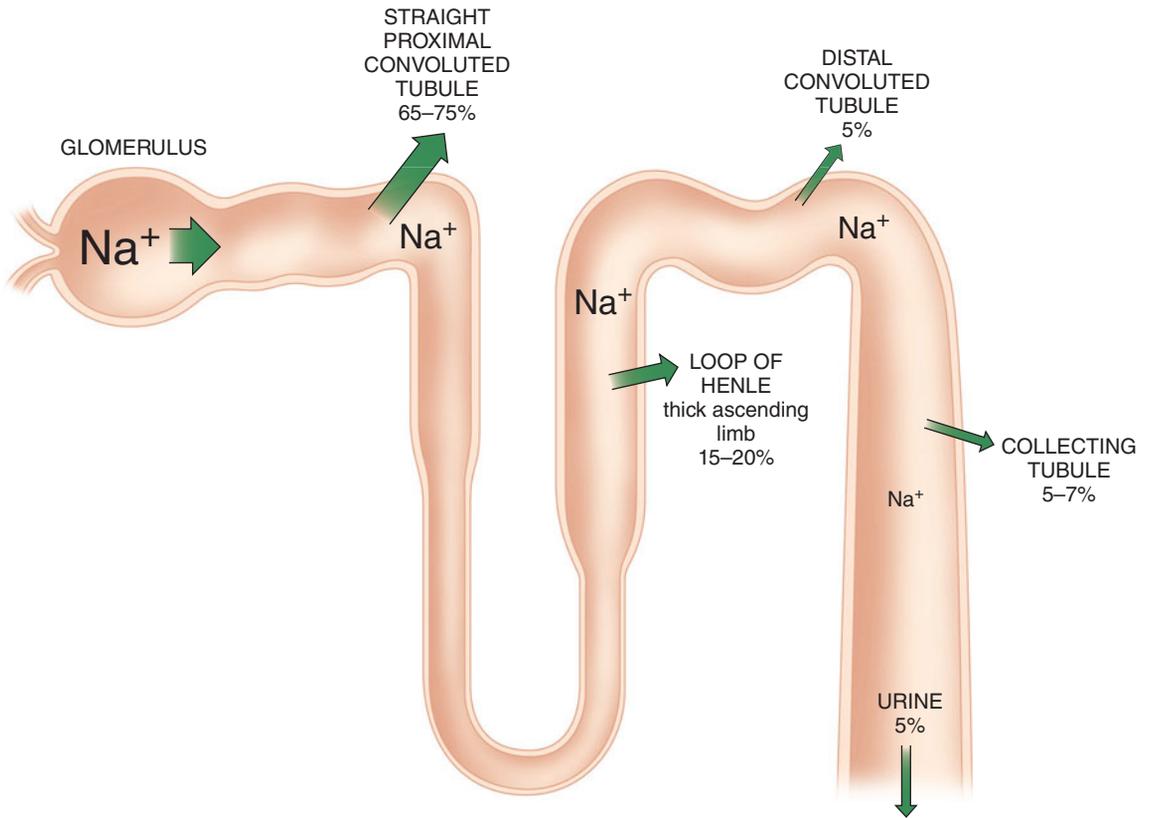

FIGURE 29-2 Sodium reabsorption in the nephron. Numbers represent the percentage of the filtered sodium reabsorbed at each site. (Reproduced, with permission, from Cogan MG: *Fluid and Electrolytes: Physiology and Pathophysiology*. Appleton & Lange, 1991.)
